FOREWORD

Merck & Co., Inc., has a long history of providing medical information to both human and animal health care professionals. For more than 60 years, the *Merck Veterinary Manual* (MVM) has provided veterinarians and other animal health professionals with concise and authoritative information on diseases and management of food-producing, companion, laboratory, and exotic animals. The 11th edition carries on this proud tradition.

This new edition has been completely updated and revised to continue to address the many diverse aspects of veterinary medicine. The first half of the book covers all body systems, including discussions of disease etiology, diagnosis, treatment, control, and prevention. The second half addresses special topics, including behavior, clinical pathology, management and nutrition, pharmacology, toxicology, and poultry medicine. Although the contents of the book have expanded with each edition, the MVM remains true to its original objective: a concise, easy-to-use, comprehensive reference that covers the diversity of species and animal diseases worldwide. Coverage is straightforward and practical, with explicit recommendations given for treatment whenever possible. The succinct discussions also serve to give readers a strong foundation for seeking out and understanding more detailed information available elsewhere.

The MVM covers all the basics, but it is also often relied on for areas not commonly encountered in the daily routine of most animal health professionals. This is no more evident than in the growing responsibility of veterinarians to society, in which general practitioners and specialists alike must vigilantly embrace their role in the international movement of animals, maintaining a safe food supply, and minimizing the spread of infectious animal disease and zoonotic agents. In this vein, a new section is dedicated to public health, covering public health functions and agencies, epidemiologic principles, disease outbreak investigations, food safety, and an extensive table of zoonoses.

Other significant new information has been added on heart disease, diagnostic imaging, emergency medicine, wound management, and pharmacology, including drug resistance. The emerging area of aquaculture is reflected in new chapters on aquaculture, aquatic systems, and aquarium fish. Veterinary responsibilities under the new Veterinary Feed Directive rule are also summarized. Additional timely new topics have been added throughout, covering subjects as diverse as backyard poultry, equine arboviral encephalomyelitis, neonatal management, smoke inhalation, rhodococcosis, scorpion bites, spider flies, xylitol toxicity, toxicologic hazards in the workplace, and the human-animal bond and service animals. And as medical knowledge of exotic and laboratory animals continues to increase, so does the MVM's coverage of pet birds, rabbits, reptiles, rodents, fish, and other nontraditional species.

The contents of the MVM are available online and as an app for handheld devices, providing enhanced capability to quickly access needed information. Digital versions are updated more frequently and include thousands of additional images and other multimedia offerings.

As always, we are deeply grateful to the authors and reviewers who have contributed to the current and past editions of the MVM. The 11th edition of the MVM is an extensive collaboration of the MVM Editorial Board and nearly 400 veterinary experts from academia, government, research organizations, and specialty practices, representing more than 20 countries worldwide. It is only through their dedication to animal health and their efforts and willingness to share their time and expertise that the MVM is possible.

Acknowledgment and thanks are also due to the following individuals for their assistance in the 11th edition of the MVM: Jennifer A. Doyle for business operations and technical troubleshooting, Lisa P. Glinski for index entry coding and other critical tasks, Jean L. Perry for general project administrative support, and Michelle A. Steigerwald for image processing. Appreciation is also expressed to Robert S. Porter, MD, for his management support.

Lastly, there is nothing more rewarding than hearing directly from our readers. Please continue to share your many thoughts, experiences, and stories about the MVM so that the book and its legacy can continue to improve, evolve, and endure.

Susan E. Aiello, DVM, ELS, Editor-in-Chief

Michael A. Moses, Executive Editor

GUIDE FOR READERS

- The Contents shows the title of each section of the *Merck Veterinary Manual* (MVM) and the corresponding thumb tab abbreviation.
- Each section has its own Table of Contents that lists chapter and subchapter titles in that section.
- Many cross-reference page numbers are found throughout the text to enable the reader to quickly find discussions of related material elsewhere in the book.
- A number of abbreviations and symbols used routinely throughout the text are listed beginning on p xiii. Other abbreviations used in the text are defined at their first use.
- Generic (nonproprietary) names of drugs are used in most instances.
- Running heads on left hand pages correspond to the chapter title of the text appearing at the top of that page. Running heads on right-hand pages correspond to the chapter title of the text appearing at the bottom of that page. In other words, running heads are used as in a standard dictionary.
- The Index is the best way to locate specific discussions of a disease, condition, or syndrome for which the name is known.
- The first half of the MVM is arranged into anatomic systems, and specific conditions are located in the system that is primarily affected. Conditions that may affect more than one system are covered in the section Generalized Conditions (GEN). The second half of the MVM covers special topics or disciplines.
- The authors, reviewers, editors, and publisher have made extensive efforts to ensure that treatments, drugs, dosage regimens, and withdrawal times are accurate and conform to the standards accepted at the time of publication. **However, constant changes in information resulting from continuing research and clinical experience, reasonable differences in opinions among authorities, unique aspects of individual clinical situations, and the possibility of human error in preparing such an extensive text require that the reader exercise individual judgment when making a clinical decision and, if necessary, consult and compare information from other sources.** In particular, the reader is advised to check the product information currently provided by the manufacturer of each drug before prescribing or administering it, especially if the drug is unfamiliar or is used infrequently. Many of the drug dosages given are considered extra-label usages, which require a valid veterinarian-client-patient relationship. Veterinarians should also be familiar and comply with the regulations set forth by the Veterinary Feed Directive.

of the Respiratory System; Systemic Phar-
macotherapeutics of the Urinary System*

Michael W. Dryden, DVM, PhD, DACVM

University Distinguished Professor of
Veterinary Parasitology, Diagnostic
Medicine/Pathobiology, College of
Veterinary Medicine, Kansas State
University, Manhattan, KS

*Ectoparasiticides: Ectoparasiticides
Used in Small Animals; Fleas and Flea
Allergy Dermatitis; Mange: Mange in
Dogs and Cats*

J. P. Dubey, MVSc, PhD

Microbiologist, Animal Parasitic Dis-
eases Laboratory, Beltsville Agricultural
Research Center, USDA, Beltsville, MD

Toxoplasmosis

Rebecca S. Duerr, DVM, MPVM, PhD

Staff Veterinarian, International Bird Res-
cue Research Center, Cordelia, CA

*Management of the Neonate: Care
of Orphaned Native Birds and
Mammals*

John Dunn, DVM, PhD

Veterinary Medical Officer, Avian Disease
and Oncology Laboratory, USDAARS,
East Lansing, MI

Neoplasms (Poultry)

**Jack Easley, DVM, MS, DABVP
(Equine)**

Equine Veterinary Practice, LLC,
Shelbyville, KY

Dentistry: Dentistry in Large Animals

**Scott H. Edwards, BSc, BVMS, PhD,
MANZCVSc**

Senior Lecturer, Veterinary Pharmacology,
Charles Sturt University, Wagga Wagga,
New South Wales, Australia

Anti-inflammatory Agents

Steve M. Ensley, DVM, PhD

Veterinary Toxicologist, Veterinary
Diagnostic and Production Animal
Medicine, College of Veterinary
Medicine, Iowa State University,
Ames, IA

Toxicology Introduction

Ronald J. Erskine, DVM, PhD

Professor, Large Animal Clinical Sciences,
College of Veterinary Medicine, Michigan
State University, East Lansing, MI

Mastitis in Large Animals

Paul Ettestad, DVM, MS

State Public Health Veterinarian, Epidemiology and Response Division, New Mexico
Department of Health, Santa Fe, NM

Plague

Timothy M. Fan, DVM, PhD, DACVIM

Associate Professor, Department of Veterinary Clinical Medicine, College of Veterinary Medicine, University of Illinois, Urbana, IL

Canine Lymphoma

Susan E. Fielder, DVM, MS, DACVP (Clinical Pathology)

Clinical Assistant Professor, Department of Pathobiology, Center for Veterinary Health Sciences, Oklahoma State University, Stillwater, OK

Reference Guides

Scott D. Fitzgerald, DVM, PhD, DACVP, DACPV

Professor, Department of Pathobiology and Diagnostic Investigation, College of Veterinary Medicine, Michigan State University, East Lansing, MI

Congenital and Inherited Anomalies of the Urinary System; West Nile Virus Infection in Poultry

Sherrill A. Fleming, DVM, DACVIM, DABVP

Associate Professor, Food and Animal Medicine, College of Veterinary Medicine, Mississippi State University, Mississippi State, MS

Pasteurellosis of Sheep and Goats

Janet E. Foley, DVM, PhD

Professor, Department of Medicine and Epidemiology; Co-Director, Center for Vector-Borne Disease, School of Veterinary Medicine, University of California, Davis, CA

Tularemia

Jonathan H. Foreman, DVM, MS, DACVIM (Large Animal)

Associate Dean, Professor, College of Veterinary Medicine, University of Illinois, Urbana, IL

Hepatic Disease in Large Animals

Mark T. Fox, BVetMed, PhD, DEVPC, FHEA, MRCVS

Professor of Veterinary Parasitology, Department of Pathology and Pathogen Biology, The Royal Veterinary College, University of London, UK

Gastrointestinal Parasites of Ruminants

Ruth Francis-Floyd, DVM, MS, DACZM

Professor, Department of Large Animal Clinical Sciences, College of Veterinary Medicine, University of Florida, Gainesville, FL

Aquaculture; Aquarium Fishes; Aquatic Systems

Robert M. Friendship, DVM, MSc, DABVP

Professor, Department of Population Medicine, Ontario Veterinary College, University of Guelph, Ontario, Canada

Gastrointestinal Ulcers in Large Animals: Gastric Ulcers in Pigs; Health-Management Interaction: Pigs

Laurie J. Gage, DVM, DACZM

Big Cat and Marine Mammal Specialist, USDA APHIS Animal Care, Center for Animal Welfare, Napa, CA

Management of the Neonate: Care of Orphaned Native Birds and Mammals

Maricarmen García, PhD

Associate Professor, Poultry Diagnostic and Research Center, Department of Population and Health, University of Georgia, Athens, GA

Infectious Laryngotracheitis

Tam Garland, DVM, PhD, DABVT

Veterinary Medical Diagnostic Laboratory, Texas A&M University, College Station, TX

Arsenic Poisoning; Gossypol Poisoning

Jack M. Gaskin, DVM, PhD, DACVM

Associate Professor Emeritus, Department of Infectious Disease and Pathology, College of Veterinary Medicine, University of Florida, Gainesville, FL

Encephalomyocarditis Virus Infection

Kirk N. Gelatt, VMD, DACVO

Emeritus Distinguished Professor, Department of Small Animal Clinical Sciences, College of Veterinary Medicine, University of Florida, Gainesville, FL

Neoplasia of the Eye and Associated Structures; Ophthalmic Emergencies; Ophthalmology

Richard W. Gerhold, DVM, MS, PhD
Department of Biomedical and Diagnostic Sciences, College of Veterinary Medicine, University of Tennessee, Knoxville, TN

Coccidiosis (Poultry); Cryptosporidiosis (Poultry); Trichomonosis

E. Paul J. Gibbs, BVSc, PhD, FRCVS
Professor Emeritus, College of Veterinary Medicine, University of Florida, Gainesville, FL

Pox Diseases

Thomas W. G. Gibson, BSc, BEd, DVM, DVSc, DACVS
Assistant Professor of Small Animal Surgery, Department of Clinical Studies, Ontario Veterinary College, University of Guelph, Ontario, Canada

Diseases of the Stomach and Intestines in Small Animals; Gastric Dilation and Volvulus in Small Animals; Gastrointestinal Obstruction in Small Animals

Robert O. Gilbert, BVSc, MMedVet, DACT, MRCVS
Professor, Reproductive Medicine, Department of Clinical Sciences, College of Veterinary Medicine, Cornell University, Ithaca, NY

Metritis in Large Animals; Retained Fetal Membranes in Large Animals; Systemic Pharmacotherapeutics of the Reproductive System; Uterine Prolapse and Eversion; Vaginal and Cervical Prolapse; Vulvitis and Vaginitis in Large Animals

Sabine Gilch, PhD
Assistant Professor, Veterinary Medicine, University of Calgary, Alberta, Canada
Chronic Wasting Disease

Eric Gonder, DVM, MS, PhD, DACPV
Veterinarian, Butterball LLC, Goldsboro, NC; Adjunct Professor, Department of Population Health and Pathobiology, College of Veterinary Medicine, North Carolina State University, Raleigh, NC
Miscellaneous Conditions of Poultry; Pendulous Crop

Sonya G. Gordon, DVM, DVSc, DACVIM (Cardiology)
Associate Professor, Department of Small Animal Clinical Sciences, Texas A&M University, College Station, TX

Systemic Pharmacotherapeutics of the Cardiovascular System

Louis Norman Gotthelf, DVM
Animal Hospital of Montgomery; Montgomery Pet Skin and Ear Clinic, Montgomery, AL

Tumors of the Ear Canal

Marcelo Gottschalk, DVM, PhD
Professor, College of Veterinary Medicine, University of Montreal, St-Hyacinthe, Quebec, Canada

Streptococcal Infections in Pigs

Gregory F. Grauer, DVM, MS, DACVIM
Professor and Jarvis Chair of Small Animal Internal Medicine, Department of Clinical Sciences, College of Veterinary Medicine, Kansas State University, Manhattan, KS

Ethylene Glycol Toxicity

Deborah S. Greco, DVM, PhD, DACVIM
Senior Research Scientist, Nestle Purina PetCare, New York, NY

The Pituitary Gland

Paul R. Greenough, FRCVS
Professor Emeritus of Veterinary Surgery, Western College of Veterinary Medicine, University of Saskatchewan, Saskatoon, Canada

Lameness in Cattle

Tara L. Grinnage-Pulley, DVM, PhD
Adjunct Lecturer and Postdoctoral Research Fellow, Department of Epidemiology, College of Public Health, University of Iowa, Iowa City, IA

Blood Parasites: Trypanosomiasis

Walter Gruenberg, DMV, MS, PhD, DECAR, DECBHM
Assistant Professor, Department of Farm Animal Health, Utrecht University, Utrecht, The Netherlands

Colisepticemia; Disorders of Phosphorus Metabolism; Dystrophies Associated with Calcium, Phosphorus, and Vitamin D; Hepatic Lipidosis: Fatty Liver Disease of Cattle; Intestinal Diseases in Ruminants; Salmonellosis

P. K. Gupta, PhD, Post Doc (USA), PGDCA, MSc VM & AH BVSc, FNA VSc, FASc, AW, FST, FAEB, FACVT (USA), Gold Medalist
Editor-in-Chief, *Toxicology International*, Bareilly-India

Herbicide Poisoning; Pentachlorophenol Poisoning

Ramesh C. Gupta, DVM, MVSc, PhD, DABT, FACT, FACN, FATS

Professor and Head, Toxicology Department, Breathitt Veterinary Center, Murray State University, Hopkinsville, KY

Insecticide and Acaricide (Organic) Toxicity

James S. Guy, DVM, PhD

Professor, Department of Population Health and Pathobiology, College of Veterinary Medicine, North Carolina State University, Raleigh, NC

Coronaviral Enteritis of Turkeys; Viral Encephalitides

Sharon M. Gwaltney-Brant, DVM, PhD, DABVT, DABT

Toxicology Consultant, Veterinary Information Network and Adjunct Faculty, College of Veterinary Medicine, University of Illinois, Urbana, IL

Food Hazards; Household Hazards; Snakebite; Toad Poisoning

Carlton L. Gyles, DVM, PhD

Professor Emeritus, Department of Pathobiology, Ontario Veterinary College, University of Guelph, Ontario, Canada

Edema Disease

Caroline N. Hahn, DVM, MSc, PhD, DECEIM, DECVN, MRCVS

Senior Lecturer in Veterinary Clinical Neuroscience, Royal (Dick) School of Veterinary Studies, University of Edinburgh, Midlothian, UK

Dysautonomia

Edward J. Hall, MA, VetMB, PhD, DECVIM-CA

Professor of Small Animal Internal Medicine, Department of Clinical Veterinary Science, University of Bristol, Bristol, UK

Diseases of the Stomach and Intestines in Small Animals; Malabsorption Syndromes in Small Animals

Jean A. Hall, DVM, PhD, DACVIM

Professor, Department of Biomedical Sciences, College of Veterinary Medicine, Oregon State University, Corvallis, OR

Disorders of Calcium Metabolism: Puerperal Hypocalcemia in Small Animals

Jeffery O. Hall, DVM, PhD, DABVT

Professor and Head of Diagnostic Toxicology, Utah State University, Logan, UT

Selenium Toxicosis

R. Reid Hanson, DVM, DACVS, DACVECC

Professor of Equine Surgery, Department of Clinical Sciences, College of Veterinary Medicine, Auburn University, Auburn, AL

Congenital and Inherited Anomalies of the Musculoskeletal System; Equine Emergency Medicine: Thermal Injuries

Joseph Harari, MS, DVM, DACVS

Veterinary Surgeon, Veterinary Surgical Specialists, Spokane, WA

Arthropathies and Related Disorders in Small Animals; Lameness in Small Animals; Myopathies in Small Animals; Osteopathies in Small Animals

Billy M. Hargis, DVM, PhD

Professor and Director, JKS Poultry Health Research Laboratory, University of Arkansas; Tyson Sustainable Poultry Health Chair, Department of Poultry Science, University of Arkansas, Fayetteville, AR

Miscellaneous Conditions of Poultry: Ascites Syndrome; Necrotic Enteritis; Spontaneous Cardiomyopathy of Turkeys

D. L. Hank Harris, DVM, PhD

Professor, Department of Animal Science, Iowa State University, Ames, IA

Intestinal Diseases in Pigs

Lynette A. Hart, PhD

Professor, Population Health and Reproduction, School of Veterinary Medicine, University of California, Davis, CA

The Human-Animal Bond

Joe Hauptman, DVM, MS, DACVS

Professor of Surgery, College of Veterinary Medicine, Michigan State University, East Lansing, MI

Diaphragmatic Hernia

Jan F. Hawkins, DVM, DACVS

Associate Professor, Veterinary Clinical Sciences, School of Veterinary Medicine, Purdue University, West Lafayette, IN

Diseases of the Esophagus in Large Animals; Diseases of the Mouth in Large Animals; Pharyngeal Paralysis; Pharyngitis

Marcus J. Head, BVetMed, MRCVS

Senior Associate, Rossdales Equine Hospital and Diagnostic Centre, Newmarket, UK

Lameness in Horses: Disorders of the Shoulder and Elbow

J. Jill Heatley, DVM, MS, DACZM, DABVP (Avian)

Associate Professor, Zoological Medicine,
College of Veterinary Medicine, Texas
A&M University, College Station, TX

Vaccination of Exotic Mammals

Charles M. Hendrix, DVM, PhD

Professor, Department of Pathobiology,
College of Veterinary Medicine, Auburn
University, Auburn, AL

*CNS Diseases Caused by Helminths and
Arthropods; Diagnostic Procedures for
the Private Practice Laboratory: Parasitology; Flies; Venomous Arthropods*

Thomas H. Herdt, DVM, MS, DACVN, DACVIM

Professor, Department of Large Animal
Clinical Sciences and Diagnostic Center
for Population and Animal Health, College
of Veterinary Medicine, Michigan State
University, East Lansing, MI

Ketosis in Cattle; Nutrition: Dairy Cattle

Laurie Hess, DVM, DABVP

Veterinary Center for Birds & Exotics,
Bedford Hills, NY

Sugar Gliders

Michael Hess, DMV

Clinic for Poultry and Fish Medicine,
Department for Farm Animals and
Veterinary Public Health, University of
Veterinary Medicine, Vienna, Austria

*Avian Spirochetosis; Miscellaneous
Conditions of Poultry: Fluke Infections*

Hugh Hildebrandt, DVM

Medford Veterinary Clinic, Medford, WI

Mink

W. Mark Hilton, DVM, DABVP

Clinical Associate Professor, Veterinary
Clinical Sciences, School of Veterinary Medicine,
Purdue University, West Lafayette, IN

*Health-Management Interaction: Beef
Cattle; Nutrition: Beef Cattle*

Katrin Hinrichs, DVM, PhD, DACT

Professor and Patsy Link Chair in Mare
Reproduction, Department of Veterinary
Physiology and Pharmacology, College
of Veterinary Medicine and Biomedical
Sciences, Texas A&M University, College
Station, TX

Cloning of Domestic Animals

Frederic J. Hoerr, DVM, PhD, DACVP, DACPV

Pathologist, Veterinary Diagnostic Pathology, LLC, Fort Valley, VA

*Aspergillosis; Miscellaneous Conditions of
Poultry: Breast Blisters, Breast Buttons,
Cannibalism; Mycotoxicoses (Poultry)*

Timothy N. Holt, DVM

Associate Professor, Clinical Sciences,
Livestock Medicine and Surgery, College
of Veterinary Medicine and Biomedical
Sciences, Colorado State University, Fort
Collins, CO

Bovine High-Mountain Disease

Sharman M. Hoppes, DVM, ABVP (Avian)

Clinical Associate Professor, Zoological
Medicine, Department of Veterinary Small
Animal Clinical Sciences, Texas A&M
University, College Station, TX

Pet Birds

Michael J. Huerkamp, DVM, DACLAM

Director, Division of Animal Resources;
Professor, Pathology and Laboratory Medicine,
Emory University, Atlanta, GA

Laboratory Animals

Martin E. Hugh-Jones, VetMB, MPH, PhD, MRCVS

Professor Emeritus, School of Veterinary
Medicine, Louisiana State University,
Baton Rouge, LA

Anthrax

Staci Hutsell, DVM

Resident, Maddie's Shelter Medicine
Program, College of Veterinary Medicine,
University of Florida, Gainesville, FL

Feline Infectious Peritonitis

Basil O. Ikede, BVetMed, DVM, PhD, FCVSN

Retired Professor and Chair, Department
of Pathology and Microbiology, Atlantic
Veterinary College, University of Prince
Edward Island, Charlottetown, Prince
Edward Island, Canada

Bovine Petechial Fever

Peter G. G. Jackson, MA, BVM&S, DVM&S, FRCVS

St. Edmund's College, University of
Cambridge, Cambridge, UK

Prolonged Gestation in Cattle and Sheep

Daral J. Jackwood, PhD

Professor, Department of Veterinary Preventive Medicine, Ohio Agricultural Research and Development Center, The Ohio State University, Wooster, OH

Infectious Bursal Disease

Mark W. Jackwood, PhD

Professor, Department of Population Health, College of Veterinary Medicine, University of Georgia, Athens, GA

Bordetellosis

Eugene D. Janzen, DVM, MVS

Professor, Production Animal Health, Faculty of Veterinary Medicine, University of Calgary, Alberta, Canada

Histophilosis; Lightning Stroke and Electrocutation; Trichomoniasis

LaRue W. Johnson, DVM, PhD

Professor Emeritus, College of Veterinary Medicine and Biomedical Sciences, Colorado State University, Fort Collins, CO

Llamas and Alpacas

Richard C. Jones, BSc, PhD, DSc, FRCPath

Emeritus Professor, School of Veterinary Science, University of Liverpool, Leahurst, Neston, Wirral, UK

Malabsorption Syndrome; Viral Arthritis

Maureen H. Kemp, BVMS, MVM, PhD, DCHP, MRCVS

Wern Veterinary Surgeons, Wales, UK

Laryngeal Disorders

Robert J. Kemppainen, DVM, PhD

Professor, Department of Anatomy, Physiology & Pharmacology, College of Veterinary Medicine, Auburn University, Auburn, AL

Endocrine System Introduction; Neuroendocrine Tissue Tumors

Safdar A. Khan, DVM, MS, PhD, DABVT

Director of Toxicology Research, ASPCA Animal Poison Control Center, Urbana, Illinois

Rodenticide Poisoning; Strychnine Poisoning; Toxicities from Human Drugs

Peter D. Kirkland, BVSc, PhD

Senior Principal Research Scientist, Officer-in-Charge, Virology Laboratory, Elizabeth Macarthur Agricultural Institute, Menangle, New South Wales, Australia

Congenital and Inherited Anomalies: Akabane Virus Infection

Mark D. Kittleson, DVM, PhD, DACVIM (Cardiology)

Professor Emeritus, School of Veterinary Medicine, University of California, Davis, CA

Heart Disease and Heart Failure

Kirk C. Klasing, BS, MS, PhD

Professor of Animal Biology, Department of Animal Science, University of California, Davis, CA

Nutrition and Management: Nutritional Requirements of Poultry

Thomas R. Klei, PhD

Boyd Professor and Associate Dean for Research and Advanced Studies, School of Veterinary Medicine and Louisiana Agricultural Experiment Station, Louisiana State University, Baton Rouge, LA

Gastrointestinal Parasites of Horses; Helminths of the Skin

Nick J. Knowles, MPhil

Head of Molecular Epidemiology Section, Vesicular Disease Reference Laboratory, The Pirbright Institute, Woking, Surrey, UK

Teschevirus Encephalomyelitis

Alexandre Kreiss, BVSc, PhD

Research Fellow, Menzies Research Institute Tasmania, University of Tasmania, Australia

Tasmanian Devils

Janice E. Kritchevsky, VMD, MS, DACVIM

Professor, Large Animal Medicine, Department of Veterinary Clinical Sciences, School of Veterinary Medicine, Purdue University, West Lafayette, IN

Equine Metabolic Syndrome; The Pituitary Gland: Hirsutism Associated with Adenomas of the Pars Intermedia; The Thyroid Gland: Non-neoplastic Enlargement of the Thyroid Gland

Thomas G. Ksiazek, DVM, PhD
Professor, Department of Pathology, University of Texas Medical Branch, Galveston, TX
Crimean-Congo Hemorrhagic Fever; Nipah Virus Infection

David F. Kuehn, DVM, MS, DACVIM
Section Chief, Internal Medicine, Michigan Veterinary Specialists, Southfield, MI
Respiratory Diseases of Small Animals; Respiratory System Introduction

Rajesh C. Kumar, BVSc, MS, PhD, ACPV
Consultant, Poultry Health & Food Safety, L. Cloud, MN
Dissecting Aneurysm in Turkeys

Lina Yu-Hsin Kung, PhD, MSc, BVSc, DVM
Principal Veterinary Epidemiologist, Animal Biosecurity and Welfare Program, Department of Agriculture, Fisheries and Forestry, Biosecurity Queensland, Queensland, Australia
Hendra Virus Infection

Nichelle A. Kutzler, DVM, PhD, DACT
Sanfield Professor of Companion Animal Industries, Department of Animal and Rangeland Sciences, Oregon State University, Corvallis, OR
Canine Transmissible Venereal Tumor; Mammary Tumors; Prostatic Diseases

Natalie A. Kwit, DVM, MPH
Foot-and-Mouth Disease

Gary M. Landsberg, BSc, DVM, MRCVS, DACVB, DECAWBM
Veterinary Behaviourist, North Toronto Veterinary Behaviour Specialty Clinic, Thornhill, Ontario, Canada
Behavioral Medicine Introduction; Normal Social Behavior and Behavioral Problems of Domestic Animals

Thomas J. Lane, BS, DVM
Professor Emeritus, University of Florida, Gainesville, FL
Health-Management Interaction: Horses

Jimmy C. Lattimer, DVM, MS, DACVR, DACVRO
Associate Professor (Radiology and Radiation Oncology), Veterinary Medicine and Surgery, College of Veterinary Medicine, University of Missouri, Columbia, MO
Diagnostic Imaging; Radiation Therapy

D. Bruce Lawhorn, DVM, MS
Relief Veterinarian; Veterinary Information Network Swine Consultant, College Station, TX
Potbellied Pigs

Andrea S. Lear, DVM
Clinical Instructor, Department of Large Animal Clinical Sciences, College of Veterinary Medicine, The University of Tennessee, Knoxville, TN
Bluetongue; Congenital and Inherited Anomalies: Border Disease; Malignant Catarrhal Fever; Sporadic Bovine Encephalomyelitis

Margie D. Lee, DVM, PhD
Professor of Population Health, Poultry Diagnostic and Research Center, College of Veterinary Medicine, University of Georgia, Athens, GA
Avian Campylobacter Infection

Steven Leeson, PhD
Professor Emeritus, University of Guelph, Ontario, Canada
Fatty Liver Hemorrhagic Syndrome; Nutrition and Management: Nutritional Deficiencies in Poultry

Michael L. Levin, PhD
Medical Entomology Laboratory Director, Rickettsial Zoonoses Branch, Centers for Disease Control and Prevention, Atlanta, GA
Ticks

Julie K. Levy, DVM, PhD, DACVIM
Department of Small Animal Clinical Sciences, College of Veterinary Medicine, and Director, Maddie's Shelter Medicine Program, University of Florida, Gainesville, FL
Feline Infectious Peritonitis; Feline Leukemia Virus and Related Diseases

Michel Lévy, DVM, DACVIM
Professor, Department of Veterinary Clinical and Diagnostic Sciences, University of Calgary, Alberta, Canada
Polioencephalomalacia

Alicja E. Lew-Tabor, BSc (Hons), PhD
Principal Research Fellow, Queensland Alliance for Agriculture & Food Innovation, The University of Queensland, Brisbane, Queensland, Australia
Blood Parasites: Anaplasmosis; Enteric Campylobacteriosis

David H. Ley, DVM, PhD

Professor, Department of Population Health and Pathobiology, College of Veterinary Medicine, North Carolina State University, Raleigh, NC

Mycoplasmosis

HuiChu Lin, DVM, MS, DACVAA

Professor, Large Animal Anesthesia, Department of Clinical Sciences, College of Veterinary Medicine, Auburn University, Auburn, AL

Malignant Hyperthermia

Dana Lindemann, DVM

Resident, Illinois Zoological and Aquatic Animal Residency Program, Wildlife Epidemiology Laboratory, College of Veterinary Medicine, University of Illinois at Urbana-Champaign, IL

Hedgehogs

Andrew Linklater, DVM, DACVECC

Clinical Instructor, Lakeshore Veterinary Specialists, Glendale, WI

Emergency Medicine Introduction; Evaluation and Initial Treatment of the Emergency Patient; Fluid Therapy; Monitoring the Critically Ill Animal; Specific Diagnostics and Therapy

Jeanne Lofstedt, BVSc, MS, DACVIM (Large Animal)

Professor of Large Animal Internal Medicine, Department of Health Management, Atlantic Veterinary College, University of Prince Edward Island, Charlottetown, Prince Edward Island, Canada

Caprine Arthritis and Encephalitis

Maureen T. Long, DVM, PhD, DACVIM

Associate Professor, Department of Infectious Diseases and Pathology, College of Veterinary Medicine, University of Florida, Gainesville, FL

Equine Arboviral Encephalomyelitis; Meningitis, Encephalitis, and Encephalomyelitis

Michael R. Loomis, DVM, MA, DACZM

Chief Veterinarian, North Carolina Zoological Park, Asheboro, NC

Zoo Animals

Ingrid Lorenz, DMV, DMVH, DECBHM

Lecturer in Bovine Medicine, School of Agriculture, Food Science and Veterinary Medicine, University College Dublin, Ireland

Diseases of the Ruminant Forestomach: Ruminant Drinking, Ruminant Parakeratosis, Subacute Ruminant Acidosis

Jodie Low Choy, BVSc, BVMS, IVAS Cert

Menzies School of Health Research; University Avenue Veterinary Hospital, Durack, Northern Territory, Australia

Melioidosis

Katharine F. Lunn, BVMS, MS, PhD, MRCVS, DACVIM

Associate Professor, Department of Clinical Sciences, College of Veterinary Medicine, North Carolina State University, Raleigh, NC

Fever of Unknown Origin; Leptospirosis

Robert J. MacKay, BVSc, PhD

Professor, Large Animal Medicine, Department of Large Animal Clinical Sciences, College of Veterinary Medicine, University of Florida, Gainesville, FL

Equine Protozoal Myeloencephalitis

Charles Mackenzie, BVSc, PhD, ACVM, AO

Professor, Department of Pathobiology and Diagnostic Investigation, Michigan State University, East Lansing, MI

Besnoitiosis

Kenneth S. Macklin, MSc, PhD

Associate Professor, Department of Poultry Science, Auburn University, Auburn, AL

Helminthiasis

John E. Madigan, DVM, MS

Distinguished Professor, Department of Medicine and Epidemiology, School of Veterinary Medicine, University of California, Davis, CA

Equine Granulocytic Ehrlichiosis

Richard A. Mansmann, VMD, PhD (Hon), DACVIM (Large Animal)

Equine Podiatry & Rehabilitation Practice; Clinical Professor Emeritus, College of Veterinary Medicine, North Carolina State University, Raleigh, NC

Prepurchase Examination of Horses

Steven L. Marks, BVSc, MS, MRCVS, DACVIM

Clinical Professor of Emergency and Internal Medicine; Associate Dean and Director of Veterinary Medical Services, College of Veterinary Medicine, North Carolina State University, Raleigh, NC

Anemia; Health-Management Interaction: Small Animals

Bret D. Marsh, DVM

Indiana State Veterinarian, Indiana State Board of Animal Health, Indianapolis, IN

Prepurchase Examination of Ruminants and Swine

Joerg Mayer, DMV, MSc, DABVP (ECM), DECZM (Small Mammal)

Associate Professor of Zoological and Exotic Animal Medicine, Department of Small Animal Medicine & Surgery, College of Veterinary Medicine, University of Georgia, Athens, GA

Rabbits

Milton M. McAllister, DVM, PhD, DACVP

Associate Professor, School of Animal and Veterinary Sciences, University of Adelaide, Roseworthy, South Australia, Australia

Neosporosis

C. Wayne McIlwraith, BVSc, PhD, DSc, FRCVS, DACVS, DACVSMR

Department of Clinical Sciences, College of Veterinary Medicine and Biomedical Sciences, Colorado State University, Fort Collins, CO

Arthropathies in Large Animals; Lameness in Horses: Tendinitis

Thomas St. C. McKenna, DVM, PhD

Assistant Director for New England, Surveillance, Preparedness and Response Services, District 1, USDA, APHIS, Veterinary Services, Sutton, MA

African Horse Sickness

Jennifer H. McQuiston, DVM, MS
Epidemiology Team Leader, Rickettsial Zoonoses Branch, Centers for Disease Control and Prevention, Atlanta, GA

Rickettsial Diseases

Mushtaq A. Memon, BVSc, PhD, DACT
Theriogenologist, Department of Veterinary Clinical Sciences, College of Veterinary Medicine, Washington State University, Pullman, WA

Reproductive Diseases of the Female Small Animal

Paula I. Menzies, DVM, MPVM, DECS-RHM

Professor, Ruminant Health Management Group, Department of Population Medicine, Ontario Veterinary College, University of Guelph, Ontario, Canada

Disorders of Calcium Metabolism: Parturient Paresis in Sheep and Goats; Hepatic Lipidosis: Pregnancy Toxemia in Ewes and Does; Management of Reproduction: Sheep; Posthitis and Vulvitis in Sheep and Goats

Sandra R. Merchant, DVM, DACVD

Professor of Dermatology, Department of Veterinary Clinical Sciences, School of Veterinary Medicine, Louisiana State University, Baton Rouge, LA

Dermatophytosis

Joanne B. Messick, VMD, PhD, DACVP

Associate Professor of Veterinary Clinical Pathology, Department of Comparative Pathobiology, College of Veterinary Medicine, Purdue University, West Lafayette, IN

Blood Parasites: Hemotropic Mycoplasmas

Samia A. Metwally, DVM, PhD

Senior Animal Health Officer (Virologist), AGAH, AGA Division, Food and Agriculture Organization of the United Nations, Rome, Italy

Nairobi Sheep Disease

Patti J. Miller, DVM, PhD

Veterinary Medical Officer, Exotic and Emerging Avian Viral Diseases Research, USDA Agricultural Research Service, Athens, GA

Newcastle Disease and Other Paramyxovirus Infections: Newcastle Disease

Kelly D. Mitchell, BSc, DVM, DVSc, DACVIM

Toronto Veterinary Emergency Clinic, Scarborough, Ontario, Canada

Diseases of the Stomach and Intestines in Small Animals: Canine Parvovirus, Feline Enteric Coronavirus, Gastritis in Small Animals, Hemorrhagic Gastroenteritis in Small Animals

Harry W. Momont, DVM, PhD, DACT
Clinical Associate Professor, Department of
Medical Sciences, School of Veterinary Medi-
cine, University of Wisconsin, Madison, WI
Reproductive System Introduction

Donald R. Monke, DVM, MBA
Vice President, Production Operations,
Select Sires, Inc., Plain City, Ohio

Associate Professor, Veterinary Pathobiology, Texas A&M University, College Station, TX

Vaccines and Immunotherapy

Lisa K. Pearson, DVM, MS, PhD, DACT

Clinical Instructor, Comparative Theriogenology, Department of Veterinary Clinical Sciences, College of Veterinary Medicine, Washington State University, Pullman, WA

Congenital and Inherited Anomalies of the Digestive System

Angela Pelzel-McCluskey, DVM

National Epidemiologist for Equine Diseases, USDA, APHIS Veterinary Services, Fort Collins, CO

Vesicular Stomatitis

Maurice B. Pensaert, DVM, MS, PhD

Emeritus Professor of Animal Virology, Faculty of Veterinary Medicine, Ghent University, Merelbeke, Belgium

Porcine Hemagglutinating Encephalomyelitis

Andrew S. Peregrine, BVMS, PhD, DVM, DEVPC, DACVM

Associate Professor, Department of Pathobiology, Ontario Veterinary College, University of Guelph, Ontario, Canada

Gastrointestinal Parasites of Small Animals

Donald Peter, DVM, MS, DACT
Veterinarian/Owner, Frontier Genetics,
Herniston, OR

*Bovine Genital Campylobacteriosis;
Equine Coital Exanthema*

Christine Petersen, DVM, PhD
Associate Professor, Department of
Epidemiology, University of Iowa, Iowa
City, IA

Blood Parasites: Trypanosomiasis

Mark E. Peterson, DVM, DACVIM
Director of Endocrinology and Nuclear
Medicine, Animal Endocrine Clinic, New
York, NY

*The Parathyroid Glands and Disorders of
Calcium Metabolism; The Thyroid Gland:
Hyperthyroidism, Hypothyroidism*

Barbara D. Petty, DVM
North Florida Aquatic Veterinary Services,
Fort White, FL

Aquarium Fishes

James R. Philips, PhD
Associate Professor of Science, Math/
Science Division, Babson College, Babson
Park, MA

Air Sac Mite; Ectoparasites of Poultry

**Carlos R. F. Pinto, MedVet, PhD,
DACT**
Associate Professor, Theriogenology Sec-
tion, Department of Veterinary Clinical
Sciences, School of Veterinary Medicine,
Louisiana State University, Baton Rouge,
LA

Embryo Transfer in Farm Animals

**Paul J. Plummer, DVM, PhD, DACVIM
(Large Animal), DECSRHM**
Department of Veterinary Diagnostic and
Production Animal Medicine, College of
Veterinary Medicine, Iowa State Univer-
sity, Ames, IA

Coxiellosis

**Robert E. Porter, DVM, PhD, DACVP,
DACPV**
Clinical Professor, Veterinary Popula-
tion Medicine, College of Veterinary
Medicine, University of Minnesota,
St. Paul, MN

*Perirenal Hemorrhage Syndrome of Tur-
keys; Poisonings (Poultry)*

Karen W. Post, DVM, MS, DACVM
Director of Laboratories, Veterinary
Bacteriologist, North Carolina Veterinary
Diagnostic Laboratory System; Consumer
Services, Rollins Animal Disease, Diagnos-
tic Laboratory, Raleigh, NC

*Diagnostic Procedures for the Private
Practice Laboratory: Clinical Microbiol-
ogy*

**David G. Pugh, DVM, MS, MAG, DACT,
DACVN, DACVM**
Department of Pathobiology, College of
Veterinary Medicine, Auburn University,
Auburn, AL

Nutrition: Goats; Nutrition: Sheep

Sarah L. Ralston, VMD, PhD, DACVN
Professor, Department of Animal Sciences,
School of Environmental and Biological
Sciences, Rutgers University, New Bruns-
wick, NJ

Nutrition: Horses

John F. Randolph, DVM, DACVIM
Professor, Department of Clinical Sci-
ences, College of Veterinary Medicine,
Cornell University, Ithaca, NY

Erythrocytosis and Polycythemia

Silke Rautenschlein, DVM, PhD
Professor, Clinic for Poultry, University of
Veterinary Medicine, Hannover, Germany

Avian Metapneumovirus

**Willie M. Reed, DVM, PhD, DACVP,
DACPV**
Dean, College of Veterinary Medicine,
Purdue University, West Lafayette, IN

Quail Bronchitis; Turkey Viral Hepatitis

**Philip T. Reeves, BVSc (Hons), PhD,
FANZCVS**
Chief Regulatory Scientist, Veterinary
Medicines and Nanotechnology, Austr-
alian Pesticides and Veterinary Medicines
Authority, Canberra, Australia

*Pharmacology Introduction: Chemical
Residues in Food and Fiber; Dosage Forms
and Delivery Systems, Drug Action and
Pharmacodynamics, Nanotechnology*

Mason V. Reichard, PhD
Associate Professor, Department of Veteri-
nary Pathobiology, Center for Veterinary
Health Sciences, Oklahoma State Univer-
sity, Stillwater, OK

Cattle Grubs; Mange in Large Animals

Hugh W. Reid, MBE, BVM&S, DTVM, PhD, MRCVS

Moredun Research Institute, Pentlands,
Science Park, Penicuik, UK

Louping Ill

Douglas J. Reinemann, PhD

Professor and Chair, Department of
Biological Systems Engineering, College of
Agricultural and Life Sciences, University
of Wisconsin, Madison, WI

Stray Voltage in Animal Housing

Christopher D. Reinhardt, BS, MS, PhD

Assistant Professor and Extension
Feedlot Specialist, Animal Sciences
and Industry, Kansas State University,
Manhattan, KS

*Growth Promotants and Production
Enhancers*

Petra Reinhold, DVM, PhD

Friedrich-Loeffler Institute, Federal
Research Institute for Animal Health, Jena,
Germany

Chlamydiosis

Alexander M. Reiter, DT, DMV, DAVDC, DEVDC

Chief, Dentistry and Oral Surgery Service,
Ryan Veterinary Hospital, School of Veteri-
nary Medicine, University of Pennsylvania,
Philadelphia, PA

*Dentistry: Dentistry in Small Animals;
Diseases of the Mouth in Small Animals*

Márcio Garcio Ribeiro, DVM, PhD

Professor, Infectious Diseases of Domes-
tic Animals, Department of Veterinary
Hygiene and Public Health, School of
Veterinary Medicine and Animal Sciences,
São Paulo State University – UNESP, Botu-
catu, São Paulo, Brazil

Nocardiosis; Rhodococcosis

Franklin Riet-Correa, PhD

Professor, Veterinary Hospital, Federal
University of Campina Grande, Patos,
Paraíba, Brazil

Cattle Grubs: Lechiguana

Yasuko Rikihisa, PhD

Professor, Veterinary Biosciences, The
Ohio State University, Columbus, OH

*Rickettsial Diseases: Salmon Poisoning
Disease and Elokomin Fluke Fever*

Guillermo R. Risatti, MV, MS, PhD

Associate Professor, Department of Patho-
biology and Veterinary Science, University
of Connecticut, Storrs, CT

Classical Swine Fever

Narda G. Robinson, DO, DVM, MS

College of Veterinary Medicine and Bio-
logical Sciences, Colorado State Univer-
sity, Fort Collins, CO

*Complementary and Alternative Veteri-
nary Medicine*

Kursten V. Roderick, DVM

Cardiology Resident, Cummings School
of Veterinary Medicine, Tufts University,
North Grafton, MA

*Cardiovascular System Introduction;
Thrombosis, Embolism, and Aneurysm*

Camille Roesch, PhD

Nanosafety Pharmacist Consultant, Aus-
tralian Pesticides and Veterinary Medi-
cines Authority, Symonston, Australia

*Pharmacology Introduction: Dosage
Forms and Delivery Systems, Drug
Action and Pharmacodynamics, Nano-
technology*

Peter Rolls, BVSc, MVS

Veterinary Officer, Tick Fever Centre,
Department of Agriculture, Fisheries and
Forestry, Biosecurity Queensland, Wacol,
Queensland, Australia

Blood Parasites: Babesiosis

Juan E. Romano, DVM, MS, PhD, DACT

Associate Professor, Department of Large
Animal Clinical Sciences, College of Vet-
erinary Medicine, Texas A&M University,
College Station, TX

Hormonal Control of Estrus

A. Gregorio Rosales, DVM, MS, PhD, DACPV

Vice President of Veterinary Services,
Aviagen Inc., Huntsville, AL

*Disorders of the Reproductive System
(Poultry)*

Stanley I. Rubin, DVM, MS, DACVIM

Clinical Professor, Department of
Veterinary Clinical Medicine, College of
Veterinary Medicine, University of Illinois,
Urbana, IL

*Digestive System Introduction; Diseases
of the Rectum and Anus*

Pamela L. Ruegg, DVM, MPVM

Professor, Department of Dairy Science,
College of Agricultural and Life Sciences,
University of Wisconsin, Madison, WI

Udder Diseases

Charles E. Rupprecht, VMD, MS, PhD

Director, LYSSA LLC, Lawrenceville, GA

Rabies

Bonnie R. Rush, DVM, MS, DACVIM

Professor, Equine Internal Medicine, College of Veterinary Medicine, Kansas State University, Manhattan, KS

Respiratory Diseases of Horses

Y. M. Saif, DVM, PhD

Professor Emeritus, Food Animal Health Research Program, The Ohio State University, Wooster, OH

Rotaviral Infections in Chickens, Turkeys, and Pheasants

Jeremiah T. Saliki, DVM, PhD, DACVM

Professor and Director, Athens Veterinary Diagnostic Laboratory, University of Georgia, Athens, GA

Peste des Petits Ruminants; Rinderpest

Jean E. Sander, DVM, MAM, DACPV

Dean, Center for Veterinary Health Sciences, Oklahoma State University, Stillwater, OK

Candidiasis; Disposal of Carcasses and Disinfection of Premises; Omphalitis

Sherry Lynn Sanderson, BS, DVM, PhD, DACVIM, DACVN

Associate Professor, Physiology and Pharmacology, College of Veterinary Medicine, University of Georgia, Athens, GA

Nutrition: Small Animals; Urinary System Introduction

Yuko Sato, DVM, MS, DACPV

Assistant Professor, Veterinary Diagnostic & Production Animal Medicine, Poultry Extension and Diagnostics, Iowa State University, Ames, IA

Backyard Poultry

Ashley B. Saunders, DVM, DACVIM (Cardiology)

Associate Professor of Cardiology, Department of Small Animal Clinical Sciences, College of Veterinary Medicine and Biomedical Sciences, Texas A&M University, College Station, TX

Systemic Pharmacotherapeutics of the Cardiovascular System

Charles M. Scanlan, DVM, PhD

Professor, Department of Veterinary Pathobiology, College of Veterinary Medicine and Biomedical Sciences, Texas A&M University, College Station, TX

Meat Inspection

Karel A. Schat, DVM, PhD

Professor, Department of Microbiology and Immunology, College of Veterinary Medicine, Cornell University, Ithaca, NY

Chicken Anemia Virus Infection

Mary M. Schell, DVM, DABVT, DABT

Senior Toxicologist, ASPCA Animal Poison Control Center, Urbana, Illinois

Rodenticide Poisoning

David G. Schmitz, DVM, MS, DACVIM (Large Animal)

Visiting Associate Professor, Department of Veterinary Large Animal Clinical Sciences, College of Veterinary Medicine, Texas A&M University, College Station, TX

Cantharidin Poisoning

Thomas Schubert, DVM, DACVIM, DABVP

Clinical Professor and Chief of Neurology Service, Small Animal Clinical Sciences, College of Veterinary Medicine, University of Florida, Gainesville, FL

Facial Paralysis; Limb Paralysis; Nervous System Introduction

James Schumacher, DVM, MS

Professor, Large Animal Clinical Sciences, College of Veterinary Medicine, University of Tennessee, Knoxville, TN

Lameness in Horses: Regional Anesthesia

John Schumacher, DVM, MS

Professor, Department of Clinical Sciences, College of Veterinary Medicine, Auburn University, Auburn, AL

Lameness in Horses: Regional Anesthesia

Philip R. Scott, BVMS, MPhil, DVM&S, DSHP, DECBHM, FHEA, FRCVS

Veterinary Clinical Sciences, University of Edinburgh, Midlothian, UK

Aspiration Pneumonia; Contagious Ecthyma; Listeriosis; Mycotic Pneumonia; Respiratory Diseases of Sheep and Goats; Ulcerative Dermatitis of Sheep

Joaquim Segalés, DVM, PhD, DECPV, DECPHM

Facultat de Veterinària, Departament de Sanitat i d'Anatomia Animals and Centre de Recerca en Sanitat Animals, Universitat Autònoma de Barcelona, Bellaterra, Barcelona, Spain

Glässer's Disease; Porcine Circovirus Diseases

Patricia L. Sertich, MS, VMD, DACT

Associate Professor-Clinician Educator, Department of Clinical Studies, New Bolton Center, School of Veterinary Medicine, University of Pennsylvania, Kennett Square, PA

Management of Reproduction: Horses

Torsten Seuberlich, DMV

Professor, NeuroCentre, Division of Neurological Sciences, OIE Reference Laboratories for BSE and Scrapie; Vetsuisse Faculty, Department of Clinical Research and Veterinary Public Health, University of Berne, Berne, Switzerland

Bovine Spongiform Encephalopathy

A. S. Shakespeare, BSc (Eng) (Natal), BVSc (Hons) (Pret), MMedVet (Med) (Pret)

Onderstepoort Veterinary Faculty, University of Pretoria, South Africa

Heartwater

Linda Shell, DVM, DACVIM (Neurology)

Professor, Small Animal Internal Medicine, Ross University School of Veterinary Medicine, Basseterre, Saint Kitts and Nevis

Systemic Pharmacotherapeutics of the Nervous System

Clifford F. Shipley, DVM, DACT

Clinical Associate Professor, Agricultural Animal Care and Use Program and College of Veterinary Medicine, University of Illinois, Urbana, IL

Management of Reproduction: Goats

Michael Shipstone, BVSc, FACVSc, DACVD

Queensland Veterinary Specialists, Brisbane, Queensland, Australia

Systemic Pharmacotherapeutics of the Integumentary System

H. L. Shivaprasad, BVSc, MS, PhD, DACPV

Professor, California Animal Health and Food Safety Laboratory System, University of California, Tulare, CA

Hemorrhagic Enteritis/Marble Spleen Disease

Wayne Simpson, MSc (Microbiology), BHort Sc, DHort

Scientist, Endophyte Mycology, Forage Improvement Section, AgResearch Limited, Palmerston North, New Zealand

Ryegrass Toxicity

Annette N. Smith, DVM, MS, DACVIM

Professor, Department of Clinical Sciences, College of Veterinary Medicine, Auburn University, Auburn, AL

Neoplasia of the Nervous System; Paraneoplastic Disorders of the Nervous System

Geof W. Smith, DVM, PhD

Associate Professor of Ruminant Medicine, Department of Population Health and Pathobiology, College of Veterinary Medicine, North Carolina State University, Raleigh, NC

Actinobacillosis; Actinomycosis

Joan A. Smyth, PhD

Director, Connecticut Veterinary Medical Diagnostic Laboratory, Department of Pathobiology and Veterinary Science, University of Connecticut, Storrs, CT

Egg Drop Syndrome '76

Victoria Smyth, PhD

Senior Scientific Officer for Avian Virology, Veterinary Sciences Division, Agri-Food and Biosciences Institute, Belfast, UK

Avian Nephritis Viral Infections

Arthur M. Spickett, BSc (Hons) Zoology

Parasites, Vectors and Vector-borne Diseases Programme, ARC-Onderstepoort Veterinary Institute, South Africa

Sweating Sickness

Anna Rovid Spickler, DVM, PhD

Veterinary Specialist, Center for Food Security and Public Health, College of Veterinary Medicine, Iowa State University, Ames, IA

Zoonoses

Sharon J. Spier, DVM, PhD, DACVIM
Professor, Department of Medicine and
Epidemiology, School of Veterinary Medi-
cine, University of California, Davis, CA

*Disorders of Calcium Metabolism: Hypo-
calcemic Tetany in Horses; Lymphadeni-
tis and Lymphangitis: Corynebacterium
pseudotuberculosis Infection of Horses
and Cattle*

**Richard A. Squires, BVSc (Hons), PhD,
DVR, DACVIM, DECVIM-CA, GCertEd,
MRCVS**

Head of Veterinary Clinical Sciences,
School of Veterinary and Biomedical Sci-
ences, James Cook University, Townsville,
Australia

Feline Panleukopenia

Henry R. Stämpfli, DVM, DMV, DACVIM
Professor, Large Animal Medicine,
Department of Clinical Studies, Ontario
Veterinary College, University of Guelph,
Ontario, Canada

Clostridial Diseases

**Jonathan Statham, MA, VetMB, DCHP,
MRCVS**

Veterinarian, Bishopton Veterinary Group,
North Yorkshire, UK

*Cystic Ovary Disease; Management of
Reproduction: Cattle*

**Bryan L. Stegelmeier, DVM, PhD,
DACVP**

Veterinary Pathologist, Poisonous Plant
Research Laboratory, USDA-ARS, Logan, UT

*Bracken Fern Poisoning; Sweet Clover
Poisoning*

**Jörg M. Steiner, DMV, PhD, DACVIM,
DECVIM-CA, AGAF**

Associate Professor and Director, Gas-
trointestinal Laboratory, Department of
Small Animal Clinical Sciences, College
of Veterinary Medicine and Biomedical
Sciences, Texas A&M University, College
Station, TX

The Exocrine Pancreas

**Allison J. Stewart, BVSC (Hons), MS,
DACVIM (Large Animal), DACVECC**
Professor of Equine Internal Medicine,
Department of Clinical Sciences, College
of Veterinary Medicine, Auburn University,
Auburn, AL

*Disorders of Magnesium Metabolism;
Intestinal Diseases in Horses and Foals*

Jamie Lynn Stewart, DVM
Department of Veterinary Clinical
Medicine, College of Veterinary Medicine,
University of Illinois, Urbana, IL

Management of Reproduction: Goats

Bruce Stewart-Brown, DVM, DACPV
Senior Vice President of Food Safety, Qua-
lity, and Live Operations, Perdue Farms,
Salisbury, MD

*Nutrition and Management Poultry:
Feeding and Management Practices*

Roger W. Stich, MS, PhD
Professor of Parasitology, Department of
Veterinary Pathobiology, College of Vet-
erinary Medicine, University of Missouri,
Columbia, MO

*Ectoparasiticides: Ectoparasiticides
Used in Large Animals*

Michael K. Stoskopf, DVM, PhD, DACZI
Professor of Wildlife and Aquatic Health,
Director of the Environmental Medicine
Consortium, College of Veterinary Medicine
North Carolina State University, Raleigh, NC

Marine Mammals

George M. Strain, PhD
Professor of Neuroscience, Comparative
Biomedical Sciences, School of Veterinary
Medicine, Louisiana State University,
Baton Rouge, LA

Deafness

Reinhard K. Straubinger, DMVH, PhD
Professor and Head for Bacteriology and
Mycology, Institute for Infectious Dis-
eases and Zoonoses, Faculty of Veterinary
Medicine, Ludwig-Maximilians University
Munich, Germany

Lyme Borreliosis

Bert E. Stromberg, PhD
Professor, Veterinary and Biomedical
Sciences, College of Veterinary Medicine,
University of Minnesota, St. Paul, MN

*Infectious Diseases of the Urinary
System in Large Animals: Swine Kidney
Worm Infection; Trichinellosis*

**David E. Swayne, DVM, PhD, DACVP,
DACPV**
Laboratory Director, USDAARS, Southeast
Poultry Research Laboratory, Athens, GA

*Avian Influenza; Newcastle Disease and
Other Paramyxovirus Infections: Other
Avian Paramyxovirus Infections*

Thomas W. Swerczek, DVM, PhD
Professor, Department of Veterinary Science, University of Kentucky, Lexington, KY
Tyzzer Disease

Jane E. Sykes, BVSc (Hons), PhD, DACVIM
Professor of Small Animal Medicine, Department of Medicine and Epidemiology, School of Veterinary Medicine, University of California, Davis, CA
Chlamydial Conjunctivitis

Joseph Taboada, DVM, DACVIM
Professor and Associate Dean, Office of Student and Academic Affairs, School of Veterinary Medicine, Louisiana State University, Baton Rouge, LA
Fungal Infections

Jaime L. Tarigo, DVM, PhD, DACVP
Assistant Professor, Veterinary Clinical Pathology, University of Georgia, Athens, GA
Blood Parasites: Cytauxzoonosis

Marcel Taverne, PhD
Emeritus Professor of Foetal and Perinatal Biology, Department of Farm Animal Health, Faculty of Veterinary Medicine, Utrecht University, Utrecht, The Netherlands
Pseudopregnancy in Goats

Charles O. Thoen, DVM, PhD
Professor, Veterinary Microbiology and Preventive Medicine, College of Veterinary Medicine, Iowa State University, Ames, IA
Tuberculosis and other Mycobacterial Infections; Tuberculosis in Poultry

Jennifer E. Thomas, DVM
Post-Doc Fellow, Department of Veterinary Pathobiology, Center for Veterinary Health Sciences, Oklahoma State University, Stillwater, OK
Lice; Mange in Large Animals

William B. Thomas, DVM, MS, DACVIM (Neurology)
Professor, Neurology and Neurosurgery, Department of Small Animal Clinical Sciences, University of Tennessee, Knoxville, TN
Diseases of the Peripheral Nerves and Neuromuscular Junction; Diseases of the Spinal Column and Cord

Sara M. Thomasy, DVM, PhD, DACVO
Vision Researcher, Department of Surgical and Radiological Sciences, School of Veterinary Medicine, University of California, Davis, CA
Equine Recurrent Uveitis

Larry J. Thompson, DVM, PhD, DABVT
Senior Research Scientist, Nestlé Purina PetCare, St. Louis, MO
Nitrate and Nitrite Poisoning; Nonprotein Nitrogen Poisoning; Salt Toxicity

Peter N. Thompson, BVSc, MMV, PhD
Professor of Veterinary Epidemiology, Faculty of Veterinary Science, University of Pretoria, South Africa
Rift Valley Fever; Wesselsbron Disease

Ahmed Tibary, DMV, PhD, DACT
Professor, Comparative Theriogenology, Department of Veterinary Clinical Sciences, College of Veterinary Medicine, Washington State University, Pullman, WA
Abortion in Large Animals; Congenital and Inherited Anomalies of the Reproductive System

John F. Timoney, MVB, PhD, Dsc, MRCVS
Keeneland Chair of Infectious Diseases, Gluck Equine Research Center, Department of Veterinary Science, University of Kentucky, Lexington, KY
Glanders

Peter J. Timoney, MVB (Hons), MS, PhD, FRCVS
Professor; Frederick Van Lennep Chair in Equine Veterinary Science, Gluck Equine Research Center, University of Kentucky, Lexington, KY
Equine Infectious Anemia; Equine Viral Arteritis

Ian Tizard, BVMS, PhD, DACVM
University Distinguished Professor of Immunology; Director, Richard M. Schubot Exotic Bird Health Center, Department of Veterinary Pathobiology, College of Veterinary Medicine and Biomedical Sciences, Texas A&M University, College Station, TX
Amyloidosis; Immunologic Diseases; The Biology of the Immune System; Vaccines and Immunotherapy

Sheila M. F. Torres, DVM, MS, PhD, DACVD
Associate Professor, Dermatology, College of Veterinary Medicine, University of Minnesota, St. Paul, MN
Diseases of the Pinna

Jerry L. Torrison, DVM, PhD, DACVPM
Swine Veterinarian, Zinpro Corporation;
Adjunct Professor, College of Veterinary
Medicine, University of Minnesota,
St. Paul, MN

Lameness in Pigs

Sandra P. Tou, DVM, DACVIM
Assistant Clinical Professor of Cardiology,
Department of Clinical Sciences, College
of Veterinary Medicine, North Carolina
State University, Raleigh, NC

*Congenital and Inherited Anomalies of
the Cardiovascular System*

**Josie L. Traub-Dargatz, DVM, MS,
DACVIM**

Professor of Equine Medicine, Depart-
ment of Clinical Sciences, College of
Veterinary Medicine and Biomedical
Sciences, Colorado State University, Fort
Collins, CO

Vesicular Stomatitis

Robert Tremblay, DVM, DVSc, DACVIM
Bovine/Equine Specialist, Boehringer
Ingelheim (Canada) Ltd, Burlington,
Ontario, Canada

Management and Nutrition Introduction

**Deoki N. Tripathy, DVM, MS, PhD,
DACVM, DACVP**

Professor Emeritus, Department of Veteri-
nary Pathobiology, College of Veterinary
Medicine, University of Illinois, Urbana, IL

Fowlpox

**Thomas N. Tully, Jr., BS, DVM, MS,
DABVP (Avian), DECZM (Avian)**

Professor, Zoological Medicine, School
of Veterinary Medicine, Louisiana State
University, Baton Rouge, LA

Ratites

Tracy A. Turner, DVM, MS

Anoka Equine Veterinary Services, Elk
River, MN

*Lameness in Horses: Imaging
Techniques*

**Stephanie J. Valberg, DVM, PhD,
DACVIM, ACVSMR**

Professor, Department of Veterinary Popu-
lation Medicine, University of Minnesota
Equine Center, St. Paul, MN

*Myopathies in Horses; Myopathies in
Ruminants and Pigs*

**Arnaud J. Van Wettère, DVM, MS, PhD,
DACVP**

Assistant Professor of Veterinary
Pathology, Utah Veterinary Diagnostic
Laboratory, Utah State University,
Logan, UT

*Avian Chlamydiosis; Bloodborne Organ-
isms; Disorders of the Skeletal System
(Poultry); Myopathies (Poultry)*

Jozef Vercruysse, DVM

Professor, Faculty of Veterinary Medicine,
Ghent University, Merelbeke, Belgium

*Anthelmintics; Blood Parasites: Shisto-
somiasis*

Alice E. Villalobos, DVM, DPNAP

Director, Animal Oncology Consultation
Service; Director, Pawspice, Hermosa
Beach, CA

Tumors of the Skin and Soft Tissues

**Pedro Villegas, DVM, MS, PhD,
DACVM, DACVP**

Professor Emeritus, Department of
Population Health, College of Veterinary
Medicine, Poultry Diagnostic & Research
Center, University of Georgia, Athens, GA

*Inclusion Body Hepatitis/Hydropericar-
dium Syndrome*

**Patricia S. Wakenell, DVM, PhD,
DACVP**

Head, Avian Diagnostics, Animal Disease
Diagnostic Laboratory; Associate Profes-
sor, Department of Comparative Patho-
biology, School of Veterinary Medicine,
Purdue University, West Lafayette, IN

Backyard Poultry; Erysipelas

Peter J. Walker, BSc, PhD, DSc

CSIRO Biosecurity, Australian Animal
Health Laboratory, Victoria, Australia

Bovine Ephemeral Fever

**Patricia Walters, VMD, DACVIM,
DACVECC**

New England Animal Medical Center, West
Bridgewater, MA

*Diseases of the Esophagus in Small
Animals*

Kevin Washburn, DVM

Professor, Large Animal Clinical Sciences,
College of Veterinary Medicine, Texas
A&M University, College Station, TX

*Lymphadenitis and Lymphangitis: Case-
ous Lymphadenitis*

Nick Whelan, BVSc, MVSc, MACVSc, DACVCP, DACVO

Animal Eye Clinic of Waterloo Region,
Cambridge, Ontario, Canada

*Systemic Pharmacotherapeutics of
the Eye*

Brent R. Whitaker, MS, DVM

Vice President of Biological Programs,
National Aquarium, Baltimore, MD

Amphibians

Trevor J. Whitbread, BSc, BVSc, MRCVS, DECVP

Pathologist, Abbey Veterinary Services,
Devon, UK

*Diagnostic Procedures for the Private
Practice Laboratory: Clinical Biochem-
istry, Clinical Hematology, Cytology,
Serology, Urinalysis*

Stephen D. White, DVM, DACVD

Professor and Chief of Service,
Dermatology, Department of Medicine
and Epidemiology, School of Veterinary
Medicine, University of California,
Davis, CA

*Eosinophilic Granuloma Complex; Food
Allergy; Miscellaneous Systemic Derma-
toses; Nasal Dermatoses of Dogs; Saddle
Sores; Seborrhea; Urticaria*

Chris Whitton, BVSc, FANZCVS, PhD

Associate Professor, Equine Centre, Uni-
versity of Melbourne, Victoria, Australia

*Lameness in Horses: Developmental
Orthopedic Disease*

Mark L. Wickstrom, DVM, MS, PhD

Associate Professor, Department
of Veterinary Biomedical Sciences,
Western College of Veterinary Medicine,
University of Saskatchewan, Saskatoon,
Canada

Antiseptics and Disinfectants

Kevin P. Winkler, DVM, DACVS

Surgeon, Georgia Veterinary Specialists,
Atlanta, GA

Wound Management

**Thomas Wittek, Univ.-Prof. Dr.med.
vet., DECBHM**

University Clinic for Ruminants, Universi-
ty of Veterinary Medicine, Vienna, Austria

*Malassimilation Syndromes in Large
Animals; Peritonitis*

**Zerai Woldehiwet, DVM, PhD, DAgric,
MRCVS**

Professor, Institute of Infection and Global
Health and School of Veterinary Science,
University of Liverpool, Wirral, UK

Tick Pyemia; Tickborne Fever

R. Darren Wood, DVM, DVSc, DACVP

Associate Professor, Department of
Pathobiology, Ontario Veterinary College,
University of Guelph, Ontario, Canada

Leukocyte Disorders

Peter R. Woolcock, BSc, MSc, PhD

Professor, Clinical Diagnostic Virology,
California Animal Health and Food Safety
Laboratory System, School of Veterinary
Medicine, University of California, Davis,
CA

Duck Viral Hepatitis

Mariko Yamamoto, PhD

Department of Population Health and
Reproduction, School of Veterinary Medi-
cine, University of California, Davis, CA

The Human-Animal Bond

Roy P. E. Yanong, VMD

Associate Professor and Extension Veteri-
narian, Tropical Aquaculture Laboratory,
Fisheries and Aquatic Sciences Program,
School of Forest Resources and Conserva-
tion, Institute of Food and Agricultural Sci-
ences, University of Florida, Gainesville, FL

Aquaculture

Laszlo Zsak, DVM, PhD

Research Leader, USDA-Agricultural
Research Center, South Atlantic Area,
Southeast Poultry Research Laboratory,
Athens, GA

Goose Parvovirus Infection

CIRCULATORY SYSTEM

THROMBOSIS, EMBOLISM, AND ANEURYSM 141

HEMATOPOIETIC SYSTEM INTRODUCTION

Blood supplies cells with water, electrolytes, nutrients, and hormones and removes waste products. The cellular elements supply oxygen (RBCs), protect against foreign organisms and antigens (WBCs), and initiate coagulation (platelets). Because of the diversity of the hematopoietic system, its diseases are best discussed from a functional perspective. Function may be classified as either normal responses to abnormal situations (eg, leukocytosis and left shift in response to inflammation) or primary abnormalities of the hematopoietic system (eg, pancytopenia from marrow failure). Furthermore, abnormalities may be quantitative (ie, too many or too few cells) or qualitative (ie, abnormalities in function).

RED BLOOD CELLS

The function of RBCs is to carry oxygen to the tissues at pressures sufficient to permit its rapid diffusion. This is accomplished through the following mechanisms: a carrier molecule, hemoglobin (Hgb); a vehicle (RBC) capable of bringing the intact Hgb to the cellular level; and a metabolism geared to protect both the RBC and the Hgb from damage. Interference with synthesis or release of Hgb, production or survival of RBCs, or metabolism causes disease.

Hgb is a complex molecule, formed of four heme units attached to four globins (two α and two β globins). Iron is added in the last step by the ferredoxinase enzyme. Interference with the normal production of heme or globin leads to anemia. Causes include copper or iron deficiency and lead poisoning. Hemoglobinopathies such as thalassemias and sickle cell anemia, important genetic diseases of people, have not been seen in other animals. In these diseases, the production of globins (α or β or both) does not balance heme production, and the Hgb is not functional. The only known hemoglobinopathy of animals is porphyria. Although described in several species, it is most important as a cause of photosensitivity in cattle (*see* p 976).

Red cell mass, and thus oxygen-carrying capacity, remains constant over time in healthy animals. Mature RBCs have a finite life span; their production and destruction must be carefully balanced, or disease ensues.

Erythropoiesis is regulated by erythropoietin, which increases in the presence of hypoxia and regulates RBC production. In

most species, the kidney is both the sensor organ and the major site of erythropoietin production, so chronic renal failure is associated with anemia. Erythropoietin acts on the marrow in concert with other humoral mediators to increase the number of stem cells entering RBC production, to shorten maturation time, and to cause early release of reticulocytes. Other factors that affect erythropoiesis are the supply of nutrients (eg, iron, folate, or vitamin B₁₂) and cell-cell interactions between erythroid precursors, lymphoid cells, and other components of the hematopoietic microenvironment. Factors that may suppress erythropoiesis include chronic debilitating diseases and endocrine disorders (such as hypothyroidism or hyperestrogenism).

Two mechanisms exist for removal of senescent RBCs; both conserve the principal constituents of the cell for reuse. Removal of aged RBCs normally occurs by phagocytosis by the fixed macrophages of the spleen. As the RBC ages it may change antigenically, acquiring senescent antigens and losing its flexibility due to impaired ATP production. Both of these changes increase the risk that the cell will become trapped in the spleen and removed by macrophages. After phagocytosis and subsequent disruption of the cell membrane, Hgb is converted to heme and globin. Iron is released from the heme moiety and either stored in the macrophage as ferritin or hemosiderin or released into the circulation for transport back to the marrow. The remaining heme is converted to bilirubin, which is released by the macrophages into the systemic circulation, where it complexes with albumin for transport to the hepatocytes; there, it is conjugated and excreted into the bile. In extravascular hemolytic anemias, RBCs have a shortened life span, and the same mechanisms occur at an increased rate.

Approximately 1% of normal aging RBCs are hemolyzed in the circulation, and free Hgb is released. This is quickly converted to Hgb dimers that bind to haptoglobin and are transported to the liver, where they are metabolized in the same manner as products from RBCs removed by phagocytosis. In intravascular hemolytic anemia, more RBCs are destroyed in the circulation (hemoglobinemia) than can be bound to haptoglobin. The excess Hgb and, therefore, iron are excreted in the urine (hemoglobinuria).

The principal metabolic pathway of RBC is glycolysis, and the main energy source in most species is glucose. Glucose enters the RBC by an insulin-independent mechanism, and most is metabolized to produce ATP and reduced nicotinamide adenine dinucleotide (NADH). The energy of ATP is used to maintain RBC membrane pumps so as to preserve shape and flexibility. The reducing potential of the NADH is utilized via the methemoglobin reductase pathway to maintain the iron in Hgb in its reduced form (Fe^{2+}).

The glucose not used in glycolysis is metabolized via a second pathway, the hexose monophosphate (HMP) shunt. No energy is produced via the HMP shunt; its principal effect is to maintain reducing potential in the form of reduced nicotinamide adenine dinucleotide phosphate (NADPH). In conjunction with the glutathione reductase/peroxidase system, NADPH maintains the sulfhydryl groups of globin in their reduced state.

Some disorders are the direct result of abnormal RBC metabolism and interference with glycolysis. Inherited deficiency of pyruvate kinase, a key glycolytic enzyme, causes ATP deficiency, which leads to reduced RBC life span and hemolytic anemia. Excessive oxidant stress may overload the protective HMP shunt or methemoglobin reductase pathways, causing Heinz body hemolysis or methemoglobin formation, respectively. Hemolytic anemia caused by a drug, such as acetaminophen in cats, is an example of this mechanism. (See also ANEMIA, p 7.)

A decreased RBC mass (anemia) may be caused by blood loss, hemolysis, or decreased production. In acute blood loss anemia, RBCs are lost, but mortality is usually related to loss of circulating volume rather than to loss of RBC. Iron is the limiting factor in chronic blood loss. Hemolysis may be caused by toxins, infectious agents, congenital abnormalities, or antibodies directed against RBC membrane antigens. Decreased RBC production may result from primary marrow diseases (eg, aplastic anemia, hematopoietic malignancy, or myelofibrosis) or from other causes such as renal failure, drugs, toxins, or antibodies directed against RBC precursors. Malignancy of RBCs or their precursors may be acute (eg, erythroleukemia) or chronic (eg, polycythemia vera). Animals with erythroleukemia are anemic despite having a marrow filled with rubriblasts, whereas those with polycythemia vera have erythrocytosis.

WHITE BLOOD CELLS

Phagocytes: The principal function of phagocytes is to defend against invading microorganisms by ingesting and destroying them, thus contributing to cellular inflammatory responses. There are two types of phagocytes: mononuclear phagocytes and granulocytes. Mononuclear phagocytes arise primarily from the marrow and are released into the blood as monocytes. They may circulate for hours to a few days before entering the tissues and differentiating to become macrophages. Granulocytes have a segmented nucleus and are classified according to their staining characteristics as neutrophils, eosinophils, or basophils. Neutrophils circulate for only a few hours before travelling to the tissues.

Five distinct stages in the process of phagocytosis have been identified: 1) attraction of phagocytes (chemotaxis) to microorganisms, antigen-antibody complexes, and other mediators of inflammation; 2) attachment to the organism; 3) ingestion; 4) fusion of cell lysosomes with ingested microorganisms and bacterial killing; and 5) digestion. In addition, many phagocytes have other specialized functions. Monocytes form a link to the specific immune system by processing antigen for presentation to lymphocytes and by producing substances such as interleukin-1, which initiates fever and lymphocyte activation and stimulates early hematopoietic progenitors.

Eosinophils, while having a role as phagocytes, also have more specific functions that include providing a defense against metazoan parasites and modulating the inflammatory process. They respond chemotactically to histamine, immune complexes, and eosinophil chemotactic factor of anaphylaxis, a substance released by degranulating mast cells. Basophils are not true phagocytes but contain large amounts of histamine and other mediators of inflammation. Eosinophilia and basophilia may be seen in response to systemic allergic reactions and invasion of tissues by parasites.

As with the RBCs, the production and circulating numbers of phagocytes are tightly regulated and controlled by various humoral factors, including colony stimulating factors and interleukins. Unlike the RBCs, which remain circulating in the blood, the phagocytes use this compartment as a pathway to the tissues. Consequently, the number of phagocytes in the blood reflects circumstances in the tissues (eg, inflammation) as well as the proliferative function of the bone marrow. The sensitivity with

which phagocytes reflect these conditions varies from species to species. Abnormal response, such as neutropenia from marrow failure, infections, drugs, or toxins, is likely to result in secondary bacterial infections. Some cases of "idiopathic" neutropenia in dogs may have an immune-mediated cause. Finally, phagocyte precursors may undergo malignant transformation, which results in acute or chronic myelogenous leukemia.

Lymphocytes: Lymphocytes are responsible for both humoral and cellular immunity. Cells of the two branches of the immune system cannot be differentiated morphologically, but they differ in their dynamics of production and circulation. Lymphocyte production in mammals originates in the bone marrow. Some of the lymphocytes destined to be involved in cellular immunity migrate to the thymus and differentiate further under the influence of thymic hormones. These become T cells and are responsible for a variety of helper or cytotoxic immunologic functions. Most circulating lymphocytes are T cells, but T cells are also present in the spleen and lymph nodes. The B cells migrate directly to organs without undergoing modification in the thymus and are responsible for humoral immunity (antibody production).

Thus, lymphoid organs have populations of both B and T lymphocytes. In the lymph nodes, follicular centers are primarily B cells, and parafollicular zones are primarily T cells. In the spleen, most of the lymphocytes of the red pulp are B cells, whereas those of the periarteriolar lymphoid sheaths are T cells. Close association of T cells and B cells within lymphoid organs is essential to immune function.

Lymphocyte function in the cellular immune system features both afferent (receptor) and efferent (effector) components. Long-lived T cells of the peripheral blood are the receptors. In response to antigens to which they have been previously sensitized, they leave the circulation and undergo blast transformation to form activated T cells, which in turn cause other T cells to undergo blast transformation, both locally and systemically. Stimulated T cells produce lymphokines with a wide range of activities, such as attraction and activation of neutrophils, macrophages, and lymphocytes.

The humoral immune system is composed of B cells that produce antibodies of several classes. When sensitized B cells encounter antigen, they divide and differentiate into plasma cells that produce antibody. Therefore, each initially stimu-

lated B cell produces a clone of plasma cells, all producing the same specific antibody.

Antibody molecules (immunoglobulins) fall into several classes, each with its own functional characteristics. For example, IgA is the principal antibody of respiratory and intestinal secretions, IgM is the first antibody produced in response to a newly recognized antigen, IgG is the principal antibody of the circulating blood, and IgE is the principal antibody involved in allergic reactions.

Antibodies perform their function by combining with the specific antigens that stimulated their production. Antigen-antibody complexes may be chemotactic for phagocytes, or they may activate complement, a process that produces both cell lysis and substances chemotactic for neutrophils and macrophages. In this manner, the humoral immune system is related to, and interacts with, the nonspecific immune system.

The humoral immune system also is related to both the nonspecific immune system and the cellular immune system in other ways. Both "helper" (CD4) and "cytotoxic" (CD8) T-cell classes have been described. Helper T cells recognize processed antigen and activate the humoral immune response. Cytotoxic T cells, after sensitization by antigen, are effector cells, which are especially important in antiviral immunity. Natural killer cells, which are a class of lymphocyte distinct from T cells and B cells, destroy foreign cells (eg, neoplastic cells) even without prior sensitization. Antigen processing by macrophages precedes recognition of an antigen by lymphocytes. These complex processes are involved in routine surveillance against neoplastic cells and recognition of "self."

Lymphocyte response in disease may be appropriate (activation of the immune system) or inappropriate (immune-mediated disease and lymphoproliferative malignancies). (See also THE BIOLOGY OF THE IMMUNE SYSTEM, p 811.) Immune-mediated disease results from failure of the immune system to recognize host tissues as self. For example, in immune-mediated hemolytic anemia, antibodies are produced against the host's own RBCs. Another inappropriate response of the immune system is allergy. In allergic individuals, IgE antibodies to allergens are bound to the surface of basophils and mast cells. When exposure to the allergen occurs, antigen-antibody complexes are formed, and degranulation of the mast cells and basophils releases vasoactive amines. Reaction to this may be mild (as in urticaria or atopy) or life-threatening (as in anaphylaxis).

Lymphocytosis occurs in some species, especially the cat, as a response to epinephrine secretion. Atypical lymphocytes may be seen in the blood in response to antigenic stimulation (eg, vaccination). Persistent lymphocytosis in cattle infected with bovine leukemia virus is a benign polyclonal increase in lymphocyte numbers. Lymphoproliferative malignancies include lymphomas and acute lymphoblastic and chronic lymphocytic leukemias. Lymphopenia may occur most commonly as a response to glucocorticoid secretion.

PLATELETS

Platelets form the initial hemostatic plug whenever hemorrhage occurs. They also are the source of phospholipid, which is needed for the interaction of coagulation factors to form a fibrin clot. Platelets are produced in the bone marrow from megakaryocytes, under the influence of thrombopoietin. Platelet production begins with invagination of the megakaryocyte cell membrane and the formation of cytoplasmic channels and islands. The cytoplasmic islands produce platelets by fragmentation from the megakaryocyte.

Mature circulating platelets are packed with dense granules containing ATP, adenosine diphosphate (ADP), and calcium, as well as serotonin, lysosomes, glycogen, mitochondria, and an intracellular canalicular system. The mitochondria and glycogen are involved in energy production, and the canalicular system serves both as a transport system for granule components and as a source of phospholipid, which is found in high concentration in the membrane lining of the canals.

When vessel walls are damaged, collagen and tissue factor are exposed, and circulating platelets adhere via von Willebrand factor and undergo a change in shape with the accompanying release of ADP. Local platelet aggregation is stimulated by ADP, with the ultimate formation of the primary platelet plug. The local accumulation of fibrin and platelets is known as a hemostatic plug. The fibrin clot that then forms is consolidated by the action of platelet contractile proteins.

Platelet disorders are either quantitative (thrombocytopenia or thrombocytosis) or qualitative (thrombocytopathy). Thrombocytopenia is one of the most common bleeding disorders of animals. In general, platelet counts must fall to $<30,000/\mu\text{L}$ before the risk of hemorrhage increases. Consumption, destruction, or sequestration of platelets causes thrombocytopenia associated with increased production by the bone marrow. Consumptive thrombocytopenia occurs with massive hemorrhage or with disseminated intravascular coagulation, secondary to a variety of diseases. Destruction occurs in immune-mediated thrombocytopenia, in which platelets become coated with antiplatelet antibodies and are removed from the circulation by the fixed phagocyte system. Excessive sequestration of platelets by an enlarged spleen (hypersplenism) may occur in conditions such as myeloproliferative diseases.

Decreased production of platelets in the marrow may be caused by drugs, toxins, or by primary marrow disorders such as aplasia, fibrosis, or hematopoietic malignancy. In primary marrow disorders, more than one hematopoietic cell line is often decreased, resulting in pancytopenia.

Thrombocytosis is rare and often idiopathic. It may be associated with primary marrow disease such as in megakaryocytic leukemia. It is often associated with chronic blood loss and iron deficiency because of increased platelet production in the marrow reacting to continued consumption and loss.

Thrombocytopathies comprise a poorly defined group of diseases in which platelet numbers are normal but their function is impaired. Von Willebrand disease is characterized primarily by a defect in platelet adhesion to the endothelium. The platelets themselves are normal. Other hereditary disorders of platelet function have been described but are relatively rare. Probably the most common platelet function defect is the irreversible inhibition of thromboxane (which is necessary for platelet aggregation) caused by aspirin administration.

ANEMIA

Anemia is defined as an absolute decrease in the red cell mass as measured by RBC count, hemoglobin concentration, and/or

PCV. It can develop from loss, destruction, or lack of production of RBCs. Anemia is classified as regenerative or nonregenerative.

With regenerative anemia, the bone marrow responds appropriately to the decreased red cell mass by increasing RBC production and releasing reticulocytes. With nonregenerative anemia, the bone marrow responds inadequately to the increased need for RBCs. Anemia caused by hemorrhage or hemolysis is typically regenerative. Anemia caused by decreased erythropoietin or an abnormality in the bone marrow is nonregenerative.

Clinical Findings: Clinical signs in anemic animals depend on the degree of anemia, the duration (acute or chronic), and the underlying cause. Acute anemia can result in shock and even death if more than a third of the blood volume is lost rapidly and not replaced. In acute blood loss, the animal usually presents with tachycardia, pale mucous membranes, bounding or weak peripheral pulses, and hypotension. The cause of the blood loss may be overt, eg, trauma. If no evidence of external bleeding is found, a source of internal or occult blood loss must be sought, eg, a ruptured splenic tumor, other neoplasia, coagulopathy, GI ulceration, or parasites. If hemolysis is present, the animal may be icteric. Animals with chronic anemia have had time to accommodate, and their clinical presentation is usually more indolent with vague signs of lethargy, weakness, and anorexia. These animals may have similar physical examination findings such as pale mucous membranes and weak peripheral pulses. The lack of expected clinical signs may alert the clinician to the time frame involved. Splenomegaly, abdominal distention, and/or heart murmur may be present, depending on the underlying cause of anemia.

Diagnosis: A complete history is an important part of the evaluation of an anemic animal. Questions might include duration of clinical signs, history of exposure to toxins (eg, rodenticides, heavy metals, toxic plants), drug treatments, vaccinations, travel history, and any prior illnesses.

A CBC, including a platelet and a reticulocyte count, will provide information on the severity of anemia and degree of bone marrow response, and also allow for evaluation of other cell lines. A blood smear should be evaluated for abnormalities in RBC morphology or size and for RBC parasites. The RBC indices (measures of size and hemoglobin concentration) are

calculated by automated cell counters calibrated for the species in question. RBC size is expressed by the mean corpuscular volume (MCV) in femtoliters and can reflect the degree of regeneration. Macrocytosis (an increase in the MCV) usually correlates with a regenerative anemia. Macrocytosis can be a heritable condition in Poodles without anemia and may be seen in anemic cats infected with feline leukemia virus. Microcytosis (a decrease in the MCV) is the hallmark of iron-deficiency anemia. The hemoglobin concentration of each RBC, measured in g/dL, is defined as the mean corpuscular hemoglobin concentration (MCHC). Terms used for description of abnormalities with MCHC include normochromia and hypochromia. Abnormalities in RBC morphology, such as basophilic stippling, can indicate lead intoxication. Heinz body formation indicates oxidative injury to the RBCs, secondary to toxin exposure (*see* TABLE 1). Cats are more susceptible to Heinz body formation than other species, and cats without anemia can have a small number of Heinz bodies. The presence of schistocytes or spherocytes may also help identify the pathophysiology associated with the cause of anemia.

The reticulocyte count is usually reported as a percent of the RBC mass. This value should be corrected for the degree of anemia to evaluate the degree of regeneration. An absolute reticulocyte count (measured by RBCs/ μ L $\times$ reticulocyte percentage) of $>50,000/\mu$ L in cats or $>60,000/\mu$ L in dogs is considered regenerative. To correct the percent reticulocytes, the formula (*see* below) can be applied. A corrected reticulocyte percent $>1\%$ indicates regeneration in dogs and cats. After acute blood loss or hemolytic crisis, reticulocytosis usually takes 3–4 days to become evident.

A serum chemistry panel and urinalysis evaluate organ function. If GI blood loss is suspected, an examination of the feces for occult blood and parasites can be useful. Radiographs can help identify occult disease, such as a penny (zinc toxicity) in the stomach of a puppy with hemolytic anemia. Bruising or bleeding may be signs of a coagulopathy and indicate the need for a coagulation profile. Presence of petechiae or ecchymotic hemorrhage suggest significant thrombocytopenia or thrombocytopathy. If hemolytic disease is suspected, blood can be evaluated for autoagglutination, or a direct Coombs' test might be indicated. A test for autoagglutination can be done by placing a

$$\text{corrected reticulocyte \%} = (\text{observed reticulocyte \%}) \times \frac{\text{PCV of the patient}}{\text{normal PCV for that species}}$$

TABLE 1 TOXIC CAUSES OF ANEMIA

Pathogenic Mechanism	Drugs	Plants, Foods	Toxins, Chemicals	Heavy Metals
Oxidation	Acetaminophen, benzocaine, dapsone, nitrofurans, primaquine, propofol, quinacrine	Fava beans, oak, onions, propylene glycol, red maple	Crude oil, naphthalene	Copper, zinc
Blood loss	Aspirin, naproxen	Bracken fern, sweet clover	Dicoumarol	
Immune-mediated hemolysis	Cephalosporins, levamisole, penicillin, propylthiouracil, sulfonamides		Pirimicarb	
Hemolysis	Fenbendazole, heparin		Indole	Lead, selenium
Decreased marrow production	Amphotericin, azidothymidine, cephalosporins, chloramphenicol, estrogen, fenbendazole, griseofulvin, meclofenamic acid, phenobarbital, phenothiazine, phenylbutazone, propylthiouracil, quinidine, recombinant human erythropoietin, sulfonamides, thiacetarsamide	Bracken fern	Benzene, trichloroethylene	Lead

drop of saline on a slide with a fresh drop of the animal's blood; the slide should be gently rotated to mix the drops together, then evaluated grossly and microscopically for macro- and microagglutination. If autoagglutination is present, there is no need to perform a Coombs' test. Serology or PCR for infectious agents such as feline leukemia virus, *Ehrlichia*, equine infectious anemia virus, and *Babesia* may also help define the cause of anemia (see TABLE 2).

Bone marrow evaluation by aspiration and/or biopsy (see p 14) is indicated in any animal with an unexplained, non-regenerative anemia. If the CBC reveals a decrease in more than one cell line, possibly indicating hypoplastic marrow, a biopsy would be indicated along with an aspirate. Biopsies and aspirates are complementary: biopsies are better to evaluate the architecture and degree of cellularity of the marrow, and aspirates allow for better evaluation of cellular morphology. Aspirates also allow for an evaluation of orderly maturation of the red and white blood cell lines, the ratio of myeloid to erythroid precursors (M:E ratio), and the number of platelet precursors. Iron stores can also be evaluated by Prussian blue staining. An M:E ratio of <1 indicates that red cell production is greater than white cell production; with an M:E ratio >1, the opposite is likely. The

M:E ratio is always interpreted in light of a recent CBC, because changes in the ratio could also be due to suppression of one cell line compared with the other.

REGENERATIVE ANEMIAS

BLOOD LOSS ANEMIA

Acute blood loss can lead to shock and even death if >30%–40% of blood is lost and the hypovolemia that develops is not treated aggressively with IV fluids or compatible blood (see p 17), or both. Causes of acute loss can be known (eg, trauma, surgery) or occult. Coagulopathies, bleeding tumors, gastric ulceration, and external or internal parasites should be excluded as causes. GI parasites, such as *Haemonchus* in ruminants and hookworms in dogs, can lead to severe blood loss, especially in young animals. Low grade, chronic blood loss eventually results in iron-deficiency anemia, although some degree of reticulocytosis may persist even after iron stores become depleted. The hallmark of an iron-deficiency anemia is microcytic, hypochromic anemia. This chronic blood loss can be due to some type of parasitism in young animals (eg, fleas, lice, intestinal parasitism), but in older animals, bleeding from GI ulcers or tumors is more common.

TABLE 2 INFECTIOUS CAUSES OF ANEMIA

Infectious Agent	Species Affected	Hemolytic	Marrow Affected
BACTERIA			
<i>Clostridium perfringens</i> A	Cattle, sheep	Yes	No
<i>Clostridium haemolyticum</i>	Cattle, sheep	Yes	No
<i>Leptospira interrogans</i>	Cattle, pigs, sheep	Yes	No
<i>Mycoplasma</i> spp	Cats	±	Rarely
<i>Haemobartonella</i> spp	Cattle, cats	±	No
VIRUSES			
Equine infectious anemia virus	Horses	±	Rarely
Feline leukemia virus	Cats	±	Yes
Feline immunodeficiency virus	Cats	No	Yes
RICKETTSIA			
<i>Mycoplasma</i> spp	Cattle, goats, llamas, pigs, sheep ^a	Yes (piglets only)	No
<i>Anaplasma</i> spp	Cattle, goats, sheep	Yes	No
<i>Ehrlichia</i> spp	Dogs	Yes	Yes
PROTOZOA			
<i>Babesia</i> spp	Cattle, cats, dogs, horses, sheep	Yes	No
<i>Theileria</i> spp ^b	Cattle, goats, sheep	±	No
<i>Cytauxzoon</i> spp	Cats	No	Yes
<i>Trypanosoma</i> spp	Cattle, horses, pigs	Yes	No
<i>Sarcocystis cruzi</i>	Cattle	Yes	No

^a In adults, only clinically relevant in splenectomized or critically ill animals.

^b Pathogenic species of *Theileria* are found in Africa, the Mediterranean, the Middle East, Asia, and Europe. Species found in North America are nonpathogenic.

HEMOLYTIC ANEMIA

Hemolytic anemias are typically regenerative and result from lysis of RBCs in either the intra- or extravascular space. Intravascular hemolysis results in hemoglobinemia and hemoglobinuria, whereas extravascular hemolysis does not. Both types of hemolysis can result in icterus. In dogs, the most common cause of hemolytic anemia is

immune mediated (60%–75%), although toxins, RBC trauma, infections, and RBC membrane defects can also cause hemolysis.

Immune-mediated Hemolytic

Anemia: Immune-mediated hemolytic anemia (IMHA, *see* p 826) can be primary or secondary to neoplasia, infectious agents, drugs, or vaccinations. In IMHA, the immune system no longer recognizes RBCs

as self and develops antibodies to circulating RBCs, leading to RBC destruction by macrophages and complement. In some cases, antibodies are directed against RBC precursors in the marrow, resulting in nonregenerative anemia. Animals with IMHA are usually icteric, sometimes febrile, and may have splenomegaly. Hematologic hallmarks of IMHA are regenerative anemia, hyperbilirubinemia, spherocytosis, autoagglutination, or a positive Coombs' test.

Another methodology to evaluate dogs for anti-RBC antibodies is flow cytometry. Flow cytometry allows for detection and quantitation of red cell surface-bound IgG and IgM. Flow cytometry was found to be 88%–100% specific for diagnosing dogs with anti-RBC antibodies. One report suggests using flow cytometry to assess response to treatment for dogs, because there is a decrease in surface anti-RBC antibodies before reticulocytosis or increase in RBC count. Flow cytometry may not be readily available to all veterinary hospitals.

Animals with IMHA can show mild, indolent signs or be in an acute crisis. It is important to tailor treatment to the animal's signs, including treating any underlying infections. Transfusion with packed RBCs is usually required. The goal of therapy is to stop the destruction of RBCs by treating with immunosuppressive drugs; supportive care is also a priority. Prednisone or prednisolone at a dosage of 1–2 mg/kg, bid, is considered first-line therapy, with azathioprine at 2 mg/kg/day (azathioprine is contraindicated in cats and may be replaced by chlorambucil) or cyclosporine at 5–10 mg/kg/day considered as a possible second agent. In one study, low-dose aspirin at 0.5 mg/kg/day improved survival times in dogs treated with azathioprine and prednisone. The veterinary literature is ambiguous on choice of second agent or when to introduce a second agent. Other immunosuppressive agents that have been used include mycophenolate and leflunomide.

In the acute hemolytic crisis, drugs such as cyclosporine (10 mg/kg/day, initially) or human intravenous immunoglobulin (IVIG, 0.5–1.5 g/kg as a single dose) may also have benefit because of rapid onset of action.

Pulmonary thromboembolism is a risk in dogs with IMHA. These dogs are often hypercoagulable, which can be documented with thromboelastography. Dogs documented to be in a hypercoagulable state should be anticoagulated with heparin, which may be used in combination with antiplatelet therapy (aspirin 0.5 mg/kg/day

with or without clopidogrel 1–2 mg/kg/day) if the platelet count is $>40,000/\mu\text{L}$. The dosing range for heparin is wide and variable, and dosage also depends on whether fractionated or unfractionated heparin is used. Heparin therapy can be monitored using activated partial thromboplastin time (APTT) or antifactor Xa concentrations (low molecular-weight heparin).

Mortality rates for IMHA range from 20%–75%, depending on the severity of clinical signs. Negative prognostic indicators may include a rapid drop in PCV, high bilirubin concentration, moderate to marked leukocytosis (28,000 to $>40,000$ cells/ μL), increased BUN, petechiae, intravascular hemolysis, autoagglutination, disseminated intravascular coagulation, and thromboembolic complications. Moderate to marked leukocytosis has been reported to be associated with tissue necrosis, most likely secondary to tissue hypoxia or thromboembolic disease. Referral to tertiary care facilities may improve survival.

Alloimmune Hemolysis: Neonatal isoerythrolysis (NI) is an immune-mediated hemolytic disease seen in newborn horses, mules, cattle, pigs, cats, and rarely dogs. NI is caused by ingestion of maternal colostrum containing antibodies to one of the neonate's blood group antigens. The maternal antibodies develop to specific foreign blood group antigens during previous pregnancies, unmatched transfusions, and from *Babesia* and *Anaplasma* vaccinations in cattle. Cats are unique in that blood type B cats have naturally occurring anti A antibodies without prior exposure, and their kittens that are type A develop hemolysis after nursing. In horses, the antigens usually involved are A, C, and Q; NI is most commonly seen in Thoroughbreds and mules. Neonates with NI are normal at birth but develop severe hemolytic anemia within 2–3 days and become weak and icteric. Diagnosis is confirmed by screening maternal serum, plasma, or colostrum against the paternal or neonatal RBCs. Treatment consists of stopping any colostrum while giving supportive care with transfusions. If necessary, neonates can be transfused with triple-washed maternal RBCs. NI can be avoided by withholding maternal colostrum and giving colostrum from a maternal source free of the antibodies. The newborn's RBCs can be mixed with maternal serum to look for agglutination before the newborn is allowed to receive maternal colostrum.

Microangiopathic Hemolysis: Microangiopathic hemolysis is caused by RBC damage secondary to turbulent flow through abnormal vessels. In dogs, it can be seen secondary to severe heartworm infection, vascular tumors (hemangiosarcoma), splenic torsions, and disseminated intravascular coagulation; in other species, causes include hemolytic uremic syndrome in calves, equine infectious anemia, African swine fever, and chronic classical swine fever. Schistocytes are common in blood smears from these animals. Treatment involves correction of the underlying disease process.

Metabolic Causes of Hemolysis:

Hypophosphatemia (*see* p 1000) causes postparturient hemoglobinuria and hemolysis in cattle, sheep, and goats. It can occur 2–6 wk after parturition. Hypophosphatemia with secondary hemolysis is seen in dogs and cats secondary to diabetes mellitus, hepatic lipidosis, and refeeding syndrome. Treatment with either oral or IV phosphorus is indicated, depending on the degree of hypophosphatemia. Cattle that drink too much water (water intoxication) are at risk of developing hemolysis secondary to hypotonic plasma. This is seen in calves 2–10 mo old and causes respiratory distress and hemoglobinuria. Clinical signs can progress to convulsions and coma. Hemolytic anemia, hyponatremia and hypochloremia, decreased serum osmolality, and low urine specific gravity in a calf would support the diagnosis of water intoxication. Treatment consists of hypertonic fluids (2.5% saline) and diuretics (eg, mannitol).

Toxins: Toxins and drugs can cause anemia by many mechanisms. Those implicated most frequently in animals and their pathogenic mechanisms are listed (*see* TABLE 1).

Infections: Many infectious agents—bacterial, viral, rickettsial, and protozoal—can cause anemia by direct damage to RBCs, leading to hemolysis, or by direct effects on precursors in the bone marrow (*see* TABLE 2).

Heritable Diseases: Several heritable RBC disorders cause anemia. Pyruvate kinase deficiencies are seen in Basenjis, Beagles, West Highland White Terriers, Cairn Terriers, and other breeds, as well as Abyssinian and Somali cats. Phosphofructokinase deficiency occurs in English Springer Spaniels. Deficiencies in these

enzymes lead to shortened RBC life span and regenerative anemia. In dogs with phosphofructokinase deficiency, the hemolytic crises are set off by alkalosis secondary to excessive excitement or exercise. If such situations are minimized, these dogs may have a normal life expectancy. There is no treatment for pyruvate kinase deficiency, and affected dogs will have a shortened life span due to myelofibrosis and osteosclerosis of the bone marrow. Affected cats will have chronic intermittent hemolytic anemia, which is sometimes helped by splenectomy and steroids. Unlike dogs, cats have not been reported to develop osteosclerosis. A hereditary hemoglobinopathy, porphyria (*see* p 986), leads to build-up of porphyrins in the body and has been described in cattle, cats, and pigs. It is most prevalent in Holstein cattle and can lead to a hemolytic crisis. Affected calves fail to thrive and are photosensitive. Diagnosis is made by finding increased levels of porphyrins in bone marrow, urine, or plasma. Teeth of affected animals fluoresce under ultraviolet light.

NONREGENERATIVE ANEMIAS

NUTRITIONAL DEFICIENCIES

Nutritional deficiency anemias develop when micronutrients needed for RBC formation are not present in adequate amounts. Anemia develops gradually and may initially be regenerative but ultimately becomes nonregenerative. Starvation causes anemia by a combination of vitamin and mineral deficiencies as well as a negative energy and protein balance. Deficiencies most likely to cause anemia are iron, copper, cobalamin (B_{12}), B_6 , riboflavin, niacin, vitamin E, and vitamin C (important only in primates and guinea pigs).

Iron deficiency is the most common deficiency seen in dogs and piglets but occurs less commonly in horses, cats, and ruminants. Iron deficiency is rarely nutritional in origin—it most commonly occurs secondary to blood loss (*see* p 9). Young animals have minimal iron stores, and milk contains very little iron. This can be especially important for piglets that grow rapidly and are often raised indoors with no access to iron. Oral iron supplementation is indicated as treatment for iron deficiency; any source of blood loss must be eliminated.

Copper deficiency can develop in ruminants fed forage grown in copper-deficient soil. Copper is necessary for the

metabolism of iron. Copper deficiency may occur secondary to high dietary molybdenum or sulfate in cattle and can develop in pigs fed whey diets. Low blood copper concentrations or low copper concentrations in liver biopsies (more definitive) are diagnostic. Treatment is oral or injectable copper supplementation.

B vitamin deficiencies are rare. Certain drugs (anticonvulsants, drugs that interfere with folate metabolism) have been associated with development of folate or cobalamin deficiency, leading to a normocytic, normochromic, nonregenerative anemia. Cobalamin malabsorption has been reported in Giant Schnauzers (their enterocytes are unable to absorb cobalamin). These dogs respond to parenteral supplementation with cobalamin. Ruminants also develop a secondary cobalamin deficiency when grazing on cobalt-deficient pasture. Treatment with oral cobalt or parenteral cobalamin is indicated.

ANEMIA OF CHRONIC DISEASE

Anemia of chronic disease can be characterized as mild to moderate, nonregenerative, normochromic, and normocytic. It is the most common form of anemia seen in animals. The anemia can be secondary to chronic inflammation or infection, neoplasia, liver disease, hyper- or hypoadrenocorticism, or hypothyroidism. The anemia is mediated by cytokines produced by inflammatory cells, which lead to decreases in iron availability, RBC survival, and the marrow's ability to regenerate. Treatment should be directed at the underlying disease and often results in resolution of the anemia. The anemia may be reduced by treatment with recombinant human erythropoietin, but the risk of antibody formation to endogenous erythropoietin may outweigh benefit. Darbepoetin appears to have less impact to induce reactive antibodies.

RENAL DISEASE

Chronic renal disease is a common cause of nonregenerative anemia in animals. Erythropoietin is normally produced by the peritubular endothelial cells in the renal cortex. Animals with renal disease produce less erythropoietin, leading to anemia. Recombinant human erythropoietin (44–132 U/kg, three times/wk, with most animals starting at 88 U/kg) has been used for treatment. PCV is monitored weekly until the desired improvement is reached (this will vary with the initial degree of

anemia), after which the dosage is decreased. Animals receiving recombinant human erythropoietin require supplemental iron to support RBC production. (See also HEMATINICS, p 2540.) Darbepoetin also has been found to be valuable in management of anemia associated with chronic kidney disease.

PRIMARY BONE MARROW DISEASES

Primary bone marrow disease or failure from any cause can lead to nonregenerative anemia and pancytopenia. With diffuse marrow involvement, granulocytes are affected first, followed by platelets and finally RBCs.

Aplastic anemia has been reported in dogs, cats, ruminants, horses, and pigs with pancytopenia and a hypoplastic marrow, replaced by fat. Most cases are idiopathic, but reported causes include infection (feline leukemia virus, *Ehrlichia*, parvovirus), drug therapy (methimazole, chemotherapeutic agents, antibiotics [trimethoprim-sulfa, chloramphenicol], fenbendazole), toxin ingestion (estrogen), and total body irradiation (see TABLES 1 and 2). There may also be an immune-mediated component to this disease. Diagnosis is confirmed by bone marrow aspiration and core biopsy. Treatment consists of eliminating the underlying cause and providing supportive measures such as broad-spectrum antibiotics and transfusions. Immunosuppressive agents such as prednisone, cyclosporine, mycophenolate, or azathioprine may be considered. Recombinant human erythropoietin and granulocyte colony-stimulating factor (5 mcg/kg/day, PO) can be used until the marrow recovers. If the disease is idiopathic or if marrow recovery is unlikely (eg, phenylbutazone toxicity in dogs), bone marrow transplantation is beneficial if a suitable donor is available (investigational and limited availability).

In **pure red cell aplasia** (PRCA), only the erythroid line is affected. It is characterized by a nonregenerative anemia with severe depletion of red cell precursors in the bone marrow. It has been reported in dogs and cats and may be primary or secondary. Primary cases are most commonly immune mediated and may respond to immunosuppressive therapy. Supportive care, including transfusion, may be indicated when anemia is severe. Feline leukemia-positive cats can have PRCA. Recombinant human erythropoietin has been reported to cause PRCA in dogs and

horses. Discontinuation of therapy may eventually lead to RBC recovery in some animals.

Primary leukemias are uncommon to rare in domestic species but have been reported in dogs, cats, cattle, goats, sheep, pigs, and horses. Retroviruses are a cause in some cattle, cats, primates, and chickens. Leukemias can develop in myeloid or lymphoid cell lines and are further classified as acute or chronic. Most affected animals have nonregenerative anemia, neutropenia, and thrombocytopenia, with circulating blasts usually present. Acute leukemias, characterized by infiltration of the marrow with blasts, generally respond poorly to chemotherapy. In animals that do respond, remission times are usually short. In acute lymphoblastic leukemia in dogs, the response rate to chemotherapy is ~30%, with a median survival of 4 mo. Acute myeloblastic leukemias are less common and even less responsive to treatment than acute lymphoblastic leukemia. In acute leukemias, the cell lineage is often difficult to identify morphologically, so cytochemical stains or immunologic evaluation of cell surface markers may be necessary for definitive diagnosis. Chronic leukemias, characterized by an overproduction of one hematopoietic cell line, are less likely to cause anemia and more responsive to treatment.

Myelodysplasia (myelodysplastic syndrome, MDS) is considered a preleukemic syndrome characterized by ineffective hematopoiesis, resulting in a nonregenerative anemia or other cytopenias. MDS has been described in dogs, cats, and people. The disease can be primary or secondary and is commonly seen in cats with feline leukemia. Primary syndromes probably arise from mutations in stem cells. Secondary syndromes are caused by other neoplasia or drug therapy. Some cats and dogs respond to treatment with recombinant human erythropoietin and prednisone. Supportive care with transfusions may be helpful. Survival is variable because MDS can progress to leukemia; many animals are euthanized or die of sepsis, bleeding, or anemia.

Myelofibrosis causes bone marrow failure secondary to replacement of normal marrow elements with fibrous tissue. It has been seen in dogs, cats, people, and goats. It can be a primary disorder or secondary to malignancies, immune-mediated hemolytic anemia, whole body irradiation, and congenital anemias (eg, pyruvate kinase deficiency). Diagnosis can be made by bone marrow biopsy. Treatment varies with the

underlying cause but usually consists of immunosuppressive therapy.

Bone Marrow Aspiration and Biopsy

Bone marrow aspiration and biopsy: Bone marrow aspiration and biopsy are techniques used to evaluate the bone marrow in domestic animal species. The basic technique involves introducing a hollow needle into the bone marrow to obtain a sample for evaluation. Bone marrow aspiration provides a sample for cytologic evaluation, and bone marrow biopsy provides a sample for histopathologic evaluation.

Specific clinical indications to evaluate bone marrow include but are not limited to investigation of nonregenerative anemia, thrombocytopenia, leukopenia, bicytopenia, pancytopenia, abnormal circulating cells of any type, monoclonal gammopathy, suspected osteomyelitis, suspected bone neoplasia, infectious disease affecting the bone, and clinical staging of neoplastic processes such as lymphoma and mast cell disease.

The conventional anatomic sites used for bone marrow aspiration include the iliac crest, the trochanteric fossa of the femur, the tibial crest, and the greater tubercle of the humerus. Some clinicians have also used the rib (costochondral junction) or sternabrae. The humerus is the most common site for bone marrow biopsy.

For bone marrow aspiration, cats and dogs generally require sedation, although some cats may require general anesthesia. General anesthesia is required for bone marrow biopsy. The animal is positioned in lateral recumbency when using the trochanteric fossa or the greater tubercle, and in sternal recumbency when using the iliac crest. The area to be accessed is shaved and aseptically prepared. The site, including the periosteum, is infiltrated with local anesthetic. A #11 scalpel blade is then used to make a stab incision through the skin.

The equipment used for these procedures may differ slightly. Most bone marrow aspiration needles (eg, Rosenthal, Illinois) are very similar and have a removable stylet. With the stylet in place, the needle is advanced with a back and forth screw like motion until the needle is well seated in the bone. The stylet is then removed, and a syringe (6–12 mL) attached for aspiration. If the animal feels any discomfort, this is when it will occur. Only a small sample is required, ie, enough to fill the syringe hub, which should be put onto slides for cytologic evaluation. The needle can then be removed.

Bone marrow biopsy generally requires a Jamshidi needle, which is rigid and hollow with a stylet. The Jamshidi needle has a cutting edge at its end, designed to obtain a core marrow sample (although it can also be used to obtain a bone marrow aspirate). The needle is driven into the bone with a back and forth, screw-like motion. Once the needle is well seated, the cap is unscrewed and the stylet removed. An aspirate can be obtained similar to the technique described above. To obtain a

core sample for histopathology, the needle is advanced further (about $\frac{1}{4}$ in.) into the marrow and twisted in one direction. The needle is then moved in a wide, circular motion to try to dislodge a core sample. The needle is removed by twisting in the opposite direction in which it was advanced. A blunt stylet is then passed retrograde to remove the core sample. The core can be gently rolled onto a slide for cytology and then placed into formalin for histopathology.

BLOOD GROUPS AND BLOOD TRANSFUSIONS

Blood groups are determined by genetically controlled, polymorphic, antigenic components of the RBC membrane. The allelic products of a particular genetic locus are classified as a blood group system. Some of these systems are highly complex, with many alleles defined at a locus; others consist of a single defined antigen. Blood group systems, in general, are independent of each other, and their inheritance conforms to Mendelian dominance. For polymorphic blood group systems, an animal usually inherits one allele from each parent and thus expresses no more than two blood group antigens of a system. An exception is in cattle, in which multiple alleles, or "phenogroups," are inherited. Normally, an individual does not have antibodies against any of the antigens present on its own or against other blood group antigens of that species' systems unless they have been induced by transfusion, pregnancy, or immunization. In some species (people, sheep, cattle, pigs, horses, cats, and dogs), so-called "naturally

occurring" isoantibodies, not induced by transfusion or pregnancy, may be present in variable but detectable titers. For example, Group B cats have naturally occurring anti-A antibody. Also, circulating antibodies to animal blood group antigens may be induced by transfusion. With random blood transfusions in dogs, there is a 30%-40% chance of sensitization of the recipient, primarily to blood group antigen DEA 1, but risk is also present for development of antibody to any other antigen lacked by the recipient. In horses, transplacental immunization of the mare by an incompatible fetal antigen inherited from the sire may occur. Immunization also may result when some homologous blood products are used as vaccines (eg, anaplasmosis in cattle). In dogs, prior pregnancy does not result in sensitization of the bitch to foreign blood group antigens.

The number of major recognized blood group systems (see TABLE 3) varies among domestic species, with cattle being the most complex and cats the simplest. Animal

TABLE 3 MAJOR BLOOD GROUPS OF CLINICAL INTEREST

Species	Blood Group
Canine	DEA 1.1 and 7
Feline	A, B, <i>mic</i>
Equine	A, C, Q
Bovine	B, J
Ovine	B, R

blood groups are typed to aid in the matching of donors and recipients and, especially in horses, to identify breeding pairs potentially at risk of causing hemolytic disease in their offspring. Because expression of blood group antigens is genetically controlled and the modes of inheritance are understood, these systems also have been used to substantiate pedigrees in cattle and horses; however, in most cases, DNA testing has replaced blood typing for paternity testing.

BLOOD TYPING

Antisera used to identify blood groups (typing reagents) usually are produced as isoimmune sera. Their in vitro serologic characteristics vary with the species. Many reagents are hemagglutinins; others are hemolytic and require complement to complete the serologic reaction, such as in cattle (because RBCs do not readily agglutinate) and horses (because RBC rouleaux are a problem). Other typing reagents, neither hemagglutinating nor hemolytic, combine with RBC antigens in an "incomplete" reaction because they lack additional combining sites to agglutinate other RBCs; addition of species-specific antiglobulin is required for agglutination.

The diversity of blood groups in animals and the lack of commercially available blood-typing reagents to all antigens make complete typing difficult but should not preclude the clinical use of transfusions. In horses and dogs, the blood group antigens most commonly implicated in transfusion incompatibilities are known; by selecting donor animals that lack these groups, or that match the recipient, the risk of sensitization of the recipient to the most important antigens can be minimized. For dogs and cats, commercially available, point-of-care testing for major antigens is available in either gel or card testing kits. Reagents are available for only some antigens, generally those that are most likely to sensitize a recipient, or those for which naturally occurring antibodies, primarily in cats, might be present. For example, dogs have more than 12 blood group systems but generally are typed for only one (DEA 1.1). An additional blood group antigen (dal) was discovered when a dal-negative, previously transfused Dalmatian reacted to many potential donors, and only a few Dalmatians were found to be compatible. It is a common antigen in most dogs but is lacking in some Dalmatians. Because multiple blood group antigens are present, it is likely that an

animal receiving a transfusion might be exposed to some antigens that are not present on its RBCs.

CROSSMATCHING

Previously sensitized recipients or those with naturally occurring antibodies can be detected by crossmatching, which is done to preclude administration of incompatible blood. In the USA, >99% of cats are of blood group A, so the risk of incompatible transfusion is low. However, certain breeds, including Abyssinian, Birman, British Shorthair, Devon Rex, Himalayan, Persian, Scottish Fold, and Somali, have a higher frequency of blood group B. Any incompatible transfusion in cats results in rapid destruction of transfused cells, so typing and crossmatching should be done before any transfusion. The *mic* antigen is present in some cats, and naturally occurring antibodies are present in cats that lack the *mic* antigen. For that reason, crossmatching should be performed for cats before the first transfusion, even if they will receive A or B matched blood.

The direct crossmatch procedure, with appropriate controls, is effective for all species. The **major crossmatch** detects antibodies already present in recipient plasma that could cause a hemolytic reaction when donor RBCs are transfused; it will not detect the potential for sensitization to develop. Anticoagulant (calcium disodium edetate or citrate) is added to blood samples from donor and recipient; the donor RBCs are washed 3 times with 0.9% saline, and a 4% RBC suspension in saline is made from the washed cells. The major crossmatch consists of combining equal volumes (0.1 mL) of the donor RBC suspension and recipient plasma. The control tube contains recipient RBCs and recipient plasma. The samples are incubated, centrifuged, and evaluated for hemolysis or agglutination. Hemolysis is evaluated by comparing the color of the supernatant in the test sample with that of the control sample. Each sample is then gently shaken until all cells in the "button" at the bottom of the tube have returned to suspension. Again, the degree of cell clumping of the test sample is compared with that of the control sample. The test is negative, or compatible, when the plasma is clear and the RBCs are readily suspended. A positive, or incompatible, test can have hemolysis or hemagglutination or both. All tests judged macroscopically to be negative for hemagglutination should be confirmed microscopically at low power. Some newer

crossmatching systems that use a gel technique are becoming available. This is particularly important in horses, because their RBCs tend to form rouleaux.

The **minor crossmatch** is the reverse of the major crossmatch, ie, recipient cells are combined with donor plasma. The minor crossmatch is important only in species such as cats with clinically significant naturally occurring isoantibodies or if the donor has been previously transfused or, in horses, those with previous pregnancies.

BLOOD TRANSFUSIONS

Frequently, the need for blood transfusions is acute, as in acute hemolysis or hemorrhage; transfusions are also appropriate in treatment of acute or chronic anemias. Animals with hemostatic disorders often require repeated transfusions of whole blood, red cells, plasma, or platelets. Blood transfusions must be given with care, because they have the potential to further compromise the recipient.

Whole blood frequently is not the ideal product to be administered. If the need is to replace the oxygen-carrying capability of the blood, then packed RBCs are more appropriate; if replacement of circulatory volume is needed, crystalloid or colloid solutions may be used, with packed RBCs added as needed. Platelet numbers rise rapidly after hemorrhage, so replacement is rarely needed. Plasma proteins equilibrate from the interstitial space, so plasma is not needed except in massive hemorrhage (>1 blood volume in 24 hr). Animals that require coagulation factors benefit most from administration of fresh-frozen plasma or cryoprecipitate if the need is specifically for factor VIII, von Willebrand factor, or fibrinogen. Platelet-rich plasma or platelet concentrates may be of value in thrombocytopenia, although immune-mediated thrombocytopenia usually does not respond to administration of platelets because they are removed rapidly by the spleen.

The decision to transfuse RBCs is determined by clinical signs, not by any pre-selected PCV. Animals with acute anemia show signs of weakness, tachycardia, and tachypnea at a higher PCV than animals with chronic anemia. The amount of RBCs required to relieve clinical signs will generally increase the PCV above 20%. Domestic animals have blood volumes of 7%–9% of their body weight; cats have a slightly lower volume of ~6.5%. By determining the recipient's blood volume and knowing the animal's PCV, the required replacement RBC volume can be calculated.

For example, a 25-kg dog has a total blood volume of ~2,000 mL; with a PCV of 15%, the RBC volume is 300 mL; if the PCV is to be increased to 20%, that equals an RBC volume of 400 mL. Therefore, 100 mL of RBCs or 200 mL of whole blood (with PCV of 50%) would be required to increase the recipient's PCV to the desired level. These calculations assume no ongoing losses of RBCs through hemorrhage or hemolysis. Obviously, the post-transfusion PCV is the most important measure of adequacy of red cell dose. No more than 20% of a donor animal's blood should be collected at one time.

Collection, storage, and transfusion of blood must be done aseptically. The anticoagulant of choice is citrate phosphate dextrose adenine (CPDA-1). Commercial blood bags containing the appropriate amount of anticoagulant for a "unit" (500 mL) are available. Heparin should not be used as an anticoagulant, because it has a longer half-life in the recipient and causes platelet activation; also, heparinized blood cannot be stored.

Blood collected in CPDA-1 with added RBC preservation or nutrient solutions may be safely stored at 4°C for 4 wk. If the blood will not be used immediately, the plasma can be removed and stored frozen for later use as a source of coagulation factors or albumin for acute reversible hypoalbuminemia. Plasma must be frozen at -20° to -30°C within 6 hr of collection to assure that levels of factor VIII are adequate and will remain so for 1 yr. Chronic hypoproteinemia is not helped by plasma, because the total body deficit of albumin is so large that it could not be improved by the small amount contained in plasma. Colloid solutions such as hetastarch are more effective for treatment of hypoalbuminemia. Human albumin has been used in dogs; however, the risk of sensitization and allergic reactions is significant.

Risks of Transfusion: The most serious risk of transfusion is acute hemolysis. Fortunately, this is rare in domestic animals. Dogs rarely have clinically significant preformed antibodies, so only those that have received repeated transfusions are at risk. The most common hemolytic reaction in dogs that have received multiple transfusions is delayed hemolysis, seen clinically as shortened survival of transfused RBCs and a positive Coombs' test. Even crossmatch-compatible RBCs given to horses or cattle survive only 2–4 days. Nonimmune causes of hemolysis include improper collection or separation of blood,

freezing or overwarming of RBCs, and infusing under pressure through a small needle.

Other complications include sepsis from contaminated blood, hypocalcemia from too much citrate, and hypervolemia (especially in animals with preexisting heart disease or in very small animals). Urticaria, fever, or vomiting are seen occasionally. Transfusions can also spread disease from donor to recipient, such as RBC parasites (eg, *Mycoplasma* in cats or *Babesia* in dogs) and viruses (eg, retroviruses in cats, horses, or cattle). Other diseases, such as those caused by rickettsia or other bacteria, can also be spread if the donor is bacteremic. Donors should be tested periodically for infectious diseases that are prevalent locally. Flea and tick prevention is also important to prevent vector borne infections in donors.

BLOOD SUBSTITUTES

(Hemoglobin-based oxygen carrier solutions)

Because of problems associated with finding compatible donors and disease transmission by transfusion, the search for a red cell substitute has been ongoing for >50 yr. An ideal substitute would carry and deliver oxygen like red cells, be easy to

produce in large quantities, be nonantigenic, and persist in the circulation at least long enough for resuscitation.

One hemoglobin-based oxygen carrier of bovine origin is currently licensed for use in dogs. The hemoglobin is collected aseptically, filtered to remove all red cell stromal elements, and polymerized to allow the product to persist in the circulation for a half-life of ~36 hr. This product has been shown to carry and deliver oxygen efficiently, can be used immediately without need for typing or crossmatching, and has a 3-yr shelf life at room temperature. Because the structure of the hemoglobin molecule is similar between species, bovine hemoglobin is minimally antigenic. Although currently licensed for use only in dogs, it has been used in cats, horses, llamas, birds, and people. Its colloidal effects are especially useful in resuscitation after trauma with acute blood loss. Because the cost of hemoglobin solution is often higher, and duration of effect is shorter than that of blood, the main value of hemoglobin is in emergency situations when blood is not immediately available. Volume overload is a potential risk if hemoglobin is given too rapidly. Another concern with hemoglobin solutions is that nitric oxide is scavenged and removed by the product. This paradoxically might cause vasoconstriction and decrease oxygen delivery to ischemic tissues.

BLOOD PARASITES

ANAPLASMOSIS

Anaplasmosis, formerly known as gall sickness, traditionally refers to a disease of ruminants caused by obligate intraerythrocytic bacteria of the order Rickettsiales, family Anaplasmataceae, genus *Anaplasma*. Cattle, sheep, goats, buffalo, and some wild ruminants can be infected with the erythrocytic *Anaplasma*. Anaplasmosis occurs in tropical and subtropical regions worldwide (~40°N to 32°S), including South and Central America, the USA, southern Europe, Africa, Asia, and Australia.

The *Anaplasma* genus also includes *A. phagocytophilum* (compiled from species previously known as *Ehrlichia phagocytophila*, *E. equi*, and human granulocytic ehrlichiosis agent, see p 803), *A. bovis*

(formerly *E. bovis*), and *A. platys* (formerly *E. platys*), all of which invade blood cells other than erythrocytes of their respective mammalian hosts. Bovine anaplasmosis is of economic significance in the cattle industry.

Etiology and Pathogenesis: Clinical bovine anaplasmosis is usually caused by *A. marginale*. An *A. marginale* with an appendage has been called *A. caudatum*, but it is not considered to be a separate species. Cattle are also infected with *A. centrale*, which generally results in mild disease. *A. ovis* may cause mild to severe disease in sheep, deer, and goats. *A. phagocytophilum* has recently been reported to infect cattle; however, natural infection is rare and it does not cause clinical disease.

Transmission and Epidemiology: Up to 17 different tick vector species (including *Dermacentor*, *Rhipicephalus*, *Ixodes*, *Hyalomma*, and *Argas*) have been reported to transmit *Anaplasma* spp. Not all of these are likely significant vectors in the field, and it has been shown that strains of *A. marginale* also coevolve with particular tick strains. *Rhipicephalus* (*Boophilus*) spp are major vectors in Australia and Africa, and *Dermacentor* spp have been incriminated as the main vectors in the USA. After feeding on an infected animal, intrastadial or trans-stadial transmission may occur. Transovarial transmission may also occur, although this is rare, even in the single-host *Rhipicephalus* spp. A replicative cycle occurs in the infected tick. Mechanical transmission via biting dipterans occurs in some regions. Transplacental transmission has been reported and is usually associated with acute infection of the dam in the second or third trimester of gestation. Anaplasmosis may also be spread through the use of contaminated needles or dehorning or other surgical instruments.

There is a strong correlation between age of cattle and severity of disease. Calves are much more resistant to disease (although not infection) than older cattle. This resistance is not due to colostral antibody from immune dams. In endemic areas where cattle first become infected with *A. marginale* early in life, losses due to anaplasmosis are minimal. After recovery from the acute phase of infection, cattle remain chronically infected carriers but are generally immune to further clinical disease. However, these chronically infected cattle may relapse to anaplasmosis when immunosuppressed (eg, by corticosteroids), when infected with other pathogens, or after splenectomy. Carriers serve as a reservoir for further transmission. Serious losses occur when mature cattle with no previous exposure are moved into endemic areas or under endemically unstable situations when transmission rates are insufficient to ensure that all cattle are infected before reaching the more susceptible adult age.

Clinical Findings: In animals <1 yr old anaplasmosis is usually subclinical, in yearlings and 2-yr-olds it is moderately severe, and in older cattle it is severe and often fatal. Anaplasmosis is characterized by progressive anemia due to extravascular destruction of infected and uninfected erythrocytes. The prepatent period of *A. marginale* is directly related to the infective

dose and typically ranges from 15–36 days (although it may be as long as 100 days). After the prepatent period, peracute (most severe but rare), acute, or chronic anaplasmosis may follow. Rickettsemia approximately doubles every 24 hr during the exponential growth phase. Generally, 10%–30% of erythrocytes are infected at peak rickettsemia, although this figure may be as high as 65%. RBC count, PCV, and hemoglobin values are all severely reduced. Macrocytic anemia with circulating reticulocytes may be present late in the disease.

Animals with peracute infections succumb within a few hours of the onset of clinical signs. Acutely infected animals lose condition rapidly. Milk production falls. Inappetence, loss of coordination, breathlessness when exerted, and a rapid bounding pulse are usually evident in the late stages. The urine may be brown but, in contrast to babesiosis, hemoglobinuria does not occur. A transient febrile response, with the body temperature rarely exceeding 106°F (41°C) occurs at about the time of peak rickettsemia. Mucous membranes appear pale and then yellow. Pregnant cows may abort. Surviving cattle convalesce over several weeks, during which hematologic parameters gradually return to normal.

Bos indicus breeds of cattle appear to possess a greater resistance to *A. marginale* infection than *B. taurus* breeds, but variation of resistance of individuals within breeds of both species occurs. Differences in virulence between *Anaplasma* strains and the level and duration of the rickettsemia also play a role in severity of clinical manifestations.

Lesions: Lesions are typical of those found in animals with anemia due to erythrophagocytosis. The carcasses of cattle that die from anaplasmosis are generally markedly anemic and jaundiced. Blood is thin and watery. The spleen is characteristically enlarged and soft, with prominent follicles. The liver may be mottled and yellow-orange. The gallbladder is often distended and contains thick brown or green bile. Hepatic and mediastinal lymph nodes appear brown. There are serous effusions in body cavities, pulmonary edema, petechial hemorrhages in the epi- and endocardium, and often evidence of severe GI stasis. Widespread phagocytosis of erythrocytes is evident on microscopic examination of the reticuloendothelial organs. A significant proportion of erythrocytes are usually found to be parasitized after death due to acute infection.

Diagnosis: *A. marginale*, together with the hemoprotezoa *Babesia bovis* and *B. bigemina*, are the causative agents of tick fever in cattle. These three species have similar geographic distributions, except that anaplasmosis occurs in the absence of babesiosis in the USA. Microscopic examination of Giemsa-stained thin and thick blood films is critical to distinguish anaplasmosis from babesiosis (see p 21) and other conditions that result in anemia and jaundice, such as leptospirosis (see p 646) and theileriosis (see p 33). Blood in anticoagulant should also be obtained for hematologic testing. In Giemsa-stained thin blood films, *Anaplasma* spp appear as dense, homogeneously staining blue-purple inclusions 0.3–1 µm in diameter. *A. marginale* inclusions are usually located toward the margin of the infected erythrocyte, whereas *A. centrale* inclusion bodies are located more centrally. *A. caudatum* cannot be distinguished from *A. marginale* using Giemsa-stained blood films. Special staining techniques are used to identify this species based on observation of characteristic appendages associated with the bacteria. *A. caudatum* has been reported only in North America and could possibly be a morphologic form of *A. marginale* and not a separate species. Inclusion bodies contain 1–3 initial bodies 0.3–0.4 µm in diameter, which are the individual rickettsiae. The percentage of infected erythrocytes varies with the stage and severity of disease; maximum rickettsemias in excess of 50% can occur with *A. marginale*. Microscopically, the infection becomes visible 2–6 wk after transmission. During the course of infection, the rickettsemia can double each

day for up to 10 days and then decreases. Severe anemia can persist for weeks after parasites cannot be detected in blood smears.

Chronically infected carriers may be identified with a fair degree of accuracy by serologic testing using the msp5 ELISA, complement fixation, or card agglutination tests. Nucleic acid based detection methods are most useful, because species and strain differentiation tests may not detect carrier levels.

At necropsy, thin blood films of liver, kidney, spleen, lungs, and peripheral blood should be prepared for microscopic examination.

Treatment, Control, and Prevention:

Tetracycline antibiotics and imidocarb are currently used for treatment. Cattle may be sterilized by treatment with these drugs and remain immune to severe anaplasmosis subsequently for at least 8 mo.

Prompt administration of tetracycline drugs (tetracycline, chlortetracycline, oxytetracycline, rolitetracycline, doxycycline, minocycline) in the early stages of acute disease (eg, PCV >15%) usually ensures survival. A commonly used treatment consists of a single IM injection of longacting oxytetracycline at a dosage of 20 mg/kg. Blood transfusion to partially restore the PCV greatly improves the survival rate of more severely affected cattle. The carrier state may be eliminated by administration of a long-acting oxytetracycline preparation (20 mg/kg, IM, at least two injections with a 1-wk interval). Withholding periods for tetracyclines apply in most countries. Injection into the neck muscle rather than the rump is preferred.

Imidocarb is also highly efficacious against *A. marginale* as a single injection (as the dihydrochloride salt at 1.5 mg/kg, SC, or as imidocarb dipropionate at 3 mg/kg). Elimination of the carrier state requires the use of higher repeated doses of imidocarb (eg, 5 mg/kg, IM or SC, two injections of the dihydrochloride salt 2 wk apart). Imidocarb is a suspected carcinogen with long withholding periods and is not approved for use in the USA or Europe.

In South Africa, Australia, Israel, and South America, infection with live *A. centrale* (originating from South Africa) is used as a vaccine to provide cattle with partial protection against the disease caused by *A. marginale*. *A. centrale* (single dose) vaccine produces severe reactions in a small proportion of cattle. In the USA, where live vaccines cannot be used,

Anaplasma marginale in bovine blood, Wright-Giemsa, 100x oil immersion. Intracellular organisms appear as basophilic, spherical inclusions generally located near the margin of erythrocytes. Echinocytes are frequently present. Courtesy of Ms. Sue Anderson, Tick Fever Centre, Wacol, Queensland, Australia.

vaccines comprising nonliving *A marginale* purified from infected bovine erythrocytes and adjuvant have been used in the past but may not currently be available. Immunity generated by using multidose killed vaccine protects cattle from severe disease on subsequent infection, but cattle can still be susceptible to challenge with heterologous strains of *A marginale*. Instances of isoerythrolysis in suckling calves have occurred due to prior vaccination of dams with preparations that contained bovine erythrocytic material. Long-lasting immunity against *A marginale* is conferred by preimmunization with live rickettsia, combined with the use of chemotherapy to control severe reactions. The use of attenuated strains of *A marginale* as a live vaccine has been reported, with instances of severe reactions also occurring. *A marginale* grown in tick cell cultures are being investigated as an alternative live vaccine source. Subunit vaccines to control bovine anaplasmosis are also under investigation. In some areas, sustained stringent control or elimination of the arthropod vectors may be a viable control strategy; however, in other areas immunization is recommended.

BABESIOSIS

Babesiosis is caused by intraerythrocytic protozoan parasites of the genus *Babesia*. Transmitted by ticks, babesiosis affects a wide range of domestic and wild animals and occasionally people. Although the major economic impact of babesiosis is on the cattle industry, infections in other domestic animals, including horses, sheep, goats, pigs, and dogs, assume varying degrees of importance throughout the world.

Two important species in cattle—*B bigemina* and *B bovis*—are widespread in tropical and subtropical areas and are the focus of this discussion. However, because there are many common features of the diseases caused by different *Babesia*, much of this information can be applied to other species.

Transmission and Epidemiology: The main vectors of *B bigemina* and *B bovis* are 1-host *Rhipicephalus* (*Boophilus*) spp ticks, in which transmission occurs transovarially. Although the parasites can be readily transmitted experimentally by blood inoculation, mechanical transmission by insects or during surgical procedures has no practical significance. Intrauterine infection has also been reported but is rare.

In *Rhipicephalus* spp ticks, the blood stages of the parasite are ingested during engorgement and undergo sexual and asexual multiplication in the replete female, infecting eggs and subsequent parasitic stages. Transmission to the host occurs when larvae (in the case of *B bovis*) or nymphs and adults (in the case of *B bigemina*) feed. The percentage of larvae infected can vary from 0–50% or higher, depending mainly on the level of parasitemia of the host at the time the female ticks engorge. Under field conditions, the rate of tick transmission is generally higher for *B bigemina* than for *B bovis*.

In endemic areas, three features are important in determining the risk of clinical disease: 1) calves have a degree of immunity (related both to colostral-derived antibodies and to age-specific factors) that persists for ~6 mo, 2) animals that recover from *Babesia* infections are generally immune for their commercial life (4 yr), and 3) the susceptibility of cattle breeds to ticks and *Babesia* infections varies; eg, *Bos indicus* cattle tend to be more resistant to ticks and the effects of *B bovis* and *B bigemina* infection than *Bos taurus*-derived breeds. At high levels of tick transmission, virtually all calves become infected with *Babesia* by 6 mo of age, show few if any clinical signs, and subsequently become immune. This situation can be upset by either a natural (eg, climatic) or artificial (eg, acaricide treatment or changing breed composition of herd) reduction in tick numbers to levels such that tick transmission of *Babesia* to calves is insufficient to ensure all are infected during this critical early period. Other circumstances that can lead to clinical outbreaks include the introduction of susceptible cattle to endemic areas and the incursion of *Babesia*-infected ticks into previously tick-free areas. Strain variation in immunity has been demonstrated but is probably not of practical significance in the field.

Clinical Findings and Pathogenesis:

B bovis is a much more virulent organism than *B bigemina*. With most strains of *B bigemina*, the pathogenic effects relate more directly to erythrocyte destruction. With virulent strains of *B bovis*, a hypotensive shock syndrome, combined with generalized nonspecific inflammation, coagulation disturbances, and erythrocytic stasis in capillaries, contribute to the pathogenesis.

The acute disease generally runs a course of ~1 wk. The first sign is fever (frequently $\geq 106^{\circ}\text{F}$ [41°C]), which persists throughout,

and is accompanied later by inappetence, increased respiratory rate, muscle tremors, anemia, jaundice, and weight loss; hemoglobinemia and hemoglobinuria occur in the final stages. CNS involvement due to adhesion of parasitized erythrocytes in brain capillaries can occur with *B. bovis* infections. Either constipation or diarrhea may be present. Late-term pregnant cows may abort, and temporary infertility due to transient fever may be seen in bulls.

Animals that recover from the acute disease remain infected for a number of years with *B. bovis* and for a few months in the case of *B. bigemina*. No clinical signs are apparent during this carrier state.

Lesions: Lesions (particularly with *B. bovis*) include an enlarged and friable spleen; a swollen liver with an enlarged gallbladder containing thick granular bile; congested, dark-colored kidneys; and generalized anemia and jaundice. Most clinical cases of *B. bigemina* have hemoglobinuria, but this is not invariably the case with *B. bovis*. Other organs, including the brain and heart, may show congestion or petechiae.

Diagnosis: Clinically, babesiosis can be confused with other conditions that cause fever, anemia, hemolysis, jaundice, or red urine. Therefore, confirmation of diagnosis by microscopic examination of Giemsa-stained blood or organ smears is essential. From the live animal, thick and thin blood smears should be prepared, preferably from capillaries in the ear or tail tip.

Smears of heart muscle, kidney, liver, lung, brain, and from a blood vessel in an extremity (eg, lower leg) should be taken at necropsy.

Microscopically, the species of *Babesia* involved can be determined morphologically, but expertise is required, especially in *B. bovis* infections in which few organisms are present. *B. bovis* is small, with the parasites in paired form at an obtuse angle to each other and measuring $\sim 1\text{--}1.5 \times 0.5\text{--}1\text{ }\mu\text{m}$. *B. bigemina* is larger ($3\text{--}3.5 \times 1\text{--}1.5\text{ }\mu\text{m}$), with paired parasites at an acute angle to each other. Single forms of both parasites are also commonly seen.

A number of serologic tests have been described for detection of antibodies to *Babesia* in carrier animals. The most commonly used are the indirect fluorescent antibody test and ELISA. A commercially produced ELISA for *B. bigemina* is available. PCR and real-time PCR assays capable of detecting extremely low parasitemias, as occur in carrier animals,

and differentiating isolates have also been described. A procedure that may occasionally be justified to confirm infection in suspected carrier animals is the subinoculation of blood ($\sim 500\text{ mL}$) into a fully susceptible animal, preferably a splenectomized calf, and subsequent monitoring of the recipient for infection.

Treatment and Control: A variety of drugs have been used to treat babesiosis in the past, but only diminazene aceturate and imidocarb dipropionate are still in common use. These drugs are not available in all endemic countries, or their use may be restricted. Manufacturers' recommendations for use should be followed. For treating cattle, diminazene is given IM at 3.5 mg/kg . For treatment, imidocarb is given SC at 1.2 mg/kg . At a dosage of 3 mg/kg , imidocarb provides protection from babesiosis for $\sim 4\text{ wk}$ and will also eliminate *B. bovis* and *B. bigemina* from carrier animals.

Supportive treatment is advisable, particularly in valuable animals, and may include the use of anti-inflammatory drugs, corticosteroids, and fluid therapy. Blood transfusions may be life-saving in very anemic animals.

Vaccination using live, attenuated strains of the parasites has been used successfully in a number of countries, including Argentina, Australia, Brazil, Israel, South Africa, and Uruguay. The vaccine is provided in either a chilled or frozen form. One vaccination produces adequate immunity for the commercial life of the animal; however, vaccine breakdowns have been reported. Several recombinant antigens have been shown experimentally to induce some immunity, but commercial vaccines are not yet available.

Although controlling or complete eradication of the tick vector can break the transmission cycle, this approach is rarely feasible in the longterm and can lead to large, susceptible populations in endemic areas with consequent risk of outbreaks of disease in naive animals.

Zoonotic Risk: A number of cases of human babesiosis have been reported. The rodent parasite *B. microti* and the cattle parasite *B. divergens* are the most commonly implicated species in North America and Europe, respectively. However, *B. duncani*, *B. venatorum*, *B. conradae*, and some less well-defined species have also been incriminated. The reservoir hosts and vectors of some of these species are not necessarily known with any certainty. Human *Babesia* infections are

acquired via bites from infected ticks or through contaminated blood from an infected transfusion donor. Cases reported in splenectomized or otherwise immunocompromised individuals are often fatal.

Other Important *Babesia* of Domestic Animals

More than 100 species of *Babesia* have been isolated from domestic animals and wildlife. The following are indicative of those affecting domestic animals, but the list is far from complete.

Cattle: *B. divergens* and *B. major* are two temperate-zone species with features comparable to those of *B. bovis* and *B. bigemina*, respectively. *B. divergens* is a small, pathogenic *Babesia* of considerable importance in the British Isles and northwest Europe, whereas *B. major* is a large *Babesia* of lower pathogenicity. *B. divergens* is transmitted by *Ixodes ricinus*, and *B. major* by *Haemaphysalis punctata*.

Horses: Equine babesiosis is caused by *Theileria* (formerly *Babesia*) *equi* or *B. caballi*. *T. equi* is a small parasite and is more pathogenic than *B. caballi*. *T. equi* was reclassified as a *Theileria* (see p 33) in 1998. Equine babesiosis is found in Africa, Europe, Asia, South and Central America, and the southern USA. It is transmitted by ticks of the genera *Rhipicephalus*, *Dermacentor*, and *Hyalomma*. Intrauterine infection, particularly with *T. equi*, is also relatively common.

Sheep and Goats: Although small ruminants can be infected by several species of *Babesia*, the two most important species are *B. ovis* and *B. motasi*, transmitted by *Rhipicephalus bursa* and *Haemaphysalis* spp, respectively. Infection is of importance in the Middle East, southern Europe, and some African and Asian countries.

Pigs: *B. traubmanni* has been recorded as causing severe disease in pigs. This parasite has been reported from Europe and Africa. Another species, *B. perroncioti*, is of similar pathogenicity but apparently has a limited distribution in the areas mentioned above. The vectors of these *Babesia* have not been clarified, although *Rhipicephalus* spp have been shown to transmit *B. traubmanni*.

Dogs and Cats: *Babesia* species have been reported in dogs from most regions.

These include *B. canis*, *B. vogeli*, and *B. rossi*. *B. canis* is transmitted by *Dermacentor reticularis* in Europe, *B. vogeli* by *Rhipicephalus sanguineus* in tropical and subtropical countries, and *B. rossi* by *Haemaphysalis leachi* in South Africa. Consequences of *Babesia* infection vary from a mild, transient illness to acute disease that rapidly results in death.

B. gibsoni is the other important *Babesia* of dogs and is a much smaller parasite. It has a more limited distribution and characteristically causes a chronic disease with progressive, severe anemia that is not readily treated with normal babesiacides.

Illness of varying severity due to *B. felis* in domestic cats has mostly been reported in southern Africa. Sporadic cases associated with other *Babesia* species have been reported elsewhere. An unusual feature of *B. felis* is its lack of response to the normal babesiacides. However, primaquine phosphate (0.5 mg/kg, IM, twice with a 24-hr interval) is reported to be effective.

CYTAUXZONOSIS

Cytauxzoonosis is an emerging, life-threatening infectious disease of domestic cats (*Felis catus*) caused by the tick-transmitted protozoan parasite *Cytauxzoon felis*. *Cytauxzoon* spp are apicomplexan parasites within the family Theileridae along with their closest relatives of *Theileria* spp. *C. felis* is transmitted to domestic cats by the lone star tick (*Amblyomma americanum*). The natural host for *C. felis* is the bobcat (*Lynx rufus*); reservoir hosts of the parasite include bobcats and domestic cats that survive infection.

Since the discovery of feline cytauxzoonosis in Missouri in the mid-1970s, the distribution of *C. felis* has been expanding. *C. felis* has been reported in domestic cats in Missouri, Arkansas, Florida, Georgia, Louisiana, Mississippi, Oklahoma, Texas, Kentucky, Kansas, Tennessee, North Carolina, South Carolina, Nebraska, Iowa, and Virginia. Anecdotal reports of *C. felis* infection in domestic cats in additional states include Alabama, southern Illinois, and Ohio.

Aberrant and Natural Hosts: The domestic cat has been considered an aberrant or dead-end host of *C. felis* given the acute and fatal course of disease; however, there are reports of domestic cats surviving natural infection with and without treatment. As a natural host, the bobcat typically experiences subclinical infection,

followed by a chronic parasitemia. Rare cases of fatal cytauxzoonosis in bobcats have been reported. Cytauxzoonosis has been reported in several other wild felids in the USA and other countries, with both fatal and nonfatal outcomes. Infection has been reported in cougars, panthers, and tigers in the USA, in addition to two suspected but unconfirmed cases in cheetahs. *C. felis* infections of wild felids reported in other countries include lions, jaguars, pumas, ocelots, and little spotted cats. In the early 1980s, interspecies transmission of *C. felis* was investigated to identify additional potential natural and aberrant hosts among 91 wildlife, laboratory, and domestic farm animals. Bobcats and domestic cats were the only animals confirmed to be susceptible to *C. felis*.

Transmission and Risk Factors: *C. felis* is transmitted by the lone star tick, *A. americanum*. Cytauxzoonosis is typically diagnosed during April through September, which correlates with climate-dependent seasonal tick activity. Cats living near heavily wooded, low-density residential areas particularly close to natural or unmanaged habitats where both ticks and bobcats may be in close proximity are at highest risk of infection. Experimental infections have been induced with parenteral injection of tissue homogenates (SC, IP, and IV) from acutely infected cats. However, infection was not induced when these tissues were administered intragastrically or when noninfected cats were housed together with infected cats in the absence of arthropod vectors, suggesting that oral and “cat-to-cat” transmission does not occur. One recent study failed to document perinatal transmission of *C. felis* from 2 chronically infected dams to 14 healthy kittens, suggesting that vertical transmission may not occur commonly, if at all.

Life Cycle and Pathogenesis: After transmission from the tick into the cat, *C. felis* undergoes two major stages: schizogony and merogony. First, sporozoites infect WBCs (mononuclear phagocytes) and undergo schizogony (asexual reproduction) to form schizonts. Schizont-infected WBCs have been detected ~12 days after experimental infection and increase in size from 15 μ m to up to 250 μ m in diameter. They are most commonly detected in lymph node, spleen, liver, lung, and bone marrow but have been documented in many organs and are occasionally seen on blood smears.

Schizont-infected WBCs are the principal cause of disease and death; they are found predominantly lining and often occluding blood vessels. These “parasitic thrombi” result in ischemia and tissue necrosis. Schizont-infected WBCs then rupture and release piroplasms (merozoites), which infect RBCs. The piroplasms in RBCs are fairly innocuous, with parasitemias ranging from 1%–4% on average; however, higher parasitemias (ie, >10%) have been documented. During acute infection, detection of merozoite-infected RBCs is variable and has been correlated with an increase in body temperature and a decrease in leukocytes. Without treatment, survivors typically remain chronically parasitemic, and at least one cat has been shown experimentally to be solidly immune to subsequent infections. Chronic parasitemia has been established via inoculation with merozoite-infected RBCs. These chronically parasitemic cats did not develop overt clinical disease but were not immune to subsequent challenge with infection of sporozoites/schizonts, suggesting that the schizogony tissue phase is required to establish immunity in domestic cats.

Clinical Findings and Lesions: Onset of clinical signs for cats infected with *C. felis* usually occurs 5–14 days (~10 on average) after infection by tick transmission. Nonspecific signs such as depression, lethargy, and anorexia are the most common presenting problems. Pyrexia and dehydration are the most common findings on physical examination; body temperature, which increases gradually, can be as high as 106°F (41°C). Other findings include icterus, lymphadenomegaly, and hepatosplenomegaly. In extremis, cats are often hypothermic, dyspneic, and vocalize as if in pain. Without treatment, death typically occurs within 2–3 days after peak in temperature. At necropsy, splenomegaly, hepatomegaly, enlarged lymph nodes, and renal edema are usually seen. The lungs show extensive edema and congestion with petechial hemorrhage on serosal surfaces and throughout the interstitium. There is progressive venous distention, especially of the mesenteric and renal veins and the posterior vena cava. Hydropericardium is often seen with petechial hemorrhage of the epicardium.

When first described, mortality of *C. felis* infection was reported to be nearly 100%. A study of *C. felis* in northwestern Arkansas and northeastern Oklahoma indicated survival of natural infection in 18 cats with and without treatment; these cats seemed

"less sick" initially, did not have temperatures $>106^{\circ}\text{F}$ (41°C), and never became hypothermic. Similar sporadic reports in other areas exist. Some hypotheses for survival in these cats have included the following: 1) an atypical route of infection, 2) innate immunity in certain cats, 3) increased detection of carriers, 4) decreased virulence with strain attenuation or occurrence of a new strain, 5) dose of infectious inoculum, and 6) timing and type of treatment.

Diagnosis: The most common abnormalities on the CBC in animals with cytauxzoonosis include leukopenia with toxic neutrophils and thrombocytopenia with a normocytic, normochromic anemia seen at later stages. The most common biochemical abnormalities are hyperbilirubinemia and hypoalbuminemia but may vary depending on organ systems affected by parasitic thrombosis and ischemia with tissue necrosis. Other, less consistently detected abnormalities include increased liver enzyme concentrations and azotemia.

Rapid diagnosis requires microscopic observation of piroplasms or schizonts. Observation of piroplasms on blood smears is variable; they are seen in association with increasing body temperature and typically become apparent approximately 1–3 days before death. There are anecdotal reports of a higher level of sensitivity when blood is collected from smaller vessels (eg, ear vein prick) to prepare blood smears. On a well-prepared, well-stained (Wright-Giemsa, Giemsa, Romanowsky most commonly) blood smear, when detectable, merozoites may be seen ranging from 1%–4% on average, with extremely high percentages (ie, $>10\%$) reported in some cases. They are pleomorphic and may be round, oval, anaplasmod, bipolar (binucleated), or rod-shaped; however, the round and oval piroplasm forms are most commonly seen. The round forms are 1–2.2 μm in diameter, whereas oval forms are 0.8–1 $\mu\text{m} \times$ 1.5–2 μm . They are pale centrally and contain a small, magenta, round to crescent-shaped nucleus on one side. Once the parasitemia is $\sim 0.5\%$, Maltese cross and paired piriforms may be seen. Smears must be examined carefully to exclude *Mycoplasma haemofelis*, Howell-Jolly bodies, stain precipitate, and water artifact.

The schizont tissue stage precedes the formation of the RBC phase. Occasionally, schizonts may be seen in peripheral blood smears, particularly at the feathered edge, and may be mistaken for large platelet

clumps at low power. In the absence of detection of RBC piroplasms or schizonts on blood smear, a rapid diagnosis should be pursued by performing fine-needle aspiration of a peripheral lymph node, spleen, or liver to identify schizonts cytologically. These phagocytes are 15–250 μm in diameter and contain an ovoid nucleus with a distinctive, prominent, large, dark nucleolus. The cytoplasm is often greatly distended, with numerous small deeply basophilic particles representing developing merozoites.

In the absence of these observations, a diagnostic PCR test with greater sensitivity and specificity than microscopy can be done. This test is recommended in suspect cases in which the parasite is not observed, as well as to confirm identification of piroplasms or schizonts.

Treatment and Control: Historically, attempts to treat cytauxzoonosis with a variety of antiparasitic drugs (parvaquone, buparvaquone, trimethoprim/sulfadiazine, sodium thiacetarsamide) have been met with little success. In one study, five of six cats and one additional cat were successfully treated with diminazene aceturate (not approved in the USA) and imidocarb dipropionate (2 mg/kg, IM, two injections 3–7 days apart), respectively.

The most consistent successful treatment in a large case series resulted in survival of 64% of cats given a combination of atovaquone (15 mg/kg, PO, tid for 10 days) and azithromycin (10 mg/kg/day, PO, for 10 days) and supportive care. Atovaquone is a ubiquinone analogue that binds cytochrome b. In one study of *C. felis*-infected cats treated with atovaquone and azithromycin, a *C. felis* cytochrome b subtype (cytb1) was identified that was associated with increased survival in the cats infected with this subtype compared with other subtypes. Future development of a rapid means to identify the cytb1 *C. felis* subtype in infected cats may help better predict the likelihood of survival with treatment.

Supportive care, including IV fluid therapy and heparin (100–200 U/kg, SC, tid) should be instituted in all cases. Nutritional support via an esophageal or nasoesophageal feeding tube is recommended, which also facilitates administration of oral medications (eg, atovaquone and azithromycin). Oxygen therapy and blood transfusions should be administered when necessary. Anti-inflammatory drugs may be warranted in cases with unrelenting fever; however, the use of NSAIDs is contraindicated in cats with azotemia or dehydration.

Once a diagnosis is achieved and treatments have begun, minimal stress and handling are recommended. Recovery, including resolution of fever, is often slow and may take as long as 5–7 days. Cats that survive have a complete clinical recovery, including resolution of hematologic and biochemical abnormalities within 2–3 wk. Some survivors remain persistently infected with piroplasms and may represent a reservoir of infection. In one study, dose-intense diaminazene diacetate (4 mg/kg/day, IM, for 5 consecutive days) failed to reduce the severity of parasitemia in cats chronically infected with *C. felis* and resulted in adverse drug reactions.

Prevention: Routine application of a tick preventive is recommended to prevent cytauxzoonosis; however, disease has occurred in cats despite this treatment. In one study, a tick-repellent collar for cats containing imidacloprid 10%/flumethrin 4.5% prevented *A. americanum* ticks from attaching, feeding, and transmitting *C. felis* in 10 cats infested with infected ticks after application of the collar. In the same study, ticks attached and fed on 10 of 10 control cats not treated with a collar, and 9 of the 10 control cats were infected with *C. felis*. Exclusion of cats from areas likely to be infested with the tick vector (ie, indoor only) is still considered the best method of prevention.

HEMOTROPIC MYCOPLASMAS

(Hemoplasmas)

Eperythrocyclic parasites previously known as *Haemobartonella* and *Eperythrozoon*

and formerly classified as rickettsial organisms are now understood to be more closely related to the order Mycoplasmales. This affiliation is based on their lack of a cell wall, use of the codon UGA to encode tryptophan, and 16S rRNA gene sequences. Although the reassignment of *Eperythrozoon* and *Haemobartonella* to the genus *Mycoplasma* is still under debate, referral to this genus has been embraced, and they are commonly referred to as hemotropic mycoplasmas or hemoplasmas. Several of these previously described red cell parasites, now also having supporting genetic data, have been renamed *Mycoplasma*, whereas newly described hemoplasmas are given the designation “*Candidatus*.” The hemoplasmas infect a wide variety of vertebrates throughout the world, including several reports of human infection. They share similar characteristics and morphologic features such as rod, coccoid, and ring shaped structures found individually or in chains on the red cell and gram-negative staining because of the lack of a cell wall; none of the hemoplasmas have been cultured outside their hosts. It is well established that the hemoplasmas attach to the surface of the red cell but may under certain conditions penetrate this host cell.

Several hemoplasmas are of veterinary importance (see TABLE 4). These organisms vary in their ability to cause clinically significant hemolytic anemia, but infected animals may remain carriers despite antibiotic therapy. Parasitemia may reemerge if the animal is stressed or immunocompromised. Once an initial infection is controlled, either naturally or after antibiotic treatment, protective immunity develops against repeat

TABLE 4 HEMOPLASMAS OF VETERINARY IMPORTANCE

Species	Hemoplasma
Dogs	<i>Mycoplasma haemocanis</i> (formerly <i>Haemobartonella canis</i>) “ <i>Candidatus Mycoplasma haematoparvum</i> ”
Cats	<i>Mycoplasma haemofelis</i> (formerly <i>Haemobartonella felis</i>) “ <i>Candidatus Mycoplasma haemominutum</i> ” “ <i>Candidatus Mycoplasma turicensis</i> ”
Pigs	<i>Mycoplasma suis</i> (formerly <i>Eperythrozoon suis</i>) <i>Mycoplasma parvum</i> (formerly <i>Eperythrozoon parvum</i>)
Cattle	<i>Mycoplasma wenyonii</i> (formerly <i>Eperythrozoon wenyonii</i>)
Sheep and goats	<i>Mycoplasma ovis</i> (formerly <i>Eperythrozoon ovis</i>)
Llamas and alpacas	“ <i>Candidatus Mycoplasma haemolamae</i> ”

M haemofelis infection; how long this immunity will last and whether this applies to other hemoplasma infections is unknown.

Transmission: Hemoplasmas may be transmitted by transfer of infected blood (blood transfusion or use of contaminated needles, surgical instruments, herd or flock management equipment) or via arthropod vectors such as lice, flies, ticks, and mosquitoes. Vertical transmission from mother to offspring has been reported in cats, swine, and camelids. Direct transmission associated with fighting is suspected in cats and supported by studies reporting presence of hemoplasma DNA in saliva, on gingiva, and on claw beds of infected cats.

Clinical Findings: Hemoplasmas are capable of causing a hemolytic anemia, but the severity varies greatly. In general, asymptomatic infections tend to occur in healthy adult animals, and more severe acute anemias are associated with splenectomy, immunocompromise, concurrent diseases (such as feline leukemia virus or feline immunodeficiency virus in cats), or coinfection with multiple hemoplasma species. The main exception is *M haemofelis*, which causes acute hemolytic anemia in healthy cats. The anemia may be severe and occasionally fatal. Typical clinical signs include lethargy, anorexia, and fever, with splenomegaly and icterus occurring less often.

M haemocanis causes acute hemolysis in dogs that are splenectomized, but infections are usually asymptomatic in healthy dogs. *M suis* causes hemolytic anemia accompanied by icterus in neonatal pigs, feeder pigs, and pregnant sows. Chronic infection is associated with poor growth rates, decreased conception rates, reproductive failure, and decreased milk production. *M wenyonii* infection in cattle is usually asymptomatic, but a syndrome of mammary gland and hindlimb edema, decreased milk production, fever, and lymphadenopathy has been described in young, nonanemic, primiparous heifers. Infection in young bulls has been reported to cause scrotal and hindlimb edema. *M ovis* infection in sheep and goats is often asymptomatic, but hemolytic anemia can occur in young animals, especially those with heavy intestinal worm burdens. Chronic infection may result in poor weight gain, exercise intolerance, decreased wool production, and mild anemia. Hemoplasma infection in camelids

can cause a severe hemolytic anemia in young crias. The prevalence of chronic infection in sheep, pigs, and kennel-raised dogs is high, and outbreaks of acute disease have been reported in animals during research studies. Whether the infection is chronic or acute, it may affect experimental results and lead to misinterpretation of data.

The hemolysis caused by hemoplasma infections is typically extravascular and results in a regenerative anemia. Erythrocyte agglutination may be present, and Coombs' test results are often positive in cats infected with *M haemofelis*. Splenectomized dogs with acute hemolysis due to *M haemocanis* may have agglutination, spherocytosis, and a positive Coombs' test. Hypoglycemia secondary to glucose consumption by the bacteria has been reported in heavily parasitized pigs, sheep, llamas, and calves; however, rapid bacterial glycolysis in vitro may also cause artifactually decreased blood glucose concentrations.

Diagnosis: Historically, diagnosis has been made based on detection of organisms on routine Wright-stained blood smears, on which they appear as small (0.5–3 μm), basophilic, round, rod, or ring-shaped structures present on erythrocytes individually or in chains, or sometimes seen free in the background. However, parasitemia in chronic infections can be cyclic, and organisms can disappear from circulation in as little as 2 hr. In addition, hemoplasmas dissociate from erythrocytes and die after a variable amount of time in EDTA, hampering detection of organisms in aged samples. Recent development of sensitive PCR assays capable of discriminating between various hemoplasmas has greatly enhanced diagnosis of these parasites and has led to identification of several new *Mycoplasma* species.

Treatment and Control: For acute infections, tetracyclines (doxycycline, oxytetracycline) have been the mainstay of treatment; enrofloxacin and marbofloxacin have also been effective against *M haemofelis*. Glucocorticoids may be useful to decrease erythrophagocytosis in cases of severe hemolysis; some animals may require blood transfusion. Treated animals remain carriers and may experience periodic clinical relapses. Blood donors should be screened using PCR-based DNA assays to prevent transmission to transfusion recipients. Iatrogenic transmission can be avoided by using properly sterilized

needles and equipment. Control of arthropod vectors is recommended, as is minimizing stress in herd and flock situations.

Zoonotic Risk: Hemoplasma infections are usually species specific, except for *M. ovis*, which infects both sheep and goats, and "*Candidatus M. haemolamae*," which infects both llamas and alpacas. There are reports of human eperythrozoonosis from Inner Mongolia, China, but supporting evidence is not compelling. However, there have been rare reports of hemoplasma infections in immunocompromised people in which molecular methods were used for confirmation. One report documented an HIV-positive human patient coinfecting with *Bartonella henselae* and a hemoplasma genetically similar to *M. haemofelis*. This individual owned five cats and had multiple scratch and bite wounds. All five cats were PCR positive for *Bartonella* spp and two were positive for *M. haemofelis*, suggesting the possibility of zoonotic transmission. The coinfection of a veterinarian in Texas with *B. henselae* and *M. ovis* also has been reported.

Feline Infectious Anemia

(Hemoplasmosis)

In cats, hemotropic mycoplasmosis can produce a disease called feline infectious anemia (FIA), previously known as hemobartonellosis. Most cases are in outdoor, male cats. *M. haemofelis* (previously the Ohio strain, or large form, of *Haemobartonella felis*) is the most pathogenic organism causing FIA, and it can cause hemolytic anemia in immunocompetent cats. "*Candidatus M. haemominutum*" (previously the California strain, or small form, of *H. felis*) is the most common hemoplasma in cat populations worldwide, but it has not been clearly associated with disease in immunocompetent cats. "*Candidatus M. turicensis*" has never been seen on blood smears, and its pathogenicity is not well understood. Both *Candidatus* species may be capable of inducing anemia in cats with underlying immunosuppressive disease, such as feline leukemia virus infection.

In the case of *M. haemofelis* infection, an incubation period of 2–30 days is followed by anemia, with some cats developing cyclical changes in PCV that coincide with the appearance of large numbers of organisms on blood smears. In untreated cats, this acute phase lasts for 3–4 wk, after which some cats

may remain chronically infected despite normal or near normal PCV values. It has been suggested that recrudescence of anemia may occur when these chronically infected cats are subject to debilitating disease, stress, or immunosuppressive therapies.

Any anemic cat, especially an anemia showing evidence of regeneration (polychromasia and/or reticulocytosis), may be suspected of having FIA. The severity of clinical signs correlates with the rapidity of onset of anemia. Clinical findings include weakness, pallor of the mucous membranes, tachypnea, tachycardia, and occasionally collapse. Acutely ill cats may be febrile, and moribund cats may be hypothermic. Other physical examination abnormalities may include cardiac murmurs, splenomegaly, and icterus. In chronic or slowly developing cases, there may be normal or subnormal body temperature, weakness, depression, and weight loss or emaciation.

Expected laboratory abnormalities include a moderate to marked regenerative anemia, increased numbers of nucleated RBCs, polychromasia, anisocytosis, Howell Jolly bodies, and an increased reticulocyte count. Coombs' tests can become positive 7–14 days after organisms appear in the blood and remain positive throughout the acute phase, reverting to negative in chronically infected carrier cats.

Laboratory confirmation has traditionally been based on identification of organisms in the peripheral blood using light microscopy, although *M. haemofelis* is visible <50% of the time in acutely infected cats. Some laboratories offer PCR assays that are considerably more sensitive and specific than blood-smear evaluation. Detection of *M. haemofelis* via PCR is more significant than detection of other hemoplasma species ("*Candidatus M. turicensis*" and "*Candidatus M. haemominutum*"), which are not as strongly associated with anemia.

Without treatment, one third of acutely ill cats may die. Treatment involves both supportive therapies, such as oxygen and blood transfusions, and specific therapy with doxycycline (10 mg/kg/day, PO, for a minimum of 2 wk). Because of the potential for esophagitis and esophageal strictures, administration of doxycycline hyclate preparations should be followed by administration of a bolus of several milliliters of water. Enrofloxacin (5 mg/kg/day, PO) is a suitable alternative to doxycycline. Treatment of PCR-positive,

healthy cats is currently not recommended, because no regimen has yet been identified that completely eliminates the organism. The use of immunosuppressive dosages of glucocorticoids to suppress immune-mediated RBC injury is controversial but may be used in cats that do not respond to antimicrobial therapy alone, or when primary immune-mediated hemolytic anemia is a possible cause.

OLD WORLD HEPATOZOOOSIS AND AMERICAN CANINE HEPATOZOOOSIS

Etiology, Epidemiology, and Transmission:

Old World hepatozoonosis is a tickborne disease of wild and domestic carnivores caused by the protozoal agent *Hepatozoon canis*. It is unclear whether infections in wild and domestic Felidae are caused by *H canis* or by another species of *Hepatozoon*. This organism is transmitted by the brown dog tick, *Rhipicephalus sanguineus*. In the late 1990s, unique features of the clinical presentation in North American dogs suggested that a different strain or species of *Hepatozoon* might be responsible for the disease in North America than in other parts of the world; in 1997, this suspicion was confirmed based on parasite morphology, tissue tropism, and pathogenesis. The disease in North America is caused by *H americanum*, which is transmitted by the Gulf Coast tick, *Amblyomma maculatum*, rather than by the brown dog tick. Accordingly, the disease in North America is now recognized as a separate entity, American canine hepatozoonosis (ACH). Genetic and antigenic differences now documented between the North American and Old World organisms further support their classification as distinct species.

The mode of transmission of hepatozoonosis is not typical in the classical sense of a tickborne disease; like other species in the genus, *H canis* and *H americanum* infections occur when an infected tick, the definitive host, is ingested by the dog (or other vertebrate intermediate host). Sporozoites released from the mature oocysts in the tick's hemocoel enter the vertebrate host via the gut. Dogs can also acquire ACH by eating paratenic (transport) hosts that contain cystozoites, a resting stage of *H americanum* encysted in their tissues. Experimentally, cystozoite-engendered infection results in the same disease manifestations seen in dogs that ingest

sporulated oocysts. It is unknown at present whether a similar path of infection may occur in *H canis* infections, although monozytic cyst stages have been reported in the spleen of both experimentally and naturally infected dogs. It is possible that canids may serve as both transport and definitive hosts of *H canis*.

In much of the world (India, Africa, southeast Asia, the Middle East, southern Europe, and islands in the Pacific and Indian Oceans), dogs with hepatozoonosis usually have subclinical infections or only mild clinical signs. In these areas, immunosuppression caused by concurrent disease or other factors appears to play an important role in the manifestation of significant clinical signs. In the USA, immunosuppression or concurrent disease does not appear necessary to induce the more severe clinical signs typically seen with ACH.

ACH is an emerging disease that has primarily spread north and east from the Gulf Coast of Texas, where it was originally detected in 1978. The distribution of this parasite parallels the distribution of the Gulf Coast tick. Most cases in the USA have been diagnosed in Texas (primarily along the Gulf Coast), Oklahoma, and Louisiana; numerous cases have been reported from Alabama, and cases have been seen as far east as Tennessee, Georgia, and Florida. Sporadic cases have been reported from such disparate geographic locations as California, Washington, and Vermont; it is assumed these dogs were relocated from enzootic areas, because the Gulf Coast tick has not become established in such distant locations. *H americanum* may be present in Central and South America, as is *A maculatum*, but to date, no autochthonous transmission of *H americanum* has been reported from these regions. *A ovale* has been identified as a vector for *H canis* in South America. It was previously thought that *H canis* did not infect canids in North America, despite the presence of *R sanguineus*, but molecular evidence has recently emerged that suggests otherwise. Still, ACH remains the more severe and more common form of hepatozoonosis in the New World.

In general, immunocompetent dogs appear to tolerate infection with *H canis* very well. Although life-threatening infections have been reported, clinical signs associated with *H canis* infection are most often subclinical to mild. However, *H americanum* causes severe clinical signs in most dogs, with death often occurring within 1–2 yr without supportive therapies.

Clinical Findings: The tissue phases of the hepatozoonosis organism, especially those of *H americanum*, induce pyogranulomatous inflammation, which results in clinical signs. These signs, which may be intermittent, include fever, depression, weight loss, poor body condition, muscle atrophy, soreness, stiffness, and weakness; mucopurulent ocular discharge is common, and bloody diarrhea occurs occasionally. Surprisingly, many dogs maintain a normal appetite if food is placed directly in front of them, but they often will not move to eat, apparently owing to intense pain. Severe hyperesthesia or pain over the paraspinal region is a common finding on physical examination; cervical, joint, or generalized pain is also seen. Hyperesthesia, presumably due to severe inflammation within muscle and sometimes along bone, manifests as stiffness and reluctance to move, as well as cervical and/or truncal rigidity. Fever, which may fluctuate with the waxing and waning of clinical signs, ranges from 102.7°–106°F (39.3°–41°C) and is unresponsive to antibiotics. Longterm sequelae include glomerulonephritis and amyloidosis. *H canis* tissue stages reside within bone marrow, lymph nodes, and spleen. Unlike in dogs with ACH, dogs infected with *H canis* typically do not appear painful at presentation; in dogs with overt disease, nonspecific symptoms including fever, lethargy, and depression may be seen.

Diagnosis: In dogs with ACH, the most consistent laboratory abnormality is a neutrophilic leukocytosis, with counts ranging from 20,000–200,000 cells/ μ L. This is typically a pronounced, mature neutrophilia, although a left shift may be present. A mild to moderate normocytic, normochromic, nonregenerative anemia is also common. The platelet count is typically normal to high. Mildly increased alkaline phosphatase, hypoalbuminemia, and increased CK may also be seen. Although profound hypoglycemia has been reported, this finding is thought to be an in vitro sampling artifact that results from increased metabolism of glucose by the overly abundant leukocytes. On radiographs, periosteal reactions may be seen involving any bone, including the skull and vertebrae. These periosteal reactions resemble those of hypertrophic osteoarthropathy, except that lesions tend to be proximal rather than distal with ACH, often markedly obvious in long bones. The physiologic basis of the bone lesions has not been determined. Definitive diagnosis of ACH is made by

finding rare gamonts in peripheral blood leukocytes (using Romanowsky-type stains) or identifying pathognomonic “onion skin” cysts or pyogranulomas in stained sections of biopsied muscle sample. Muscle biopsy, although invasive, is considered the gold-standard method for diagnosing ACH, because parasite and parasite-induced lesions are often extensively distributed throughout muscle tissue (especially in areas with observable atrophy). However, in some dogs, multiple or sequential biopsies may be necessary to detect the organism.

Unlike in *H americanum* infections, parasitemia in dogs with clinical *H canis* infection is often quite high, and a diagnosis can readily be achieved by microscopic examination of stained blood films to visualize parasite-containing leukocytes. The most common abnormality on bloodwork in dogs infected with *H canis* is anemia. Serum chemistry abnormalities may be similar to those seen in dogs with ACH. Hepatitis, pneumonia, and glomerulonephritis associated with *H canis* meronts have been reported postmortem in some animals with extremely high parasitemia. Although experimental serologic assays have been developed to detect both *H americanum* and *H canis* infections, none is available commercially. PCR methods developed to detect circulating *Hepatozoon* are available through several different institutions (including Auburn University and North Carolina State University), although they may lack sensitivity in *H americanum* infections because of typically low levels of parasitemia. These molecular tests have led to the realization that classical hepatozoonosis caused by *H canis* is more common in North America than previously known. Moreover, recognized variation in an 18S rDNA sequence from infected dogs has raised new questions about canine hepatozoonosis. It may be that still more species (or strains) that vary in pathogenicity and/or life cycle patterns will be found to cause disease in dogs.

Treatment: Hepatozoonosis is generally considered a lifelong infection in dogs. No known therapeutic regimen completely clears the body of the organism. In the past, treatment of ACH has been frustrating, because most dogs showed only temporary improvement with frequent relapses within 3–6 mo and death within 2 yr of diagnosis. Remission of clinical signs can usually be achieved through a 14-day course of combination therapy, referred to as TCP, which consists of trimethoprim-sulfadiazine

(15 mg/kg, PO, bid), clindamycin (10 mg/kg, PO, tid), and pyrimethamine (0.25 mg/kg/day, PO). Unfortunately, remission with this therapy has often been short-lived, and dogs frequently relapse within 2–6 mo. However, an adjunctive treatment using decoquinate has been useful. Decoquinate does not resolve active clinical disease but may prevent clinical relapses; it is given after resolution of clinical signs as an adjunct to TCP therapy. The recommended dosage of decoquinate is 10–20 mg/kg, PO, bid continuously for 2 yr. The advent of TCP combination therapy followed by daily decoquinate therapy has resulted in marked improvement in the prognosis for dogs with ACH. NSAIDs may be the best treatment for control of fever and pain, especially during the first few days of TCP therapy. Glucocorticoid administration should be avoided because, although steroids may provide temporary relief, longterm use can exacerbate the disease.

H canis infections are treated with imidocarb dipropionate, twice monthly, at 5–6 mg/kg, SC, until the parasite is no longer evident in blood smears for 2–3 consecutive months. Prognosis often depends on the degree of parasitemia; dogs with low parasitemia typically respond well to treatment, whereas those with high parasitemia may not, especially if afflicted by concurrent illness.

Preventing access to ticks and discouraging predation are the most effective forms of control for hepatozoonosis. Predation presents a dual risk for acquiring ACH: prey captured/ingested by dogs could have infected ticks on their coats that would provide a source of sporozoites; additionally, the prey could contain cystozoites (at least in the case of *H americanum*) that are also infectious. Additionally, dogs diagnosed with hepatozoonosis should not be bred because transplacental transmission of *H canis* has been documented, and although vertical transmission of *H americanum* has not been reported, the possibility should not be disregarded.

There is no known zoonotic risk with hepatozoonosis.

SCHISTOSOMIASIS

Schistosomiasis is a common parasitic infection in cattle and rarely in other domestic animals in Africa and Asia. Although schistosomes may act as important pathogens under rare conditions favoring intensive transmission, most infections in endemic areas are subclinical.

However, high prevalence rates of subclinical infections cause significant losses due to longterm effects on growth and productivity and increased susceptibility to other parasitic or bacterial diseases.

Schistosomes are members of the genus *Schistosoma*, family Schistosomatidae. Adult worms are obligate parasites of the vascular system of vertebrates. Schistosomes are dioecious. The mature female is more slender than the male and normally is carried in a ventral groove, the gynaecophoric canal, that is formed by ventrally flexed lateral outgrowths of the male body.

Of the 19 species reported to naturally infect animals, 8—all parasites of ruminants—have received particular attention, mainly because of their recognized veterinary significance: *S mattheei*, *S bovis*, *S curassoni*, *S spindale*, *S indicum*, *S nasale*, *S incognitum*, and *S japonicum*. *S mattheei* is found in southeastern Africa, from the Cape Province in South Africa northward to Tanzania and Zambia. *S bovis* is found in the Mediterranean region and Middle East, and is common in northern, western, and eastern Africa (except Egypt) extending southward to Central Angola, southern Congo, and possibly northern Zambia. *S curassoni* has been found in ruminants in Senegal, Mauritania, Mali, Niger, and Nigeria. *S spindale* has been recorded from India, Sri Lanka, Indonesia, Malaysia, Thailand, and Vietnam. The distribution of *S indicum* appears confined to the Indian subcontinent. *S nasale* is found in India, Sri Lanka, Bangladesh, and Myanmar. *S incognitum* has been reported from India, Thailand, and Indonesia. *S japonicum* is endemic in several countries of the Far East. Some of these species are known to interact in areas where they coexist, and instances of interspecific hybridization have been reported, eg, the cattle parasites *S bovis* and *S curassoni*. Novel molecular tools have also provided evidence for the natural hybridization between *S haematobium*, a parasite of people, and *S mattheei*, *S bovis*, and *S curassoni*. The hybridization between human and ruminant schistosomes is of particular interest, because for this to occur, host switching must have taken place of *S mattheei*, *S bovis*, or *S curassoni* into people or of *S haematobium* into domestic livestock.

To differentiate the different *Schistosoma* spp, egg morphology (size, shape) can be used. The species can also be differentiated through such taxonomic features as morphologic (adult worms), life-cycle, or

behavioral characteristics; chromosomes; host specificity; or enzyme and DNA studies.

Life Cycle, Transmission, and Epidemiology:

Schistosomes live in the mesenteric and hepatic veins of the host (except for *S nasale*, which lives in the nasal veins), where they feed on blood and produce eggs with a characteristic terminal or lateral spine. Eggs passed in the feces must be deposited in water if they are to hatch and release miracidia, which invade suitable water snails and develop through primary and secondary sporocysts to become cercariae. When fully mature, the cercariae leave the snail and swim freely in the water, where they remain viable for several hours. Ruminants are usually infected with cercariae by penetration of the skin, although infection may be acquired orally while animals are drinking. During penetration, cercariae develop into schistosomula, which are transported via the lymph and blood to their predilection sites. The prepatent period varies according to the species but is generally 45–70 days.

The occurrence of cattle schistosomes within their range is discontinuous, depending on the presence of intermediate snail hosts, their level of infection, and the frequency of water contacts. In areas where conditions are favorable, prevalence rates of infections in cattle may be 40%–70% and commonly higher.

The increased host range of the hybrid parasites and changes in host distribution seen in Africa may have a direct impact on transmission of these schistosomes. Laboratory hybrids have been observed to acquire enhanced characteristics such as infectivity, fecundity, and growth rates.

There is strong evidence that acquired immunity to schistosome infection in cattle exists. This immunity mainly acts through suppression of worm fecundity. Examination of naturally infected animals has shown that partial protection against reinfection also occurs, and acquired resistance to schistosomes is of major importance in the regulation of infection intensity in the field.

Clinical Findings and Lesions: In the great majority of cases, **visceral schistosomiasis** in endemic areas is subclinical and characterized by a high prevalence of low to moderate worm burdens in the cattle population. Although few or no overt clinical signs

may be recognized in the short term, high prevalence rates of chronic schistosome infections cause significant losses on a herd basis. These losses are due to less easily recognizable effects on growth and productivity, as well as increased susceptibility to other parasitic and bacterial diseases.

Occasional outbreaks of clinical intestinal schistosomiasis due to *S mattheei*, *S bovis*, or *S spindale* have been reported. They are usually restricted to young livestock and adult animals undergoing relatively heavy primary infections under conditions of intensive transmission. The disease is characterized by diarrhea, weight loss, anemia, hypoalbuminemia, hyperglobulinemia, and severe eosinophilia that develop after the onset of egg excretion. Severely affected animals deteriorate rapidly and usually die within a few months of infection, while those less heavily infected develop chronic disease with growth retardation.

In the intestinal and hepatic forms, adult flukes are found in the portal, mesenteric, and intestinal submucosal and subserosal veins. However, the main pathologic effects are associated with the eggs. In the intestinal form, passage of eggs through the gut wall causes the lesions, while in the hepatic form, granulomas form around eggs trapped in the tissues. Other hepatic changes include medial hypertrophy and hyperplasia of the portal veins, development of lymphoid nodules and follicles throughout the organ, and periportal fibrosis in more chronic cases. Extensive granuloma formation also is seen in the intestine. In severe cases, numerous areas of petechiation and diffuse hemorrhage are seen in the mucosa, and large quantities of discolored blood may be found in the intestinal lumen. Frequently, the parasitized blood vessels are dilated and tortuous. Vascular lesions also may be found in the lungs, pancreas, and bladder of heavily infected animals.

The hybridization events reported between animal and human schistosomes may result in phenotypic characteristics that influence pathology (and drug sensitivity).

Nasal schistosomiasis is associated with cauliflower like growths on the nasal mucosa, causing partial obstruction of the nasal cavity and snoring sounds when breathing. Hemorrhagic and/or mucopurulent nasal discharge is a common feature. Adult flukes are found in the blood vessels of the nasal mucosa, but again, the main

pathogenic effects are associated with the eggs, which cause abscesses in the mucosa. The abscesses rupture and release eggs and pus into the nasal cavity, which eventually leads to extensive fibrosis. In addition, large granulomatous growths are common on the nasal mucosa and occlude the nasal passages and cause dyspnea.

Diagnosis: Because signs and history alone are insufficient to distinguish visceral schistosomiasis from other debilitating diseases, diagnosis should be confirmed by the presence and identification of eggs in the feces of the infected animal. At necropsy, macroscopic examination of the mesenteric veins for the presence of adult worms or microscopic examination of scrapings of the intestinal mucosa or of crushed liver tissue (both for eggs) may prove easier.

Eggs of *S bovis*, *S curassoni*, and *S matthei* are spindle-shaped. Because of the interspecific hybridization between *S bovis* and *S curassoni* and the natural hybridization between *S haematobium* and *S matthei*, *S bovis*, and *S curassoni*, eggs of intermediate morphology may be seen. The eggs of *S spindale* are more elongated and flattened on one side, and those of *S nasale* are boomerang-shaped. The oval eggs of *S japonicum* are relatively small, with a rudimentary spine.

Very low fecal egg excretion is commonly seen in chronic infections; therefore, it may be preferred to use quantitative miracidial hatching techniques which, in addition to being more sensitive, also provide information on the viability of the eggs excreted in the feces.

Treatment and Control: Praziquantel (25 mg/kg) is highly effective, although two treatments 3–5 wk apart may be required. However, for practical and economic reasons, schistosomiasis in domestic stock is rarely treated. Only in China, where infected livestock constitute important reservoirs of human infection, have mass treatments with praziquantel been practiced widely.

The most effective way to control cattle schistosomiasis in endemic areas is to prevent contact between the animals and the parasite by fencing of dangerous waters and supplying clean water. Unfortunately, this is not always possible in parts of the world where nomadic conditions of management prevail. Other methods of control include destruction of the snail intermediate host population at transmission sites, either by chemical or biologic

methods, or their removal by mechanical barriers or snail traps. Ecologic measures against the snails that aim to render their habitat unsuitable for survival, such as drainage, removal of water weeds, and increased water flow, have also proved valuable. These measures not only help reduce the transmission of schistosomiasis but also help control other parasitic trematodes such as *Fasciola gigantica* and paramphistomes, which also have water snails as intermediate hosts and frequently are found in the same localities as schistosomes.

THEILERIASES

Theilerias are a group of tickborne diseases caused by *Theileria* spp. A large number of *Theileria* spp are found in domestic and wild animals in tick-infested areas of the Old World. The most important species affecting cattle are *T parva* and *T annulata*, which cause widespread death in tropical and subtropical areas of the Old World. *T lestoquardi*, *T luwenshuni*, and *T uilenbergi* are important causes of mortality in sheep.

Both *Theileria* and *Babesia* are members of the suborder Piroplasmorina. Although *Babesia* are primarily parasites of RBCs, *Theileria* use, successively, WBCs and RBCs for completion of their life cycle in mammalian hosts. The infective sporozoite stage of the parasite is transmitted in the saliva of infected ticks as they feed. Sporozoites invade leukocytes and, within a few days, develop to schizonts. In the most pathogenic species of *Theileria* (eg, *T parva* and *T annulata*), parasite multiplication occurs predominantly within the host WBCs, whereas less pathogenic species multiply mainly in RBCs. Development of the schizont stage of pathogenic *Theileria* causes the host WBC to divide; at each cell division, the parasite also divides. Thus, the parasitized cell population expands and, through migration, becomes disseminated throughout the lymphoid system. Later in the infection, some of the schizonts undergo merogony, releasing merozoites that infect RBCs, giving rise to piroplasms. Uptake of piroplasm-infected RBCs by vector ticks feeding on infected animals is the prelude to a complex cycle of development, culminating in transmission of infection by ticks feeding in their next instar (trans-stadial transmission). There is no transovarial transmission as occurs in *Babesia*. Occurrence of disease is limited to the geographic distribution of the appropriate tick vectors. In some

endemic areas, indigenous cattle have a degree of innate resistance. Mortality in such stock is relatively low, but introduced cattle are particularly vulnerable. Unlike in babesiosis, in theileriasis there is no evidence of increased resistance in calves <6 mo old.

East Coast Fever

East Coast fever, an acute disease of cattle, is usually characterized by high fever, swelling of the lymph nodes, dyspnea, and high mortality. Caused by *Theileria parva*, and transmitted by the tick vector *Rhipicephalus appendiculatus*, it is a serious problem in east and southern Africa.

Etiology and Transmission: The African buffalo (*Syncerus caffer*) is an important wildlife reservoir of *T parva*, but infection is asymptomatic in buffalo. *T parva* transmitted by ticks from either cattle or buffalo cause severe disease in cattle, but buffalo-derived parasites differentiate poorly to merozoites in cattle and generally are not transmitted by ticks. Hence, buffalo *T parva* are maintained as a separate population. Buffalo *T parva* were previously considered a separate subspecies (*T parva laurencei*), but DNA typing indicate that the cattle and buffalo parasites are a single species. *T parva* is usually highly pathogenic, causing high levels of mortality, although some less pathogenic isolates have been identified.

Pathogenesis, Clinical Findings, and Diagnosis: *T parva* sporozoites are injected into cattle by infected vector ticks. An occult phase of 5–10 days follows before infected lymphocytes can be detected in Giemsa-stained smears of cells aspirated from the local draining lymph node. Subsequently, the number of parasitized cells increases rapidly throughout the lymphoid system, and from about day 14 onward, cells undergoing merogony are observed. This is associated with widespread lymphocytolysis, marked lymphoid depletion, and leukopenia. Piroplasms in RBCs infected by the resultant merozoites assume various forms, but typically they are small and rod-shaped or oval.

Clinical signs vary according to the level of challenge, and they range from inapparent or mild to severe and fatal. Typically, fever occurs 7–10 days after parasites are introduced by feeding ticks, continues throughout the course of infection, and may be >106°F (41°C). Lymph node swelling becomes pronounced and generalized. Lymphoblasts in Giemsa-stained smears of

needle aspirates from lymph nodes contain multinuclear schizonts. Anorexia develops, and the animal rapidly loses condition; lacrimation and nasal discharge may occur. Terminally, dyspnea is common. Just before death, a sharp decrease in body temperature is usual, and pulmonary exudate pours from the nostrils. Death usually occurs 18–24 days after infection. The most striking postmortem lesions are lymph node enlargement and massive pulmonary edema and hyperemia. Hemorrhages are common on the serosal and mucosal surfaces of many organs, sometimes together with obvious areas of necrosis in the lymph nodes and thymus. Anemia is not a major diagnostic sign (as it is in babesiosis) because there is minimal division of the parasites in RBCs, and thus no massive destruction of them.

Animals that recover are immune to subsequent challenge with the same strains but may be susceptible to some heterologous strains. Most recovered or immunized animals remain carriers of the infection.

Treatment and Control: Treatment with parvaquone and its derivative buparvaquone is highly effective when administered in the early stages of clinical disease but is less effective in the advanced stages, in which there is extensive destruction of lymphoid and hematopoietic tissues. Immunization of cattle against *T parva* using an infection-and-treatment procedure is practical and continues to gain acceptance in some regions. The components for this procedure are a cryopreserved sporozoite stabilate of the appropriate strain(s) of *Theileria* derived from infected ticks and a single dose of long-acting oxytetracycline given simultaneously; although oxytetracycline has little therapeutic effect when administered after development of disease, it inhibits development of the parasite when given at the outset of infection. Cattle should be immunized 3–4 wk before being allowed on infected pasture. Parasitized bovine cells containing the schizont stage of *T parva* and *T annulata* can be cultivated in vitro as continuously growing cell lines. In the case of *T annulata*, cattle can be infected with a few thousand cultured cells. Attenuated strains produced by serial passage of such cultures form the basis of live vaccines used in several countries, including Israel, Iran, India, and the former USSR.

Incidence of East Coast fever can be reduced by rigid tick control, but this is not feasible in many areas because of cost and the high frequency of acaricidal treatment required.

Tropical Theileriosis

Theileria annulata, the causal agent of tropical theileriosis, is widely distributed in north Africa, the Mediterranean coastal area, the Middle East, India, the former USSR, and Asia. It is transmitted by several species of ticks of the genus *Hyalomma*. *T. annulata* can cause mortality of up to 90%, but strains vary in their pathogenicity. The kinetics of infection and the main clinical findings are similar to those produced by *T. parva*, but unlike in East Coast fever, anemia is often a feature of the disease. Characteristic signs include fever and swollen superficial lymph nodes. If the disease progresses, cattle rapidly lose condition. The schizonts and piroplasms are morphologically similar to those of *T. parva*. Animals that recover from infection are immune to subsequent challenge. Treatment and control are as described for East Coast fever (see p 34).

Other Theilerias of Cattle

The *Theileria orientalis* group, consisting of the closely related parasites *T. orientalis*, *T. buffeli*, and *T. sergenti*, has a worldwide distribution. These parasites are transmitted by ticks of the genus *Haemaphysalis*. The piroplasms are larger than those of *T. parva* and *T. annulata*, and they multiply principally by intraerythrocytic division. Mortality, particularly in indigenous cattle, is rare, but infection can sometimes result in progressive chronic anemia.

T. mutans and *T. velifera* are found in Africa, where they are transmitted by ticks of the genus *Amblyomma*. Multiplication occurs mainly by intraerythrocytic division. The piroplasms are morphologically indistinguishable from those of *T. orientalis* and *T. taurotragi* (an African parasite of eland and cattle), but the parasites can be differentiated by serologic tests such as indirect fluorescent antibody and by DNA typing. Some strains of *T. mutans* are pathogenic as well. In addition, concurrent infection may add to the pathogenicity of *T. parva*.

Ovine and Caprine Theilerias

Theileria lestoquardi (formerly *T. hirci*) causes a disease in sheep and goats similar to that produced in cattle by *T. annulata*, with which it is closely related. *T. lestoquardi* is transmitted by ticks of the genus *Hyalomma*. The limited available epidemiologic data indicate that *T. lestoquardi* has a more restricted geographic distribution than that of *T. annulata*, being particularly prevalent in the Middle East and northeast

Africa. Mortality can approach 100%. Schizonts can readily be demonstrated in Giemsa-stained smears of needle biopsies from swollen superficial lymph nodes.

Recently, two species of *Theileria*, *T. luwenshuni* and *T. uilenbergi*, have been identified as the causal agents of a severe disease in sheep in China. These species are morphologically indistinguishable and cause similar disease but can be distinguished by DNA typing methods. They are transmitted by ticks of the genus *Haemaphysalis*. Schizonts are detected in a range of tissues, but later and in smaller numbers than in other pathogenic *Theileria* spp. Piroplasms are consistently detected in RBCs. Morbidity and mortality rates of up to 65% (*T. luwenshuni*) and 75% (*T. uilenbergi*) have been seen in susceptible animals introduced into endemic areas. Affected animals show sustained fever and anemia.

Several other nonpathogenic *Theileria* spp (eg, *T. ovis*) are also widely distributed. Piroplasms of these species are polymorphic.

Equine Theileriasis

Babesia equi was reclassified as *T. equi* in 1998, based on DNA analysis and other biologic data (see p 21).

TRYPANOSOMIASIS

Tsetse-transmitted Trypanosomiasis

This group of diseases caused by protozoa of the genus *Trypanosoma* affects all domesticated animals. The major veterinary species are *T. congolense*, *T. vivax*, *T. brucei brucei*, and *T. simiae*. *T. brucei rhodesiense* and *T. brucei gambiense* are zoonotic, with people as the predominant host. For the animals mainly affected by these tsetse-transmitted trypanosomes and the geographic areas where tsetse-transmitted trypanosomiasis occurs, see TABLE 5.

Cattle, sheep, and goats are infected, in order of importance, by *T. congolense*, *T. vivax*, and *T. brucei brucei*. In pigs, *T. simiae* is the most important. In dogs and cats, *T. brucei* is probably the most important. It is difficult to assign an order of importance for horses and camels. *T. vivax* is found outside tsetse-infested areas of sub-Saharan Africa, carried mechanically by biting flies.

The trypanosomes that cause tsetse-transmitted trypanosomiasis (sleeping sickness) in people, *T. brucei rhodesiense* and *T. brucei gambiense*, closely resemble *T. brucei brucei*, and suitable precautions should be taken when working with such

TABLE 5 TSETSE-TRANSMITTED TRYPANOSOMES

<i>Trypanosoma</i> spp	Animals Mainly Affected	Major Geographic Distribution
<i>T. congolense</i>	Cattle, sheep, goats, dogs, pigs, camels, horses, most wild animals	South and eastern Africa
<i>T. vivax</i>	Cattle, sheep, goats, camels, horses, various wild animals	Africa, Central and South America, West Indies ^a
<i>T. brucei brucei</i>	All domestic and various wild animals; most severe in dogs, horses, cats	South and eastern Africa
<i>T. brucei rhodesiense</i>	Cattle, wild hooved stock, people	South and eastern Africa
<i>T. brucei gambiense</i>	Cattle, sheep, goats, people	West and central Africa, including Uganda
<i>T. simiae</i>	Domestic and wild pigs, horses, camels	South and eastern Africa

^a In non-tsetse areas, transmission is by biting flies.

isolates. Domestic animals act as reservoirs of human infections.

Transmission and Epidemiology:

Most tsetse transmission is cyclic and begins when blood from a trypanosome-infected animal is ingested by the fly. The trypanosome alters its surface coat, multiplies in the fly, then alters its surface coat again, and becomes infective. *T. brucei* spp migrate within the tsetse from the gut and eventually to the salivary glands; the cycle for *T. congolense* stops at the hypopharynx, and the salivary glands are not invaded; the entire cycle for *T. vivax* occurs in the proboscis. Therefore, the location within the tsetse can be useful in identifying the parasite species. The animal-infective form in the tsetse salivary gland is referred to as the metacyclic form. The life cycle in the tsetse may be as short as 1 wk with *T. vivax* or extend to a few weeks for *T. brucei* spp.

Tsetse flies (genus *Glossina*) are restricted to Africa from about latitude 15°N to 29°S. The three main species inhabit relatively distinct environments: *G. morsitans* usually is found in savanna country, *G. palpalis* prefers areas around rivers and lakes, and *G. fuscus* lives in high forest areas. All three species transmit trypanosomes, and all feed on various mammals.

Mechanical transmission can occur through tsetse or other biting flies. In the case of *T. vivax*, *Tabanus* spp and other biting flies seem to be the primary mechanical vectors outside tsetse-endemic areas, as in Central and South America. Mechanical transmission

requires only that blood containing infectious trypanosomes be transferred by bite from one animal to another.

Pathogenesis: Infected tsetse inoculate metacyclic trypanosomes into the skin of animals, where the trypanosomes reside for a few days and cause localized inflammation (chancres). They enter the lymph and lymph nodes, then the bloodstream, where they divide rapidly by binary fission. In *T. congolense* infection, the organisms attach to endothelial cells and localize in capillaries and small blood vessels. *T. brucei* species and *T. vivax* invade tissues and cause tissue damage in several organs.

The immune response is vigorous, and immune complexes cause inflammation, which contributes to fever and other signs and lesions of the disease. Antibodies against the surface-coat glycoproteins kill the trypanosomes. However, trypanosomes have a large family of genes that code for variable surface-coat glycoproteins that are switched in response to the antibody response, evading immunity. This antigenic variation results in persistence of the organism. Antigenic variation has prevented development of a protective vaccine and permits reinfections when animals are exposed to a new antigenic type.

Clinical Findings and Lesions: Severity of disease varies with species and age of the animal infected and the species of trypanosome involved. The incubation period is usually 1–4 wk. The primary clinical signs are intermittent fever, anemia, and weight loss. Cattle usually

have a chronic course with high mortality, especially if there is poor nutrition or other stress factors. Ruminants may gradually recover if the number of infected tsetse flies is low; however, stress results in relapse.

Necropsy findings vary and are nonspecific. In acute, fatal cases, extensive petechiation of the serosal membranes, especially in the peritoneal cavity, may occur. Also, the lymph nodes and spleen are usually swollen. In chronic cases, swollen lymph nodes, serous atrophy of fat, and anemia are seen.

Diagnosis: A presumptive diagnosis is based on finding an anemic animal in poor condition in an endemic area. Confirmation depends on demonstrating trypanosomes in stained blood smears or wet mounts. The most sensitive rapid method is to examine a wet mount of the buffy coat area of a PCV tube after centrifugation, looking for motile parasites. Other infections that cause anemia and weight loss, such as babesiosis, anaplasmosis, theileriosis, and haemonchosis, should be excluded by examining a stained blood smear.

Various serologic tests measure antibody to trypanosomes, but their use is more

suitable for herd and area screening than for individual diagnosis. Rapid agglutination tests to detect circulating trypanosome species-specific antigens in peripheral blood are available for both individual and herd diagnosis, although their reliability remains varied. Molecular techniques for trypanosome detection and differentiation have been developed, but they are not generally available for routine field use.

Treatment and Control: Several drugs can be used for treatment (see TABLE 6). Most have a narrow therapeutic index, which makes administration of the correct dose essential. Drug resistance occurs and should be considered in refractory cases.

Control can be exercised at several levels, including eradication of tsetse flies and use of prophylactic drugs. Tsetse flies can be partially controlled by frequent spraying and dipping of animals, aerial and ground spraying of insecticides on fly-breeding areas, use of insecticide-impregnated screens and targets, bush clearing, and other habitat removal methods. The Sterile Insect Technique (SIT) has been used with success in Zanzibar and may be used in other area wide control operations after suppression of tsetse populations by insecticides.

TABLE 6

DRUGS COMMONLY USED FOR TRYPANOSOMIASIS IN DOMESTIC ANIMALS

Drug	Animal	<i>Trypanosoma</i>	Main Action
Diminazene aceturate	Cattle	<i>vivax, congolense, brucei</i>	Curative
Homidium bromide	Cattle	<i>vivax, congolense, brucei</i>	Curative, some prophylactic activity
Homidium bromide	Equids	<i>vivax</i>	Curative, some prophylactic activity
Homidium chloride	Equids	<i>vivax</i>	Curative, some prophylactic activity
Isometamidium chloride	Cattle	<i>vivax, congolense</i>	Curative and prophylactic
Quinapyramine sulfate	Horses, camels, pigs, dogs	<i>vivax, congolense, brucei, evansi, equiperdum, simiae</i>	Curative
Quinapyramine dimethylsulfate	Horses, camels, pigs, dogs	<i>vivax, congolense, brucei, evansi, equiperdum, simiae</i>	Prophylactic
Suramin	Horses, camels, dogs	<i>brucei, evansi</i>	Curative, some prophylactic activity
Melarsomine dihydrochloride	Camels	<i>evansi</i>	Curative

Trypanosoma vivax, blood smear of a cow.
Courtesy of Dr. Corrie Brown.

There is renewed international interest in large-scale tsetse eradication through the Pan African Tsetse and Trypanosomiasis Eradication Campaign (PATTEC) supported by the African Union. Animals can be given drugs prophylactically in areas with a high population of trypanosome-infected tsetse. Drug resistance must be carefully monitored by frequent blood examinations for trypanosomes in treated animals.

Several breeds of cattle and water buffalo have been identified that have innate resistance to trypanosomiasis and could play a valuable role in reducing the impact of the disease in these areas. However, resistance may be lost because of poor nutrition or heavy tsetse challenge.

Control is ideally achieved by combining methods to reduce the tsetse challenge and by enhancing host resistance with prophylactic drugs.

Surra

(*Trypanosoma evansi* infection)

Surra is usually transmitted by other biting flies that are found within and outside tsetse fly areas. It occurs in North Africa, the Middle East, Asia, the Far East, and Central and South America. The distribution of *T. evansi* in Africa extends into the tsetse areas, where differentiation from *T. brucei* is difficult. It is essentially a disease of camels and horses, but all domestic animals are susceptible. The disease can be fatal, particularly in camels, horses, and dogs. *T. evansi* in other animals appears to be nonpathogenic, and these animals serve as reservoirs of infection.

Transmission is primarily by biting flies, probably resulting from interrupted feedings. A few wild animals are susceptible to infection and may serve as reservoirs.

Pathogenesis, clinical findings, lesions, diagnosis, and treatment are similar to those

of the tsetse-transmitted trypanosomes (see p 35).

Dourine

Dourine is a chronic venereal disease of horses that is transmitted during coitus and caused by *T. equiperdum*. The disease is recognized on the Mediterranean coast of Africa and in the Middle East, southern Africa, and South America; distribution is probably wider.

Signs may develop over weeks or months. Early signs include mucopurulent discharge from the urethra in stallions and from the vagina in mares, followed by gross edema of the genitalia. Later, characteristic plaques 2–10 cm in diameter appear on the skin, and the horse becomes progressively emaciated. Mortality in untreated cases is 50%–70%.

Demonstration of trypanosomes from urethral or vaginal discharges, skin plaques, or peripheral blood is difficult unless the material is centrifuged. Infected horses can be detected with the complement fixation test but only in areas where *T. evansi* or *T. brucei* are not found because they have common antigens. An ELISA test may become available for diagnosis.

In endemic areas, horses may be treated (see TABLE 6). When eradication is required, strict control of breeding and elimination of stray horses has been successful. Alternatively, infected horses may be identified using the complement fixation test; euthanasia is mandatory.

Chagas' Disease

(*Trypanosoma cruzi* infection)

Chagas' disease, or American trypanosomiasis, is a zoonotic, vectorborne disease transmitted by triatomine bugs and caused by *T. cruzi*. All mammals are considered susceptible to infection, with infection demonstrated in >100 mammalian species. Avian species are not susceptible. The disease is best recognized in dogs and people, with dogs serving as a major domestic reservoir. Domestic pigs and cats can also be infected, but their role as reservoirs for human infection is limited. Wildlife reservoirs include opossums, armadillos, raccoons, woodrats, and nonhuman primates.

Transmission and Epidemiology:

Chagas' disease is endemic in 21 countries of South America, Central America, and Mexico, and is increasingly reported in the southern USA. Chagas' was once confined

to the Americas, but human and animal migration has resulted in distribution to Europe, where it is an emerging disease of Spain, Switzerland, France, Italy, Germany, and England. Seropositivity in dogs in endemic regions can vary from 5%–92%. In some areas such as Venezuela, the seropositivity of dogs is similar to that of people, whereas in other areas, such as Campeche, Mexico, seropositivity can be higher in dogs than people.

The nocturnal and hematophagous triatomine insects of the *Triatoma*, *Rhodnius*, and *Panstrongylus* genera serve as vectors for *T. cruzi*. Common names include the “kissing bug,” “assassin bug,” “cone-nosed bug,” “vinchuca,” “chinche,” and “barbeiro.” There are >130 species of triatomines in the Americas, and most are considered competent vectors. Insects take an infected blood meal ingesting extracellular *T. cruzi* trypomastigotes. These differentiate in the midgut to epimastigotes and divide. Epimastigotes travel to the hindgut, where they differentiate back into metacyclic trypomastigotes. Infective metacyclic trypomastigotes are shed in insect feces. In insectivorous animals, including dogs, consumption of infected bugs or materials contaminated with infected triatomine feces is a major mode of transmission. The opossum (*Didelphis* species) is a unique host for *T. cruzi*, because the parasite can complete its entire life cycle without the need for a vector. *T. cruzi* maturation occurs in the anal odoriferous glands, and infective trypomastigotes can be shed in feces or urine and ingested. Additional methods of transmission include transplacentally or via blood transfusions and organ transplant.

Pathogenesis: Once metacyclic trypomastigotes enter the bloodstream, they actively invade many cell types, exiting the parasitophorous vacuole and becoming nonflagellated amastigotes. Intracellular amastigotes divide every 15–18 hr for 5–6 days. *T. cruzi* transforms back into trypomastigotes and lyses the cell. Released trypomastigotes invade new cells. *T. cruzi* has a tropism for cardiac and smooth muscle but can be found in numerous other tissues.

Clinical Findings and Lesions: Chagas' disease is divided into acute and chronic phases, with the chronic phase further subdivided into latent and symptomatic chronic disease. Incubation ranges from 5–42 days before acute disease. Acute infections may be asymptomatic or consist of nonspecific febrile illness with a chancre

at the site of parasitic entry. Dogs may also present with regional or generalized lymphadenopathy, anorexia, lethargy, vomiting, diarrhea, and hepatomegaly or splenomegaly. Rarely, acute clinical myocarditis is seen. Parasitemia peaks 2–3 wk after infection and dissipates after the first month as the organism moves to predominantly tissue-borne disease.

The latent phase can last for months to years. Chronic disease symptoms can include generalized weakness or sudden death. Symptomatic dogs commonly present with right side congestive heart failure. This can progress to myocarditis, with arrhythmias and bilateral cardiac dilation. Histologic examination of cardiac muscle may contain unruptured pseudocysts without inflammation or contain ruptured pseudocysts with lymphocytic, monocytic, and/or neutrophilic inflammation. Death secondary to heart failure is common.

Diagnosis: Diagnosis of Chagas' disease can be made by visualization of the organism, detection of DNA, or antibody detection. Parasitemia during the acute phase allows for detection on a microscopy of a routine peripheral blood smear. Although samples can be tested for *T. cruzi* DNA by PCR or cultured, these diagnostic tests are uncommon in the field. On Giemsa stain, *T. cruzi* is an extracellular, C-shaped protozoan with a single flagellum.

Antibody testing is of primary importance during the chronic phase. Whole blood, plasma, or serum can be submitted. Testing methodologies include immunochromatographic “dipstick,” immunofluorescent antibody, or ELISA. Notably, cross-reaction with antibodies to *Leishmania* species, another trypanosomatid, can occur. Because of cross reactivity of serologic tests, testing with at least two different methodologies or antigens is recommended. Additionally, cardiac tissue in the chronic phase can be analyzed by PCR for *T. cruzi* DNA or by immunohistochemical analysis for amastigotes.

Treatment and Control: Benznidazole is the drug of choice for treatment, but nifurtimox can also be used. In dogs, benznidazole is administered at 5–10 mg/kg/day, PO, for 2 mo. In the USA, both of these drugs lack FDA approval, and their use requires permission from the CDC as investigational protocols. Symptomatic treatment for heart failure and arrhythmias is also recommended.

No vaccine is available; thus, control focuses on preventing disease transmission.

Vector control methods include pesticide application to eliminate triatomine vectors and decreasing vector attraction to dwellings at night by turning off outdoor lighting. Breeding of positive bitches is discouraged. Screening of blood donors is recommended. To avoid iatrogenic transmission, disinfection with 10% bleach or 70% ethanol is suggested for contaminated surfaces. Dead infected insects can remain a source of infective *T. cruzi* for up to 6 days at 10°C or up to 2 mo at 26°–30°C.

Nonpathogenic Trypanosomes

Trypanosoma theileri or markedly similar trypanosomes have been detected in

peripheral blood from cattle on every continent. Infection with similar trypanosomes also has been detected in domestic and wild buffalo and various other wild ungulates. In the few areas studied, transmission is by contamination after a cycle of development in species of tabanid flies. Although most parasitemias are subpatent, the trypanosomes may be seen in a blood smear being examined for pathogenic protozoa or in a hemocytometer chamber. Pathogenicity has never been proved experimentally.

T. melophagium of sheep also has a worldwide distribution and is transmitted by the sheep ked. *T. theodori*, reported in goats, may be a synonym for the same trypanosome.

CANINE LYMPHOMA

Canine lymphoma is a disease term comprising a heterogeneous group of malignancies with varying biologic aggressiveness derived from the uncontrolled and pathologic clonal expansion of lymphoid cells of either B- or T-cell immunophenotype. Although neoplastic transformation of lymphocytes is not restricted to specific anatomic compartments, canine lymphoma most commonly involves organized primary and secondary lymphoid tissues, including the bone marrow, thymus, lymph nodes, and spleen. In addition to these lymphoid-rich organs, extranodal sites affected by lymphoma include the skin, intestinal tract, liver, eye, CNS, and bone. Lymphoma is reported to be the most common hematopoietic neoplasm in dogs, with an incidence reported to approach 0.1% in susceptible dogs. Despite the prevalence of malignant lymphoma, the underlying causes for its development remain poorly characterized; however, advanced genetic studies have revealed that canine lymphoma can be molecularly distinguished and categorized into discrete groups that correlate with biologic aggressiveness. Hypothesized causes include retroviral infection with Epstein-Barr virus-like viruses, environmental contamination with phenoxyacetic acid herbicides, magnetic field exposure, chromosomal abnormalities, and immune

dysfunction. With the completion of the dog genome, it is anticipated that genome-wide association studies will identify specific genetic and chromosomal signatures involved in the pathogenesis of lymphoma.

Clinical Findings: Canine lymphoma is a heterogeneous cancer, with variable clinical signs, responses to therapy, and survival times. The heterogeneity associated with canine lymphoma is influenced in part by several tumor and host factors, including anatomic involvement, extent of disease, morphologic subtype, host constitution, and immunocompetence. In dogs, the most common clinical variants of lymphoma are high-grade T- or B-cell variants, and four conventionally recognized anatomic forms of lymphoma have been described: multicentric, alimentary, mediastinal, and extranodal (renal, CNS, cutaneous, ocular, bone, etc). Multicentric lymphoma is by far the most common anatomic form, accounting for ~80%–85% of all diagnosed cases. The most common and overt clinical manifestation of multicentric lymphoma is the rapid and nonpainful development of generalized lymphadenopathy. In addition to peripheral lymphadenopathy, most affected dogs will have malignant lymphocytes that are detectable by sensitive diagnostic tests, including flow cytometry or PCR for antigen receptor rearrangement

(PARR) that involve internal organs, including the spleen, liver, bone marrow, and other extranodal sites. In dogs with significant tumor burden, systemic constitutional signs, including profound lethargy, weakness, fever, anorexia, and dehydration, may become evident.

Alimentary lymphoma accounts for <10% of all canine lymphomas. Dogs with focal intestinal lesions may exhibit clinical signs consistent with partial or complete luminal obstruction (eg, vomiting, constipation, abdominal pain). With diffuse involvement of the intestinal tract, dogs with alimentary lymphoma may show significant and debilitating GI signs, including anorexia, vomiting, diarrhea, hypoproteinemia, and weight loss secondary to malabsorption and maldigestion.

Exclusive involvement of the cranial mediastinum with lymphoma comprises only a small fraction of diagnosed cases; however, sternal lymph node enlargement is frequently observed in dogs with multicentric disease. Mediastinal lymphoma is typically characterized by enlargement of the cranial mediastinal lymph nodes, thymus, or both. Mediastinal lymphoma arising from the thymus is predominantly comprised of high-grade malignant T lymphocytes, and with advanced disease, clinical signs may include respiratory distress associated with pleural fluid accumulation, direct compression of adjacent lung lobes, or caval syndrome. In addition to respiratory signs, some dogs with mediastinal lymphoma may have primary polyuria with secondary polydipsia resulting from humoral hypercalcemia of malignancy, a paraneoplastic syndrome seen in 10%–40% of dogs with lymphoma. Confirmation of humoral hypercalcemia of malignancy can be documented through the measurement of ionized calcium, parathyroid hormone, and parathyroid hormone–related peptide within circulating blood.

The clinical signs associated with various high-grade extranodal lymphomas (which may involve the skin, lungs, kidneys, eyes, CNS, etc) are often variable and dictated by the organs infiltrated. The most common extranodal form of lymphoma involves the skin, referred to as cutaneous lymphoma. Cutaneous lymphoma (epitheliotropic and nonepitheliotropic) may appear as solitary, raised, ulcerative nodules or generalized, diffuse, scaly lesions. Involvement of peripheral lymph nodes and mucocutaneous junctions is frequent. Clinical signs associated with lymphoma involving other

extranodal sites may include respiratory distress (lungs), renal failure (kidneys), blindness (eyes), seizures (CNS), and skeletal pain or pathologic fracture (bone).

Although high-grade lymphoma of either B- or T-cell origin is most commonly diagnosed in dogs, low-grade or indolent lymphoma is a recently described molecular variant of canine lymphoma and comprises up to 30% of all lymphoma diagnoses. Like high grade lymphoma, indolent lymphoma consists of several histopathologic subtypes, including marginal zone, follicular, mantle cell, and T-zone lymphoma. Collectively, indolent lymphomas are slowly progressive, and dogs often remain asymptomatic for a prolonged time regardless of therapy.

Lesions: Commonly, peripheral and various internal lymph nodes are 3–10 times normal size (multicentric form) and nonpainful on digital palpation. Affected nodes are freely movable, firm, and gray-tan; they bulge on cut surface and have no cortical-medullary demarcation. Frequently, there is hepatosplenomegaly with either diffuse enlargement or multiple, pale nodules of variable size disseminated in the parenchyma. In the alimentary form, any part of the GI tract or mesenteric lymph nodes may be affected. Involvement of the bone marrow, CNS, kidney, heart, tonsils, pancreas, and eyes can be seen but is less common.

Diagnosis: The definitive diagnosis of lymphoma is often uncomplicated and can be obtained by either cytologic or histopathologic evaluation of the affected organ system. Fine-needle aspiration of enlarged peripheral lymph nodes or affected visceral organs usually provides specimens of adequate cellular content and detail to make a definitive diagnosis. Cytologically, lymph node or tissue aspirates may identify a monomorphic population of lymphoid cells, either of large (lymphoblastic), intermediate, or small size. Despite the ease of diagnosis, conventional cytology is limited for differentiating or categorizing the heterogeneous spectrum of lymphomas with regard to morphologic subtype (diffuse versus follicular, cleaved versus noncleaved) and histologic grade (high versus low). Specialized cytology utilizing lineage-specific antibodies can differentiate between B- and T-cell lymphomas and can provide some information regarding prognosis based on immunophenotype. However, because of the inherent limitations associated with cytology, histopathologic tissue evaluation

remains the gold standard for the diagnosis of lymphoma, providing additional morphologic information required for definitive classification, as well as guiding therapeutic decisions.

In rare situations when cytology or histopathology fails to confirm the diagnosis of lymphoma, more advanced molecular techniques are available for definitive diagnosis, including flow cytometry for specific cell surface markers called cluster of differentiation (CD) antigens and PCR for PARR. The use of PCR allows for the amplification of DNA sequences that confirms or denies the presence of lymphocytes of either clonal, oligoclonal, or polyclonal origin. Because most neoplastic outgrowths result from the clonal expansion of one malignantly transformed cell, PCR techniques can differentiate lymphocyte expansion as a consequence of cancer (lymphoma) versus inflammation (reactive or hyperplastic lymphocytosis). Although PCR techniques are highly sensitive, the methodology should be reserved for cases in which conventional cytology and histopathology prove nondiagnostic, or when results are discordant with clinical signs and disease progression.

Treatment: Treatment of high-grade, multicentric canine lymphoma with aggressive, multi-agent chemotherapy protocols is often rewarding, with >90% of all dogs achieving complete reduction of tumor burden, termed complete remission. The most common chemotherapeutic agents used in combination protocols are vincristine, doxorubicin, cyclophosphamide, L-asparaginase, and prednisone. Individual treatment protocols vary with respect to dosage, frequency, and duration of treatment; advantages and disadvantages of each treatment protocol can be found in medical oncology textbooks. With combination chemotherapy, the expected survival time for dogs with B-cell lymphoma is ~12 mo, whereas for dogs with T-cell lymphoma, expected survival times are often in the range of 6 mo. Although immunophenotype (B- versus T-cell) provides a general guideline for treatment prognosis, multiple factors (tumor and host) contribute to the overall response duration and survival time of dogs diagnosed with lymphoma. Dogs that do not respond to traditional combination chemotherapy or that relapse may achieve disease remission, added survival times, or both with the use of various rescue protocols (eg, lomustine, MOPP, ADIC, DMAC).

Although systemic chemotherapy remains the cornerstone to treat high-grade lymphoma, the idea that both induction and maintenance phases of chemotherapy are necessary to achieve durable remission times has changed. Shorter and more dose-intense chemotherapy protocols (eg, Madison Wisconsin protocol) without maintenance provide disease-free intervals and survival times equivalent to protocols that include chronic maintenance therapy. Additionally, the use of half body radiation in replacement of maintenance chemotherapy has been demonstrated to be safe and clinically efficacious, providing another option to achieve durable remission times without the need for chronic chemotherapy. For select cases, autologous canine bone marrow transplant after systemic chemotherapy and whole-body radiation can afford some dogs extended, progression-free intervals and survival times.

Despite the favorable outcomes expected in treating high-grade multicentric lymphoma, the successful management of other anatomic forms of lymphoma is often more difficult and less rewarding. Alimentary lymphoma, if focal, can be treated effectively with surgical resection and combination chemotherapy. However, with diffuse involvement of the intestinal tract, low constitutional reserve, severe malabsorption of nutrients, and loss of proteins often result in poor clinical responses and short survival times (ie, <3 mo). The use of combination chemotherapy with or without palliative radiation therapy can afford dogs with mediastinal lymphoma considerable improvement in survival times and quality-of-life scores. Lymphoma involving other extranodal sites (such as the skin) can be managed with either single-agent oral lomustine or combination systemic chemotherapies (eg, CHOP); however, the development of refractory and progressive disease is common and ultimately life limiting.

Clinical prognosis for dogs diagnosed with low-grade, indolent lymphoma tends to be good. The institution of low-intensity oral chemotherapy protocols (chlorambucil and prednisone) often provides prolonged survival times (>2 yr), and in specific dogs with localized and low-grade disease (eg, splenic involvement), splenectomy can be an effective and durable treatment option without the necessity of adjuvant chemotherapy administration. (See *also* TREATMENT OF CANINE LYMPHOMA, p 40.)

ERYTHROCYTOSIS AND POLYCYTHEMIA

Erythrocytosis is a relative or absolute increase in the number of circulating RBCs, resulting in a PCV increased above reference ranges. Polycythemia is frequently used synonymously with erythrocytosis; however, polycythemia may imply leukocytosis and thrombocytosis, as well as erythrocytosis.

Relative Erythrocytosis: Relative erythrocytosis is an increase in RBC numbers without an increase in total RBC mass. Usually, this is caused by loss of plasma volume with resultant hemoconcentration, as seen in severe dehydration attributable to vomiting and diarrhea. Alternatively, a mild, transient form of relative erythrocytosis unassociated with clinical signs may develop in dogs when fear or excitement causes splenic contraction with release of RBCs into the circulation.

Absolute Erythrocytosis: Absolute erythrocytosis, defined as increased RBC numbers because of increased RBC mass, develops from primary or secondary causes.

Primary erythrocytosis (polycythemia vera) is a myeloproliferative disease of unknown cause that has been reported in dogs, cats, cattle, and horses. RBC production is dramatically increased, while serum erythropoietin (EPO) activity typically is low or low-normal. **Secondary erythrocytosis**, in contrast, generally develops from excessive production of EPO. If EPO is secreted because of systemic hypoxia, then the resultant erythrocytosis is an appropriate compensatory response. This may be seen with severe pulmonary disease or heart anomalies resulting in right-to-left shunting with blood bypassing the lungs (eg, reversed patent ductus arteriosus, tetralogy of Fallot). If EPO production increases without systemic hypoxia, then the response is inappropriate. EPO-secreting tumors of the kidneys or other organs, or non-neoplastic renal disorders resulting in local hypoxia with EPO production, may cause inappropriate erythrocytosis. Another type of secondary erythrocytosis, called **endocrinopathy-associated erythrocytosis**, results from hormones other than EPO (eg, cortisol, androgen, thyroxine, growth hormone) that stimulate erythropoiesis. The mild erythrocytosis in dogs with adrenocortical

hyperactivity or in cats with hyperthyroidism or acromegaly is insufficient to cause clinical signs.

Clinical Findings: Clinical signs of absolute erythrocytosis include red mucous membranes, bleeding tendencies, polyuria, polydipsia, and neurologic disturbances (ataxia, weakness, seizures, blindness, behavioral change). On retinal examination, dilated, tortuous vessels may be visualized. These collective clinical features are attributed to hyperviscosity from the increased RBC mass.

Diagnosis: The dehydration and hemoconcentration of relative erythrocytosis may be identified by clinical findings (dry mucous membranes, loss of skin turgor), laboratory variables (hyperproteinemia, prerenal azotemia), and response to rehydration. Excitable dogs with mild erythrocytosis attributed to splenic contraction usually have normal PCV on subsequent blood samples collected less stressfully. Sighthounds (eg, Greyhounds) normally have mild erythrocytosis compared with standard canine reference ranges.

With absolute erythrocytosis, serum EPO determinations have been recommended to differentiate primary from secondary causes. Unfortunately, considerable overlap exists in EPO activity among normal animals, animals with primary erythrocytosis, and animals with secondary erythrocytosis. Furthermore, current availability of validated EPO assays for companion animals is limited. Routine examination of bone marrow is not useful to distinguish primary from secondary erythrocytosis because both conditions show erythroid hyperplasia. As a result, primary erythrocytosis usually is diagnosed by eliminating secondary causes.

To investigate types of secondary erythrocytosis, assessment of tissue oxygenation may be helpful. Arterial blood pO_2 <80 mmHg and pulse oximetry oxygen saturation <90%–95% are consistent with the hypoxemia and tissue hypoxia of appropriate secondary erythrocytosis. Examination of heart and lungs by auscultation, radiographs, electrocardiography, and echocardiography may reveal the underlying problem. Selective angiography or contrast echoangiography

may be needed to confirm right-to-left cardiac shunting. If systemic hypoxia is not present, then locating the potential source of inappropriate EPO production is facilitated by physical and neurologic examinations, abdominal ultrasonography, IV urography, and CT or MRI.

Treatment: For relative erythrocytosis due to dehydration, therapy consists of rehydration with IV fluids and treating the underlying cause.

For polycythemia vera, treatment initially consists of phlebotomy (5–20 mL/kg to reduce the PCV to ~50%–60%) with simultaneous fluid replacement. Periodic phlebotomy with or without administration of hydroxyurea (30 mg/kg/day, PO, for 7–10 days, then 15 mg/kg/day, PO, titrated) has

been advocated in affected dogs and cats. RBC, WBC, and platelet counts should be monitored during hydroxyurea treatment.

For inappropriate secondary erythrocytosis, EPO-secreting tumors should be managed with surgery, chemotherapy, or radiation therapy. Phlebotomy to normalize the PCV helps reduce hyperviscosity.

For appropriate secondary erythrocytosis, the underlying problem should be addressed. If corrective treatment of that disease process is not feasible, clinical signs associated with hyperviscosity may be alleviated by judicious phlebotomy (5–10 mL/kg) and hydroxyurea therapy. However, because this type of erythrocytosis is a compensatory response to hypoxia, the PCV should be maintained at values above normal reference ranges.

HEMOSTATIC DISORDERS

Effective hemostasis depends on an adequate number of functional platelets, an adequate concentration and activity of plasma coagulation and fibrinolytic proteins, and a normally responsive blood vasculature. The diagnosis, treatment, and monitoring of hypo- and hypercoagulable animals is difficult with regard to both progression of disease and monitoring blood component and/or anticoagulation therapy. Citrated plasma samples are often used in veterinary medicine to determine fibrinogen concentration, activated partial thromboplastin time (APTT), prothrombin time (PT), and D-dimer or fibrinogen degradation product (FDP) concentration. The introduction of the cell-based, tissue factor (TF)/Factor VII-dependent model of hemostasis has increased understanding of the complex biochemistry of physiologic hemostasis, leading to reevaluation of the traditional understanding of physiologic hemostasis divided into the intrinsic and extrinsic pathways of coagulation. Although citrated plasma contains many of the factors involved in coagulation, whole blood contains both the soluble factors and intravascular cells active in physiologic and pathologic hemostasis, incorporating TF and phospholipid-bearing cells, such as platelets and leukocytes.

Physiologic Understanding of Hemostasis

A cell based model of hemostasis has been introduced that explains physiologic hemostasis through a complex process in which the interaction of vascular tone, blood flow, endothelial cells, platelets, leukocytes, coagulation factors, and fibrinolytic factors and their cofactors and inhibitors result in balanced hemostasis and formation of a clot at the injured site. This dynamic model involves cellular regulation of coagulation in three phases: initiation, amplification, and propagation.

TF-bearing cells initiate hemostasis. TF is a transmembrane glycoprotein receptor found in extravascular tissues, including organ capsules and the adventitia of blood vessel walls. It is constitutively expressed on fibroblasts and, on cellular activation, on vascular smooth muscle cells, monocytes, and neutrophils. The TF-bearing cells and platelet surfaces act as the main cellular surfaces for assembly of the procoagulant complexes. Any vessel injury leads to TF exposure. Factor VII binding to TF results in activation to Factor VIIa. Factor VIIa bound to TF on the cell surface activates Factor IX to Factor IXa and Factor X to Factor Xa. Initially, the formed Factor Xa is limited to the TF-bearing cell, because Factor Xa that

diffuses away from the cell is rapidly inhibited by TF pathway inhibitor (TFPI) or antithrombin.

Together with formed Factor Va, Factor Xa is assembled into the prothrombinase complex on the surface of the TF-bearing cell. An initial small amount of thrombin close to the cell independent of the presence of platelets is generated and is responsible for activation of platelets, release of Factor V from the platelets, activation of Factor V, activation of Factor VIII and release of Factor VIII from von Willebrand factor, and activation of Factor XI. Platelets also are activated by other mechanisms, including vessel wall collagen and von Willebrand factor, leading to adhesion and aggregation at the injured site.

As an essential part of the platelet activation process, the procoagulant phospholipid phosphatidylserine becomes available. The initially generated Factor IXa binds to the activated platelet surfaces, promoting formation of the "tenase" complex; this results in major Factor Xa formation and amplification of the coagulation process. The formed Factor IXa diffuses to the platelets, because it is not inhibited by TFPI and is inhibited slowly by antithrombin. The formed Factor Xa complexes with Factor Va on the activated platelet surface, forming the "prothrombinase" complex that leads to cleavage of prothrombin and to the major subsequent burst of thrombin responsible for cleaving fibrinogen and forming the hemostatic plug. Additional Factor IXa is supplied by Factor XIa on the platelet surface. Factor XIa activates the antifibrinolytic pathway.

The second wave of thrombin activates plasmin, thereby initiating fibrinolysis. This keeps the clot controlled at the site of injury. To control fibrinolysis, the antifibrinolytic pathway is activated by thrombin activation of thrombin-activatable fibrinolysis inhibitor (TAFI). TAFI slows the fibrinolytic process by inhibiting plasmin activity; this prevents premature clot lysis and allows clot propagation. The balance of fibrin formation and fibrinolysis regulates the size and quality of the fibrin plug and localizes it to the site of injury. The quality of the clot has a significant impact on how effectively it provides hemostasis.

Clinical Approach to Hemostasis

Although the traditional division between primary and secondary hemostasis is not biologically accurate, it is still a useful diagnostic approach to hemostasis in animals with acquired or hereditary

hemostatic disorders. Primary hemostasis is accomplished by interaction of platelets with exposed subendothelial surfaces. Simultaneously, plasma coagulation proteins are activated in a sequential cascade that depends on the phospholipid provided by the activated platelets and calcium ions from plasma to form a stable clot (secondary hemostasis). Circumstances that activate platelets and the coagulation proteins also activate plasma fibrinolytic proteins, which ensure localization of the clot and its timely dissolution.

Hemostatic capabilities are traditionally assessed by tests of primary hemostasis (platelet count and buccal mucosal bleeding time) and secondary hemostasis through plasma-based assays designed to further localize defects, such as the APTT (intrinsic and common pathway) and PT (extrinsic and common pathway). The fibrinolytic system is traditionally evaluated with measurements of degradation products such as FDP and D-dimer, and endogenous anticoagulant ability has been evaluated through antithrombin, protein C, and protein S. Additional specialized individual coagulation factor tests can further localize congenital defects. Thus, plasma-based coagulation screening tests can help identify the defective or deficient coagulation protein. Although this traditional approach makes it possible to effectively and systematically localize the cause of bleeding, it may be difficult from a clinical perspective to evaluate general hemostatic capability and to predict or monitor the effect of anticoagulant or procoagulant treatment. This may partially be because plasma-based tests of the secondary and fibrinolytic systems target specific elements of the hemostatic system, thus potentially ignoring other factors that may contribute significantly to overall hemostatic capability in acquired disorders. Another plausible reason is the low sensitivity of APTT and PT; usually, activity of a coagulation protein must be <30% and sometimes <10% of normal before an abnormality is detected.

Tests for increased risk or tendency toward thrombosis are generally available only through some academic and research laboratories. Measurement of antithrombin activity is being offered by increasing numbers of laboratories. Tests for measurement of activities of plasminogen, protein C, α_2 -antiplasmin, tissue plasminogen activator, and plasminogen activator inhibitor have been established in some domestic animals.

Assessment of Hemostatic Function in Whole Blood

Because whole blood contains all the intravascular factors and cells involved in physiologic and pathologic hemostasis, incorporating TF and phospholipid-bearing cells, whole blood assays may provide a more accurate reflection of *in vivo* hemostasis than traditional plasma-based hemostasis assays. However, few whole blood assays to assess both primary and secondary hemostasis have been used in veterinary studies to date.

PFA-100: The platelet function analyzer, PFA-100, is a method for quantitative, simple, and rapid *in vitro* assessment of primary platelet-related hemostasis at high shear stress. The test requires a small volume (0.8 mL) of citrated whole blood, which is drawn under vacuum through a 200- μ m diameter stainless steel capillary and a 150- μ m diameter aperture in a nitrocellulose membrane coated with collagen and epinephrine (CEPI) or collagen and ADP (CADP). In response to the high shear rates and the agonists, a platelet aggregate forms that blocks blood flow through the aperture; the time taken to occlude the aperture is reported as the closure time. Prolonged closure times with only the CEPI cartridge are seen with mild inherited platelet function disorders (eg, storage pool disorders) and with aspirin ingestion, while prolonged closure times with both CEPI and CADP cartridges are seen with more severe inherited platelet dysfunctions and with von Willebrand disease. The PFA 100 also has the ability to monitor response to treatment with both desmopressin acetate and glycoprotein IIb/IIIa antagonists. The quality of blood bank platelet concentrates for transfusion can be evaluated, as well as response to platelet transfusion. The PFA 100 is a good screening method to detect platelet function defects. It also has been evaluated in many other studies for its use in assessing drug effects or for evaluation of overall primary hemostasis in various clinical disorders or during surgical procedures.

Thromboelastography (TEG): TEG allows for rapid assessment of hemostatic function in whole blood. It evaluates all of the steps in hemostasis, including initiation, amplification, and propagation, as well as fibrinolysis, including the interaction of platelets and leukocytes with the proteins of the coagulation cascade. Thus, TEG combines evaluation of the traditional

plasma components of coagulation with the cellular components. TEG is performed on unstabilized fresh whole blood within 4–6 min of taking the blood sample. This is generally not practical in a routine clinical setting, and using citrated stabilized whole blood (with recalcification immediately before analysis) has been proposed to increase the time span from sampling to analysis. A TF-activated TEG assay on citrated whole blood has been validated in dogs and shown to have a low analytical variation and good correlation to clinical signs of bleeding compared with many traditional plasma-based coagulation assays.

TEG is the first modality available to clinicians that can evaluate hypercoagulability. It is especially useful in dogs with disseminated intravascular coagulation, neoplasia, sepsis, and parvoviral infection, and to evaluate platelet dysfunction in dogs with hypothermia. TEG analysis is a valuable aid in the diagnostic evaluation of animals with abnormal hemostasis and a supplement to traditional coagulation tests such as PT, APTT, D-dimer, and fibrinogen assays.

COAGULATION DISORDERS

Bleeding diatheses may be caused by congenital or acquired defects in the vasculature, platelets, or the coagulation proteins. Congenital or acquired defects or deficiencies of platelets usually manifest as superficial petechial and ecchymotic hemorrhages (especially of mucous membranes), epistaxis, melena, or prolonged bleeding at injection and incision sites, whereas congenital or acquired deficiencies in coagulation proteins usually manifest clinically as delayed deep tissue hemorrhage, hematoma formation, and bleeding into joints and body cavities.

Pathologic thrombosis may occur because of primary or inherited disorders of anticoagulant protein factors or because of secondary or acquired disorders. Collectively, these conditions are called hypercoagulable states. Systemic syndromes, such as disseminated intravascular coagulation, that enhance platelet responsiveness to agonists and alter the balance between anticoagulant and procoagulant protein factors or that increase the reactivity of endothelium are more common in animals than inherited disorders.

PLATELET DISORDERS

Disorders of platelets can be divided into acquired or congenital thrombocytopenias and acquired or congenital functional

disorders (thrombocytopathias), with acquired thrombocytopenia being the most common.

Congenital Thrombocytopenia

Hereditary Macrothrombocytopenia in Cavalier King Charles Spaniels:

This benign, inherited giant platelet disorder affects ~50% of dogs in the breed. It is characterized by thrombocytopenia with macrothrombocytes in 30% of cases and variable platelet aggregation in response to adenosine diphosphate, depending on the platelet count. No correlation has been found between macrothrombocytopenia and age, gender, neuter status, coat color, weight, or heart murmur status. The disorder is detected by a routine CBC. Affected dogs have normal coagulation protein activity.

Cyclic Hematopoiesis in Gray Collie Dogs:

This autosomal recessive disorder is characterized by 12-day cycles of cytopenia. All marrow stem cells are affected, but neutrophils are most affected because of their short half-life (usually <24 hr). Mild to severe thrombocytopenia can be seen, and excessive bleeding is a potential complication. The disorder is fatal; affected dogs usually die from fulminating infections before 6 mo of age. Even dogs that receive intensive antibiotic therapy usually die by 3 yr of age with amyloidosis (*see p 592*) secondary to chronic antigenic stimulation from recurrent infections. Treatment with recombinant granulocyte colony-stimulating factor has been temporarily successful in alleviating the neutropenic cycles until antibodies are produced against the noncanine proteins.

Fetal and Neonatal Alloimmune

Thrombocytopenia: This disorder occurs when maternal antibodies are produced against a paternal antigen on fetal platelets. It has been reported in a 1-day-old Quarter horse foal. Immunoglobulins bound to the foal's platelets were identified in the mare's plasma, serum, and milk by indirect assays. The immunoglobulins were further shown to recognize platelets from the foal's full brother, born 1 year earlier. This diagnosis should be considered for foals with severe thrombocytopenia when other causes can be excluded.

A group of lambs artificially reared and fed bovine colostrum had prolonged bleeding from puncture wounds from ear tag placement, subcutaneous bruising, weakness, and pale mucous membranes.

All affected lambs died within 48 hr of birth. Thrombocytopenia was seen in whole blood, and platelets were markedly decreased on blood smears. The presence of antibodies directed against platelets was suspected because the cows from which colostrum was obtained had been used in a previous experiment in which they had been immunized against sheep blood.

Acquired Thrombocytopenia

Acquired thrombocytopenias are reported frequently in dogs and cats, less often in horses, and rarely in other species. Numerous causes have been identified, most involving immunologic or direct destruction of platelets.

Primary Immune-mediated Thrombocytopenia:

This condition (also called idiopathic thrombocytopenia or idiopathic thrombocytopenic purpura) is characterized by immune-mediated destruction of either circulating platelets or, less commonly, marrow megakaryocytes. It has been seen in dogs, horses, and rarely cats. Clinical signs include petechiae of the gingivae or skin and ecchymosis, melena, or epistaxis. Platelet concentration is usually <50,000/ μ L and often <10,000/ μ L at the time of diagnosis. Evaluation of megakaryocytes (by bone marrow aspiration) helps determine whether circulating platelets or marrow megakaryocytes are targeted by antibody. A test for platelet factor 3 released from damaged platelets has been unreliable or not readily available commercially. A megakaryocyte immunofluorescence assay that detects antibodies on megakaryocytes has been done, but an adequate bone marrow aspiration sample must be obtained. A direct test for the presence of antiplatelet antibodies—an ELISA that detects platelet bound antibodies—has been reported to have good sensitivity (94%) but is not highly specific for primary immune-mediated thrombocytopenia. A negative test result likely excludes primary immune-mediated thrombocytopenia as the cause of thrombocytopenia; however, a positive test result could indicate either primary immune-mediated thrombocytopenia or secondary immune-mediated thrombocytopenia (eg, thrombocytopenia associated with autoimmune hemolytic anemia, lymphoproliferative diseases, systemic lupus erythematosus).

Affected animals should be kept at rest, and treatment is based on administration of corticosteroids, starting at a high dose and

then tapering (as in the treatment of IMMUNE-MEDIATED HEMOLYTIC ANEMIA, p 10). Transfusion with fresh whole blood should be performed in animals with a PCV <15%; however, whole blood transfusion to replenish platelets is often futile with regard to normalization of primary hemostasis, because the platelets are removed from circulation within a couple of hours. Splenectomy should be reserved as a treatment for animals that have recurrent episodes of thrombocytopenia. Vincristine has been used to enhance the release of platelets from marrow megakaryocytes. It also coats platelets and has a cytotoxic effect on macrophages that ingest coated platelets. A single dose of vincristine at the time corticosteroids are started shortens the time to recovery of the platelet count.

Rickettsial Diseases: *Anaplasma platys*, *A. phagocytophilum*, or *Ehrlichia canis* infections cause mild to severe thrombocytopenia in dogs. *A. platys* infection (see p 803) usually is characterized by mild, often cyclic thrombocytopenia in the acute stages of disease. Chronic infections often have constant mild to moderate thrombocytopenia. Morula (single to multiple, round to oval basophilic inclusions) can sometimes be identified in platelets of infected dogs. The thrombocytopenia is seldom severe enough to result in clinical bleeding tendencies. Ticks are the likely vectors. *E. canis* infections are characterized by variable alterations in total WBC count, PCV, and platelet count. In acute infections, there is usually thrombocytopenia and possibly anemia or leukopenia. In chronic infections, there may or may not be thrombocytopenia or anemia; however, there is often leukocytosis and sometimes hyperglobulinemia (monoclonal or polyclonal). Infected dogs may have epistaxis, melena, gingival bleeding, retinal hemorrhage, hematoma formation, and prolonged bleeding after venipuncture or surgery.

A. phagocytophilum infection has been documented in a wide variety of domestic and wild animals. It is characterized by fever, lethargy, and a reluctance to move. Changes in blood parameters include thrombocytopenia and lymphopenia accompanied by increased serum alkaline phosphatase and hypoalbuminemia.

Neoplasia: Hemangiosarcoma, lymphoma, and adenocarcinoma may be associated with consumptive thrombocytopenia due to disseminated intravascular coagulation. Immunologic and inflamma-

tory mechanisms cause increased platelet consumption and decreased platelet survival. However, bleeding tendencies without thrombocytopenia occasionally exist. Altered platelet function due to an acquired membrane defect has been associated with hyperglobulinemia. Vasculitis also may contribute to the hemostatic disorder.

Vaccine-induced Thrombocytopenia:

Dogs vaccinated repeatedly with modified-live adenovirus and paramyxovirus vaccines may develop thrombocytopenia 3–10 days after repeat vaccination. The thrombocytopenia is usually transient and may be sufficiently mild that a bleeding tendency will not be evident unless superimposed on another platelet or coagulation disorder. Studies have failed to confirm an association between recent vaccination and development of idiopathic thrombocytopenic purpura; however, it might still occur rarely.

Drug-induced Thrombocytopenia:

Thrombocytopenia associated with administration of certain drugs has been reported in dogs, cats, and horses. One mechanism is marrow suppression of megakaryocytes or generalized marrow stem cell suppression (after administration of estrogen, chloramphenicol, phenylbutazone, diphenylhydantoin, and sulfonamides). Another mechanism is increased platelet destruction and consumption (after administration of sulfoxazole, aspirin, diphenylhydantoin, acetaminophen, ristocetin, levamisole, methicillin, and penicillin). Drug reactions are idiosyncratic and therefore unpredictable. Platelets usually return to normal shortly after the drug is discontinued. Drug-induced bone marrow suppression may be prolonged. The chemotherapy drug lomustine has sometimes caused prolonged thrombocytopenia that persists after the drug is stopped.

Other: Quantitative platelet disorders have been reported in liver disease with or without coagulation protein deficiencies. In two studies of cats with thrombocytopenia, 29%–50% had infectious diseases, including feline leukemia, feline infectious peritonitis, panleukopenia, or toxoplasmosis. The mechanism of thrombocytopenia has not been identified in many cases. Feline leukemia virus replicates and accumulates in megakaryocytes and platelets; aplasia or hypoplasia of marrow stem cells, immune destruction of infected platelets, or

extravascular sequestration of platelets within lymphoid tissues may contribute to thrombocytopenia in this disease.

Congenital Platelet Function Disorders

Congenital disorders of platelet function affect platelet adhesion, aggregation, or secretion. They can be either intrinsic or extrinsic to platelets. Testing of intrinsic platelet function requires careful handling of samples and specialized equipment that is not routinely available in diagnostic laboratories; therefore, the incidence of intrinsic functional defects in platelets is not known accurately. However, if a bleeding disorder (especially mucosal bleeding or superficial petechiation) exists in an animal that has not received any medication and that has normal coagulation screening test results, platelet concentration, and von Willebrand factor concentration, then an intrinsic platelet defect should be suspected.

There is no specific treatment for any of the intrinsic platelet function disorders. In instances of severe hemorrhaging, fresh, platelet-rich plasma can be administered. Whole blood may be administered if the affected animal is anemic.

Von Willebrand Disease: This disorder, caused by a defective or deficient von Willebrand factor (vWF, also called Factor VIII-related antigen), is the most common inherited bleeding disorder in dogs (reported in nearly all breeds and in mixed breeds). It has also been reported in cats, rabbits, cattle, horses, and pigs. It is relatively frequent (10%–70% prevalence) in several breeds of dogs: Doberman Pinschers, German Shepherds, Golden Retrievers, Miniature Schnauzers, Pembroke Welsh Corgis, Shetland Sheepdogs, Basset Hounds, Scottish Terriers, Standard Poodles, and Standard Manchester Terriers. Canine von Willebrand disease is classified into three subtypes based on clinical severity, plasma vWF concentration, and vWF multimer composition. Type 1 is the most common form and is characterized by mild to moderate clinical signs, low vWF concentration, and a normal multimer distribution. Type 2 is characterized by moderate to severe clinical signs, low vWF concentration, and a loss of high-molecular-weight multimers. Type 3, seen most often in Shetland Sheepdogs and Scottish Terriers, is a severe disorder characterized by total absence of vWF. Two modes of inheritance are known. In the less common autosomal recessive

pattern of inheritance, homozygosity is usually fatal, and heterozygosity results in asymptomatic carriers. In the more common inheritance pattern of autosomal dominant with incomplete penetrance, homozygotes and heterozygotes can have variable bleeding tendencies. Affected animals may have gingival bleeding, epistaxis, and hematuria. Some puppies may bleed excessively only after injection, venipuncture, or surgery, such as tail docking, ear cropping, and dewclaw removal.

vWF circulates as a complex with coagulation Factor VIII (also called Factor VIII-coagulant) and mediates platelet adhesion to subendothelial surfaces—the first step in clot formation. Defective or deficient vWF mimics disorders caused by thrombocytopenia or intrinsic platelet defects. Von Willebrand disease should be suspected in animals with clinical signs of a bleeding disorder that have normal results on coagulation screening tests (APTT and PT) and adequate platelet concentrations, long buccal mucosa bleeding time, and prolonged platelet function analysis closure times. Quantitative tests of vWF are diagnostic. Diagnosis is confirmed by identifying low vWF concentration in plasma or via DNA screening. Occasionally, affected animals may have decreased Factor VIII-coagulant and therefore have prolonged APTT and activated clotting time (ACT). Drugs known to interfere with normal platelet function should be avoided in animals with suspected disease. Transfusion of cryoprecipitate, fresh plasma, or fresh whole blood effectively alleviates a bleeding episode. Type 1 von Willebrand disease may respond to treatment with desmopressin acetate, which causes Weibel-Palade release (high-molecular weight multimers) from the endothelium through an unknown method of action. Desmopressin may also be used in these dogs before surgery to minimize bleeding complications.

Concomitant hemostatic abnormalities may exacerbate von Willebrand disease. Hypothyroidism (*see* p 553) previously had been thought to be associated with von Willebrand disease; both conditions are prevalent in many of the same breeds of dogs, eg, Doberman Pinschers and Golden Retrievers. In one study, administration of thyroid supplementation to hypothyroid dogs without deficiency of vWF did not increase vWF activity; in fact, in most of the tested dogs, vWF activity actually decreased. Therefore, administration of levothyroxine as a treatment of von

Willebrand disease cannot be recommended and may even exacerbate the disease.

Chédiak-Higashi Syndrome: This autosomal recessive disorder is characterized by abnormal granule formation in leukocytes, melanocytes, and platelets (*see* p 59). The defect appears to be in microtubule formation; therefore, granules, which are abnormally large but reduced in number, are evident in numerous types of cells. Diluted coat color results from the defect in the melanocytes. Leukocytes may have decreased functional ability to phagocytize and kill organisms (an inconsistent finding in animals), and platelets have decreased aggregation and release reactions. Platelets are almost devoid of dense granules and have markedly decreased storage quantities of adenosine diphosphate and serotonin. Prolonged bleeding in affected blue smoke Persian cats occurs after venipuncture or surgery. The syndrome has been diagnosed in mink, cattle, and beige mice with similar bleeding tendencies.

Canine Thrombopathia: This disorder has been described in Basset Hounds. Affected dogs have epistaxis, petechiation, and gingival bleeding. Results of studies suggest that inheritance is autosomal with variable penetrance. Platelets have abnormal fibrinogen receptor exposure and impaired dense granule release. Basset Hounds with mucosal bleeding and petechiation and normal concentrations of platelets and vWF should be suspected of having thrombopathia. Specific diagnosis of this disorder requires specialized platelet function testing. Results of the clot retraction test are usually normal.

Bovine Thrombopathia: This autosomally inherited platelet function defect is seen in Simmental cattle. Bleeding can be mild to severe in affected cattle and is exacerbated by trauma or surgery. Platelets have impaired aggregation responses. Bovine viral diarrhea virus (*see* p 1436) may cause thrombocytopenia in cattle.

Glanzmann Thrombasthenia: This autosomally transmitted disorder, previously thrombasthenic thrombopathia, has been diagnosed in Otterhounds and Great Pyrenees dogs, and in Thoroughbred-cross, Quarter horse, and Oldenburg filly horses. Affected animals have prolonged bleeding times and form hematomas at sites of venipuncture or injury. Numerous

(30%–80% of all platelets), bizarre, giant platelets are seen on blood smears. Due to a decreased synthesis of either glycoprotein IIb or IIIa, the membrane receptor glycoprotein IIb-IIIa is reduced or lacking on the surface of platelets. All affected animals to date have had a defect in IIb synthesis.

Blood from affected animals does not have normal clot retraction, and the platelets do not aggregate normally after stimulation with adenosine diphosphate, collagen, or thrombin.

Acquired Platelet Function Disorders

Dogs with immune-mediated thrombocytopenia also may have an acquired platelet functional defect. Dogs can have excessive bleeding tendencies without severely decreased platelet concentrations. In dogs with immune-mediated thrombocytopenia, abnormal platelet function in addition to decreased platelet concentration may contribute to their bleeding tendency.

Several diseases have been associated with acquired platelet function disorders. Hyperglobulinemia associated with multiple myeloma induces a platelet membrane defect resulting in impaired hemostatic function. In uremia associated with any form of renal disease, platelet adhesion and aggregation are decreased.

Numerous drugs can impair platelet function. Drugs reported to block platelet receptor binding or to change platelet membrane charge or permeability include furosemide, penicillin, carbenicillin, lidocaine, phentolamine, and chlorpromazine. Drugs that inhibit transduction of messages received at the platelet surface include caffeine, theophylline, dipyridamole, and papavarine. Drugs that inhibit execution of platelet responses (aggregation, secretion, or thromboxane production) include aspirin, indomethacin, acetaminophen, phenylbutazone, ticlopidine, pentobarbital, and sulfapyrazone. Clinical bleeding problems may not be caused by drug-induced impairment of platelet function unless another disorder associated with a hemostatic defect is also present.

VASCULAR DISORDERS

Congenital Vascular Disorders

Cutaneous asthenia (Ehlers-Danlos syndrome, rubber puppy disease) is caused by a defect in the maturation of type I

collagen. This causes weak structural support of blood vessels and can result in hematoma formation and easy bruising. The disorder has been reported in dogs, cats, mink, horses, cattle, sheep, and people but is rare in domestic animals. The most striking clinical abnormality is loose, hyperextensible skin that tears easily. No treatment is available.

Acquired Vascular Disorders

Several diseases cause severe, often generalized vasculitis and are characterized by bleeding disorders.

Rocky Mountain spotted fever (see p 806) is caused by *Rickettsia rickettsii*, which is transmitted by the ticks *Dermacentor variabilis* and *D. andersoni*. The rickettsial organisms invade endothelial cells and cause cellular death with resultant perivascular edema and hemorrhage. Variable degrees of coagulation cascade activation can occur along with thrombocytopenia. Infected dogs may have epistaxis, petechial and ecchymotic hemorrhages, hematuria, melena, or retinal hemorrhages. In severely affected dogs, disseminated intravascular coagulation may occur.

Canine herpesvirus generally affects puppies 7–21 days old. Generalized necrotizing vasculitis is accompanied by perivascular hemorrhage. The disease is usually rapidly fatal, and most puppies die within 24 hr after showing signs.

COAGULATION PROTEIN DISORDERS

Congenital Coagulation Protein Disorders

In a severe deficiency or functional defect of coagulation proteins, clinical signs appear at an early age. Marked reductions in activity of coagulation proteins essential to hemostasis are usually fatal. Animals may be stillborn if there is <1% of normal activity or die shortly after birth owing to massive hemorrhage. Insufficient production of coagulation proteins or limited access to vitamin K by the immature neonatal liver may exacerbate a coagulation defect. If activity of any particular coagulation protein is 5%–10% of normal, the neonate may survive, but signs usually appear before 6 mo of age. It is during this time, when numerous routine procedures (eg, vaccination, declawing, tail docking, dewclaw removal, ear cropping, and castration or ovariohysterectomy) are

usually done, that a bleeding tendency may become apparent.

Most of the congenital coagulation protein disorders reported in domestic animals are deficiencies or abnormalities of a single factor.

Congenital afibrinogenemia (Factor I deficiency) has been reported in a family of Saanen dairy goats but not in dogs or cats. **Hypofibrinogenemia**, accompanied by severe bleeding, has been reported in Saint Bernards and Vizslas and in one mixed-breed dog; the ACT, APTT, PT, and thrombin time (TT) were prolonged. **Dysfibrinogenemia** has been reported in an inbred family of Russian Wolfhounds (Borzois). The ACT, APTT, PT, and TT were prolonged, but fibrinogen was present by quantitative testing. Affected dogs had mild bleeding episodes with epistaxis and lameness, but trauma or surgery resulted in life-threatening bleeding. IV administration of fresh frozen plasma or cryoprecipitate is the best treatment to stop the bleeding.

Factor II (prothrombin) disorders are rare. Boxer dogs have been reported to have abnormally functioning prothrombin but normal concentrations; the defect was inherited as an autosomal recessive trait. A disorder of Factor II has been reported in English Cocker Spaniels; clinical signs in affected puppies (epistaxis and gingival bleeding) decrease with age, and adults bruise easily or have dermatitis. In affected puppies, TT is normal, while ACT, APTT, and PT are prolonged. Treatment is by transfusion of fresh-frozen plasma or fresh whole blood if RBCs are needed.

Factor VII deficiency has been reported in Beagles, English Bulldogs, Alaskan Malamutes, Alaskan Klee Kai, Miniature Schnauzers, Boxers, and mixed-breed dogs. It is inherited in an autosomal pattern with incomplete dominance. Usually, it is not associated with spontaneous clinical bleeding, but affected dogs may have bruising or prolonged bleeding after surgery. Prolonged postpartum hemorrhaging has been reported. Factor VII deficiency is most often diagnosed coincidentally when coagulation screening tests are performed; the PT is prolonged, while APTT and other test results are normal.

Factor VIII deficiency (hemophilia A) is the most common inherited bleeding disorder in dogs and cats; it has also been reported in several breeds of horses, including Arabians, Standardbreds, Quarter horses, and Thoroughbreds. There is an X linked pattern of inheritance, so usually females are asymptomatic carriers and males are affected. Rarely, in highly inbred

families, a carrier female mated with an affected male can produce affected female offspring.

In affected puppies, prolonged bleeding is seen from the umbilical vessels after birth; from the gingiva during tooth eruption; and after surgery such as tail docking, dewclaw removal, or ear cropping. Hemarthrosis accompanied by intermittent lameness, spontaneous hematoma formation, and hemorrhagic body cavity effusions also are common clinical findings in dogs with <5% of normal Factor VIII activity. Animals with 5%–10% of normal activity often do not bleed spontaneously but exhibit prolonged bleeding after trauma or surgery. Affected cats and sometimes small dogs may show prolonged bleeding after surgery or trauma but rarely bleed spontaneously, probably because of their agility and light weight. Affected animals usually have very low concentrations of Factor VIII (<10%) and prolonged ACT and APTT. Von Willebrand factor (Factor VIII-related antigen) concentrations are normal or greater than normal. Carrier animals have intermediate concentrations of Factor VIII (40%–60%), and results of coagulation screening tests are usually normal. Care should be taken in diagnosis if animals are <6 mo old because of possible low production of coagulation factors by an immature liver. Usually, results of coagulation screening tests are normal in carrier animals.

Treatment of bleeding diatheses requires repeated transfusions of cryoprecipitate or fresh-frozen plasma (10 mL/kg) 2–3 times/day until bleeding has been controlled. Fresh-frozen plasma or cryoprecipitate is preferable to whole blood because of the possible sensitization of the animal to RBC antigens with repeated transfusions.

Factor IX deficiency (hemophilia B) is diagnosed less often than Factor VIII deficiency. It has been reported in several breeds of purebred dogs, a mixed-breed dog, Himalayan cats, a family of Siamese-cross cats, and a family of British Short-haired cats. The defect is X-linked with carrier females and affected males, although affected females can be seen in closely inbred families. Clinical presentation is similar to that of animals with Factor VIII deficiency. Animals with extremely low Factor IX activity (<1%) usually die at birth or shortly thereafter. Animals with 5%–10% of normal Factor IX activity may spontaneously form hematomas, hemarthroses, hemorrhagic body cavity effusions, or organ hemorrhage. Gingival bleeding during tooth eruption or

prolonged bleeding after tail docking or dewclaw removal can occur. Some animals are asymptomatic until trauma or surgery. The ACT and APTT are prolonged. Carrier animals with 40%–60% of normal Factor IX activity are usually asymptomatic, and results of coagulation screening tests are normal. Treatment requires transfusion with fresh-frozen plasma (10 mL/kg), bid, until bleeding resolves. Often, internal hemorrhage into the abdomen, thorax, CNS, or between muscle fascial planes occurs and may be undetected until a crisis.

Factor X deficiency has been reported in a single family of American Cocker Spaniels and a mixed-breed dog. In the former, the inheritance pattern was autosomal dominant with variable penetrance. Homozygotes usually die early in life or are stillborn because of massive internal hemorrhage. Heterozygotes have mild to severe bleeding problems. The ACT, APTT, and PT are usually prolonged when animals have <30% normal activity of Factor X. Transfusions with fresh or fresh-frozen plasma are required to control hemorrhage.

Factor XI deficiency has been recognized in Kerry Blue Terriers, a female English Springer Spaniel, a Great Pyrenees dog, Weimaraners, and Holstein cattle. Mild deficiencies usually go undetected. In severe deficiencies with Factor XI at 30%–40% or less of normal activity, mild prolonged bleeding may occur after trauma or surgery. Bleeding tendencies usually are not immediate but delayed for 3–4 days. The ACT and APTT are usually prolonged. Transfusion with fresh-frozen plasma (10 mL/kg) is sufficient to stop the bleeding for up to 3 days. Inheritance is autosomal, but it has not been determined whether the gene is dominant or recessive. A single case involving an adult cat with epistaxis and diagnosed with systemic lupus erythematosus was attributed to the presence of a circulating inhibitor against Factor XI.

Factor XII (Hageman) deficiency has been reported in German Shorthaired Pointers, Standard Poodles, a family of Miniature Poodles, and in cats. Affected animals do not have clinical bleeding problems. The deficiency is usually diagnosed coincidentally when coagulation screening tests are performed and the APTT is prolonged. People with Factor XII deficiency do not have bleeding problems but are predisposed to thrombosis or infections, which is attributed to the normal role of Factor XII in fibrinolysis and

complement activation. Tendencies for thrombosis or infection have not been reported in animals. Factor XII deficiency has been found to coexist with von Willebrand disease in a dog and with Factor IX deficiency in a cat, but bleeding tendencies were not exacerbated. Factor XII is not present in the plasma of birds, marine mammals, and reptiles, with no untoward effects.

Deficiency of Factors II, VII, IX, and X has been described in Devon Rex cats that experienced bleeding, most commonly after surgery. The bleeding can be controlled by vitamin K administration, and some of these cats appear to overcome the bleeding tendency as adults.

Prekallikrein deficiency has been reported in Poodles, a family of miniature horses, and a family of Belgian horses. Clinical bleeding problems are not usually apparent. One horse bled excessively after castration. The diagnosis is usually made coincidentally when coagulation screening tests are performed. The ACT and APTT are usually prolonged.

Poor clot strength in Greyhounds has been found to cause delayed postoperative bleeding. An abnormal maximum amplitude is observed on TEG in these dogs. Epsilon aminocaproic acid is effective to prevent or stop bleeding in affected dogs.

Acquired Coagulation Protein Disorders

Liver Disease: Most coagulation proteins are produced primarily in the liver. Therefore, liver disease characterized by necrosis, inflammation, neoplasia, or cirrhosis often is associated with decreased production of coagulation proteins, anticoagulants, and fibrinolytic proteins. Because the various coagulation proteins have a relatively short half-life (4 hr to 2 days), mild to marked deficiencies can result in secondary to severe hepatopathies. The APTT and/or PT are prolonged in 50%–85% of dogs with severe liver disease, meaning that the factor activity is <30% of normal. Nevertheless, <2% actually develop hemorrhage and, when bleeding does occur, it is usually associated with concurrent disease. Coagulation tests are often performed before liver biopsy.

Severe hepatic diseases can also lead to disseminated intravascular coagulation. Fibrinogen, an acute phase reactant, and von Willebrand factor, which is produced extrahepatically, can be increased in liver disease.

Vitamin K Deficiency: Vitamin K is solubilized in mixed micelles before passive diffusion across the brush border. Fat malabsorption associated with inadequate amounts of bile salts (eg, biliary obstruction), lymphangiectasia, or severe villous atrophy may result in vitamin deficiency and coagulopathy owing to the lack of production of the functional vitamin K–dependent Factors II, VII, IX, and X.

Ingestion of Anticoagulant Rodenticides: Ingestion of certain rodenticides by dogs and cats causes a coagulopathy owing to the lack of production of functional vitamin K–dependent factors (see p 3165). Inactive precursor coagulation Factors II, VII, IX, and X are still produced by the liver, but γ -carboxylation of the inactive precursors does not occur, because the rodenticide inhibits the epoxide-reductase enzyme required for recycling of active vitamin K. There are two general classes of anticoagulant rodenticides: the coumarin compounds (warfarin, coumatufuryl, brodifacoum, and bromadiolone) and the indanedione compounds (diphacinone, pindone, valone, and chlorophacinone). The anticoagulant rodenticides are further divided into first- and second-generation based on their toxicity and half-life. In general, the half-life of the coumarins (up to 55 hr) is much shorter than that of the indanedione compounds (15–20 days). Various concurrently administered drugs and coexisting disease may exacerbate the toxicity of the ingested anticoagulant.

Affected animals may have hematoma formation (especially over pressure points) and bruising of superficial and deep tissues. Often, the animals do not bleed within the first 24 hr after ingestion of the toxin. The APTT, PT, and ACT are usually prolonged. Factor VII has the shortest half-life of the vitamin K–dependent coagulation proteins; therefore, the PT is often abnormal before other tests and can be used to monitor response to treatment. With acute ingestion, emetics, absorbents, and cathartics are used to minimize absorption. Vitamin K therapy is often initiated even in asymptomatic animals. Vitamin K₁, 2.5–5 mg/kg, SC, divided between several injection sites, is recommended for initial treatment of coumarin toxicity, followed by 1.25–2.5 mg/kg, PO, bid for 4–6 days if the ingestion is thought to be minimal. PT should be measured 48 hr after termination of treatment, and if prolonged, treatment should be continued for another 14 days. If the initial PT is normal, another PT should

be performed in 48 hr. If that test is normal, treatment can be discontinued. Dosages of vitamin K₁ as high as 5 mg/kg, PO, for 3–6 wk may be required for treatment of indanedione toxicity; however, these high dosages should be administered cautiously, because Heinz body anemia has been reported in dogs given 4 mg/kg for 5 days. IV administration of vitamin K₁ is not recommended, because anaphylactic reactions can result. Administration of vitamin K₃ is not useful.

Disseminated Intravascular Coagulation (DIC): DIC is not a primary disease but occurs secondary to numerous underlying diseases, such as bacterial, viral, rickettsial, protozoal, or parasitic diseases; heat stroke; burns; neoplasia; or severe trauma. The underlying disease causes an uncontrolled systemic inflammatory response characterized by massive activation and consumption of coagulation proteins, endogenous inhibitors, fibrinolytic proteins, and platelets.

In the initial stage of DIC, the animal is hypercoagulable because of circulating inflammatory mediators that cause activation of hemostasis through increased exposure of TF and inhibitor consumption. With time, consumption of coagulation factors, if not compensated by increased production, may lead to a hypocoagulable state with overt clinical symptoms. Because of the progressive nature of DIC, the clinical findings vary considerably and range from no overt signs of disease, accompanied by no or perhaps only subtle changes in traditional hemostasis parameters (APTT, PT, D-dimer, fibrinogen, and platelet count), to clinical signs of organ failure, associated with microvascular thrombosis in vital organs, finally culminating in overt bleeding symptoms. The latter presentation is traditionally thought of as the characteristic DIC patient, in which there are also pronounced alterations in hemostasis parameters and a drop in the platelet count.

Thromboelastography can differentiate the stage of DIC in dogs. Dogs diagnosed in the hypercoagulable stage have a much better chance of survival than dogs diagnosed in the hypocoagulable stage. This is likely because of early and aggressive intervention through supportive and/or antithrombotic therapy while the underlying disease is treated. Aggressive treatment likely minimizes thromboembolic complications and delays or even prevents progression to overt signs.

In veterinary medicine, the laboratory diagnosis of DIC is not standardized and the hemostatic function tests used are not consistent, but DIC is often diagnosed based on three or more abnormal hemostatic parameters such as APTT, PT, fibrinogen, D-dimer, platelet count, and RBC morphology, along with predisposing disease, which is a sensitive but unspecific approach. Postmortem fibrinolysis makes necropsy an insensitive diagnostic criterion.

Therapy is often empirically directed at correcting the imbalance in the hemostatic system while treating the underlying disease aggressively. Administration of balanced electrolyte solutions and plasma expanders to maintain effective circulating volume is imperative. The response to treatment with fresh-frozen plasma and heparin is unpredictable, and their use is controversial.

PATHOLOGIC THROMBOSIS

Primary or Inherited Anticoagulant Disorders

Congenital deficiency of any anticoagulant protein has not been recognized in domestic animals. If such a condition exists in animals, it is probably incompatible with life.

Secondary or Acquired Procoagulant Disorders

The presence of hypercoagulability is difficult to assess antemortem in dogs, and the importance of hypercoagulability and thromboembolic disease has not been well defined in veterinary medicine. Thromboelastography (TEG, *see* p 46) enables global assessment of hemostatic function in whole blood; advantages of TEG include the evaluation of the viscoelastic properties of the developing blood clot (including clot formation, kinetics, strength, stability, and resolution) and immediate detection of hyper- and hypocoagulable states.

Certain diseases in animals have been associated with increased risk of thrombosis. Cats with cardiomyopathy, more commonly the dilated form but also the hypertrophic and restrictive forms, can develop large thromboemboli in the aorta or brachial artery. Thrombosis has been seen in dogs with protein-losing nephropathies, hyperadrenocorticism, neoplasia, chronic hypothyroidism accompanied by atherosclerosis, and instances of autoimmune hemolytic anemia. Thrombi and thromboemboli have been seen in horses with systemic inflammatory diseases (such as

colic, laminitis, or equine ehrlichial colitis) and in instances of prolonged jugular catheter placement and infusion of drugs that irritate the vasculature.

Neoplasia is a risk factor for hypercoagulability and likely associated complications, such as thromboembolic disease. Many of the cells and proteins involved in maintaining hemostasis are also involved in the processes of cancer growth, invasion, metastasis, and angiogenesis. Deep venous thrombosis is a significant clinical complication in human cancer patients, but whether this is true in dogs with cancer is unknown.

In protein-losing nephropathies (eg, glomerulopathies, nephrotic syndrome, renal amyloidosis), a deficiency of antithrombin has been well documented. Antithrombin has a molecular weight of 57,000 kilodaltons (kD), which is similar in size to albumin (60,000 kD); therefore, glomerular lesions sufficient to result in albumin loss also result in loss of antithrombin. Other abnormalities identified in renal disease include increased responsiveness of platelets to agonists, increased procoagulant activities, and decreased antiplasmin activity. Currently, the cause of thrombosis is thought to be multifactorial.

Hypercholesterolemia has been associated with increased risk of thromboembolism. It is hypothesized that endothelial and platelet membrane phospholipid concentrations are altered, which leads to damaged vasculature and increased platelet responsiveness to agonists, respectively. Increased production of thromboxane via the cyclooxygenase pathway in platelets has been seen. Diseases characterized by hypercholesterolemia include hyperadrenocorticism, diabetes mellitus, nephrotic syndrome, hypothyroidism, and pancreatitis. All have been associated with increased risk of thrombus formation, often pulmonary thrombosis.

Cats with cardiomyopathy have increased risk of thromboembolism. Endomyocardial lesions and turbulent blood flow through the heart chambers and valves secondary to altered myocardial functioning are thought to initiate thrombus formation. Specific deficiencies of anticoagulant or fibrinolytic proteins have not been seen. Interestingly, antithrombin is markedly increased but does not provide protective benefits. Cats with cardiac disease secondary to hyperthyroidism are often treated with drugs (eg, propranolol, atenolol, or diltiazem) that abate clinical signs of cardiac dysfunction. These drugs appear to protect against increased risk of thrombosis

by altering platelet responsiveness to agonists.

Horses with colic associated with endotoxemia have decreased plasminogen activity and protein C antigen concentration. These horses have increased mortality and risk of thrombus formation. Laminitis is thought to be the end result of several diverse systemic disorders. Microthrombi in the vasculature of the hoof lamina have been identified in the early stages of laminitis. One theory is that endotoxin has direct effects on the vasculature and activates contact factors in the coagulation cascade. Ischemia of the lamina secondary to edema, vascular compression, and possible blood shunting at the level of the coronet also damage endothelium. When circulation is reestablished, reperfusion injury results, and the exposed subendothelial collagen promotes thrombosis.

The most appropriate treatment of an animal with thrombi or thromboemboli is diagnosis and management of the underlying disease process, along with good supportive care. Maintenance of adequate tissue perfusion is critical. Dissolution of clots and prevention of clot recurrence by administration of anticoagulants (eg, heparin and coumarin) has had mixed success. Heparin facilitates the action of antithrombin, but to be effective, adequate antithrombin must be present. In dogs with protein-losing nephropathies or in horses with endotoxemia, plasma transfusion may be necessary before heparin therapy is effective. Coumarin has been most useful for control or prevention, rather than for treatment. Fibrinolytic compounds have been administered to animals to enhance dissolution of clots. Tissue plasminogen activator (TPA) has more fibrin specificity than does streptokinase or urokinase and, therefore, provides more localized fibrinolytic effects (although not totally). The main deterrent to use of TPA is its high cost. One study of cats with aortic thrombosis treated with TPA found a risk of reperfusion injury after the clot dissolved. Streptokinase is more available and less expensive, but the therapeutic dose is difficult to determine. Many animals have naturally occurring antibodies to streptokinase as a result of previous streptococcal infections. Administration of streptokinase must be sufficient to neutralize all antibodies but not produce a systemic fibrinolytic state with resultant bleeding diathesis.

LEUKOCYTE DISORDERS

Leukocytes, or WBCs, in the blood of healthy mammals include segmented neutrophils, band neutrophils, lymphocytes, monocytes, eosinophils, and basophils. Abnormal leukocytes include neutrophils less mature than bands (eg, metamyelocytes, myelocytes, progranulocytes), blast cells of any hematopoietic lineage, mast cells, and other neoplastic cells. WBCs vary in their site of production, their duration of circulation, and the stimuli that affect their release into and migration out of the vascular system. Differences in leukocyte physiology account for species differences in normal blood cell concentrations and their responses in disease.

The leukogram, a component of the CBC, is an organized tabulation of the total nucleated cell concentration, along with the concentrations of specific WBC types present in the sample, also known as the differential. Knowledge of species-specific WBC physiology and the influence of disease processes form the basis for interpreting abnormalities of the leukogram into diagnostic information. Most leukogram interpretations define a process rather than a specific diagnosis. Processes generally fall into four groups: 1) transient physiologic responses that alter vascular hemodynamics; 2) inflammatory, infectious, and immunologic responses; 3) bone marrow responses to injury; and 4) hematopoietic cell neoplasia. (See also **WHITE BLOOD CELLS**, p 1612.)

PHYSIOLOGY OF LEUKOCYTES

Blood Vascular System

The blood vascular system is conceptually divided into two compartments: the central pool and the marginal pool. The marginal pool consists of the microcirculation at the capillary tissue interface. The central pool consists of larger vessels. Blood samples taken by venipuncture are inherently most representative of the central pool. Flow rate, fluid movement to the extravascular space, and selective WBC adhesion to endothelium are factors that may contribute to marked differences in cell concentration in the two pools. Furthermore, these pools are in hemodynamic equilibrium with each other and the extravascular space. Therefore, WBC concentration may change

appreciably because of movement of cells and/or fluid from one pool to the other as a result of a change in equilibrium. In most species, WBCs are roughly equally distributed between the two pools. Cats have a greater distribution of leukocytes within the marginal pool. WBCs in the circulating pool can be increased by certain mechanisms: epinephrine can redistribute WBCs from the marginal pool to the circulating pool, and corticosteroids can inhibit neutrophil endothelial adherence and tissue migration.

Granulocytes

Granulocytes include neutrophils, eosinophils, and basophils, all of which are produced in the bone marrow from a common stem cell. Granulopoiesis is the term used to describe production of these cells. The proliferative (or mitotic) stages of development consist of myeloblasts, promyelocytes, and myelocytes. Promyelocytes have azurophilic primary granules (lysosomes) that become inapparent in later stages. The storage (or maturation) pool consists of metamyelocytes, band neutrophils, and segmented neutrophils that are functionally mature. Specific granules, which define final cell types, are first produced at the myelocyte stage. Cell types are recognized by characteristic granule staining affinity, eg, basophilic granules for basophils, eosinophilic granules for eosinophils, and neutral or nonstaining granules for neutrophils. The population of segmented and band neutrophils in the bone marrow can be substantial in some species and is referred to as the marrow granulocyte reserve.

Neutrophils: In blood, neutrophils typically are mature (segmented), with occasional more immature band forms. Neutrophils from bone marrow enter the blood, where they remain for an average of 8 hr. They tend to adhere to the microcirculatory endothelium and then unidirectionally enter tissues, where they may participate in host defense. Given the short lifespan of neutrophils in blood, maintenance of blood neutrophil concentration depends on a relatively high, steady delivery from bone marrow. This balance may change dramatically when there is either

increased tissue demand associated with the development of an inflammatory process or a stem cell injury that reduces the marrow production rate. During initiation of an inflammatory lesion, local mononuclear cell release of specific stimulating factors rapidly stimulates bone marrow to release neutrophil reserve and accelerate granulopoiesis. When the tissue demand is intense, marrow production and release may accelerate dramatically, resulting in a left shift and toxic changes (see p 57).

Eosinophils: Eosinophils function in parasite killing and also contain enzymes that modulate products of mast cells released in response to antigen-IgE receptor mast cell degranulation in allergic disease. For example, histamine released by mast cells is modulated by histaminase in eosinophils. Eosinophilia is primarily induced by allergic inflammatory responses and tissue invading parasitic infestations. Less commonly, neoplasia may be associated with paraneoplastic induction of eosinophilia. Localized eosinophilic tissue lesions do not necessarily produce a peripheral eosinophilia, eg, the eosinophilic granuloma dermatopathies and oral lesions of cats. Eosinopenia is a component of corticosteroid-induced (stress) leukograms.

Basophils: Basophils are rare in all common domestic animals. Basophil granules contain histamine, heparin, and sulfated mucopolysaccharides; understanding of their function is limited. As a result, there is no clear interpretation for basophilia. Basophilia is uncommon but may accompany eosinophilia, and it is the latter that is interpreted. Although blood basophils and tissue mast cells have similar enzymatic contents, basophils do not become mast cells. They appear to arise from separate marrow stem cells.

Monocytes

Monocytes are formed in the bone marrow from monoblasts and then develop to promonocytes and finally mature monocytes. Monocytes enter the peripheral blood for ~24–36 hr and exit into tissues to mature into tissue macrophages. Monocytes and macrophages perform phagocytosis of organisms and cellular debris at sites of inflammation or tissue injury. They may form multinucleated giant cells, particularly in response to foreign bodies or complex organisms that elicit granuloma formation, such as *Mycobacterium* spp. Monocytes

and macrophages are a major source of colony-stimulating factors and cytokines that regulate inflammatory responses, and they function as antigen-processing cells.

Lymphocytes

Lymphocytes originate from a bone marrow stem cell and mature in lymph nodes, spleen, and other subepithelial lymphoid tissues. Mature lymphocytes consist of two major subpopulations, B cells and T cells. **B cells** (for bone marrow or bursa equivalent) are potential precursors of plasma cells that produce antibodies for humoral immunity. **T cells** (for thymus) engage in cellular immunity (eg, histocompatibility and delayed-type hypersensitivity). Lymphocytes in tissue may return to the vascular system and recirculate. Some lymphocytes are very long-lived compared with other WBC types.

LEUKOGRAM ABNORMALITIES

Abnormalities of the leukogram include quantitative or numerical concentration abnormalities and WBC morphologic abnormalities.

Numerical Abnormalities: WBC concentration values are interpreted by comparison with species-specific reference values. Interpretations should be made only by considering the absolute numbers. For reference values for total WBC and differential WBC concentrations in absolute numbers for common domestic species, see TABLE 6, p 3176. The total WBC concentration is more variable and often higher in neonates than in adults. Age-related reference values should be used to evaluate leukograms in young animals, especially species in which lymphocytes are more numerous (and neutrophils less numerous) in adults, such as ruminants. Generally, differential WBC patterns of adults are reached at about the age of sexual maturity.

Abnormality in the total WBC concentration is useful only to alert the clinician to look for and interpret abnormalities in the cell distributions in the differential. When the total WBC is abnormal, one or more distributional abnormalities in the differential are likely. When the total WBC is normal, there still may be one or more distributional abnormalities in the differential. As a result, evaluation of the differential absolute values is the most important component of the leukogram.

Leukocytosis is an increase in the total WBC concentration, whereas leukopenia is

a decrease in the total WBC concentration. Changes in the concentrations of specific leukocyte types are more important for clinical interpretation purposes.

Neutrophilia or neutrophilic leukocytosis is an increase in neutrophil concentration. Lymphocytosis is an increase in lymphocyte concentration. Monocytosis is an increase in monocyte concentration. Eosinophilia refers to an increase in eosinophil concentration, and basophilia to an increase in basophil concentration. Metarubricytosis is an increase in nucleated RBCs (nRBCs) in blood. Mastocytosis is an increase in mast cells in blood.

Decreases in concentration of a cell type are indicated by the suffix "penia." This is applied only to cell types in which a decrease is possible. It does not apply to cell types for which the concentration may be 0, such as monocytes, basophils, nRBCs, and any other abnormal cell type. Hence, neutropenia is a decrease in neutrophil concentration, lymphopenia is a decrease in lymphocyte concentration, and eosinopenia is a decrease in eosinophil concentration. Cytopenia is a nonspecific term indicating a decrease in cell concentration(s), but the cell type is not specified. Pancytopenia indicates all cell types are decreased, often to a severe degree.

Terms used to describe or qualify abnormalities most often associated with inflammatory responses include various left shifts and leukemoid response. A left shift is an increase in concentration of immature, nonsegmented neutrophils, typically bands, but may also include metamyelocytes or even more immature forms. A regenerative left shift describes leukocytosis characterized by the combination of neutrophilia and a left shift. In this situation, the segmented neutrophils will be greater in concentration than bands and less mature forms. A **degenerative left shift** describes a neutrophil pattern characterized by normal to decreased total neutrophil concentration, but with a left shift in which the concentration of bands and less mature forms is greater than segmented neutrophils. This is an indication of maximal release from bone marrow in response to inflammation and signifies the presence of an acute, severe lesion. A **leukemoid response** describes a marked neutrophilia of a magnitude sufficient to indicate chronicity of an inflammatory response and corresponding substantial increase in granulopoiesis in the bone marrow. The magnitude is also such that myeloproliferative disease becomes a diagnostic consideration. Guidelines for neutrophilic leukocytosis considered to

indicate a leukemoid response are $>70,000/\mu\text{L}$ ($70 \times 10^9/\text{L}$) for dogs, $>50,000/\mu\text{L}$ ($50 \times 10^9/\text{L}$) for cats, $>30,000/\mu\text{L}$ ($30 \times 10^9/\text{L}$) for horses, and $>20,000/\mu\text{L}$ ($20 \times 10^9/\text{L}$) for ruminants.

Morphologic Abnormalities: Abnormalities of morphology may be associated with either acquired or inherited disease.

Toxic changes are identified only in neutrophils. The term originates from historical observation that certain cell features were associated with general, usually overwhelming, toxic states, such as systemic bacterial infections and severe, acute inflammatory lesions. The term is misleading in that it implies neutrophil injury. The cells are not injured and have normal function. Toxic change is best defined as a set of morphologic changes observed on the blood smear that occur as a result of accelerated marrow production of neutrophils. The accelerated production is in response to relatively severe inflammatory states that maximally stimulate the bone marrow. Morphologic changes include (in order of frequency) diffuse cytoplasmic basophilia, Döhle bodies, and fine cytoplasmic vacuolation. More rare changes include increased prominence of cytoplasmic azurophilic granules, cellular gigantism, and binucleation. Toxic change is almost always associated with the concurrent presence of a left shift. It is graded as mild, moderate, or severe by subjective evaluation of the more common changes noted on examination of a blood smear. Döhle bodies, blue-gray cytoplasmic inclusions, are aggregates of endoplasmic reticulum. They are unique in that they may be found in clinically healthy cats and therefore are not interpreted as toxic change in this species unless accompanied by other features.

Reactive lymphocytes have increased, distinctly basophilic cytoplasm and may have irregular or clefted nuclei. They may vary considerably in diameter. They have condensed chromatin and therefore are not blasts. They are interpreted as immunologically stimulated B cells.

Granular lymphocytes have condensed chromatin and increased pale blue-gray cytoplasm that contains several small pink or azurophilic granules. The nucleus may be round to clefted. These are large granular lymphocytes and may be either natural killer (NK) lymphocytes or T lymphocytes.

Blast cells are usually an indication of hematopoietic cell neoplasia if they are reproducible or present in large numbers.

Their lineage may be tentatively identified by morphologic criteria, but flow cytometric analysis is required to definitively identify lineage.

Many of the following morphologic changes are uncommon.

Chédiak-Higashi syndrome (see p 50) described in Persian cats, people, mink, foxes, Hereford and Brangus cattle, mice, and killer whales is an autosomal recessive defect involving lysosomal granules. There is hyperfusion of granules resulting in large, eosinophilic cytoplasmic inclusions. Susceptibility to bacterial infections is increased, as is the tendency to bleed because of both neutrophil and platelet function abnormalities. Partial oculocutaneous albinism due to abnormal melanin granule formation may occur.

The **mucopolysaccharidoses** are a group of lysosomal storage disorders in which there is a defect in degradation of glycosaminoglycans. Both neutrophils and lymphocytes may contain accumulated mucopolysaccharide product in the form of purple or metachromatic intracytoplasmic granules. Lymphocytes may also be vacuolated. These disorders are associated with a variety of systemic clinical abnormalities and are seen in dogs and cats.

Another group of lysosomal storage disorders recognized in dogs and cats may result in **cytoplasmic vacuoles** predominantly in lymphocytes and occasionally in neutrophils. These disorders include gangliosidoses, α -mannosidosis, Niemann-Pick disease variants, acid-lipase deficiency, and fucosidosis. Most of these disorders result in severe, progressive neurologic disorders resulting from accumulated product in neuronal tissue.

Locoweed toxicity is regarded as an acquired form of lysosomal storage defect in large animals. It is due to toxic principle from the plant that inhibits one or more enzymes of oligosaccharide metabolism. This may result in vacuolation in lymphocytes.

Pelger-Huët anomaly is a nuclear hyposegmentation defect of granulocytes in people, cats, rabbits, horses, and dogs that are heterozygous for the anomaly. Neutrophils have normal function but a near absence of segmented nuclear morphology. Most or all of the neutrophils appear as bands and metamyelocytes and may appear as a marked left shift in an otherwise normal leukogram. Eosinophils and basophils, if present, also exhibit nuclear hyposegmentation. Affected heterozygote animals are clinically normal; the homozygous inheritance of the trait is lethal.

Hypersegmentation is an increased degree of nuclear segmentation resulting in multiple lobes connected by nuclear filaments. It is a nonspecific indication of increased time in circulation and is normal aging of the cell. This may be seen with stress leukograms or corticosteroid administration.

Leukocyte agglutination may occur with either neutrophils or lymphocytes. This is seen on low magnification as aggregates of 5–15 tightly clumped leukocytes. Avid agglutination may result in a markedly false low total WBC concentration on some cell counting instruments. This is likely due to the presence of a naturally occurring cold agglutinin that is operative only in vitro at laboratory temperature. There is no known clinical significance.

Infectious disease inclusions are occasionally recognized. Canine distemper inclusions may be seen in neutrophils, monocytes, and lymphocytes, as well as in newly produced erythrocytes. The ehrlichioses of various animal species and canine hepatozoonosis may have cytoplasmic inclusions of respective organisms of these tickborne diseases.

Specific Interpretative Leukogram Responses

The abnormal leukogram is typically interpreted into one of several responses, each of which may consist of one or more abnormalities in the differential. Some may also be associated with concurrent changes in erythrocytes and platelets. Important species differences in leukogram responses are described below.

Corticosteroid-induced or Stress Response:

In this very common leukocyte response, endogenous steroid release from stress or treatment with exogenous corticosteroids results in a leukogram with multiple changes. Lymphopenia is the most consistent change, and mature neutrophilia is usually present. Monocytosis and eosinopenia are expected changes in dogs but are more variable in other species. Neutrophilia is due to decreased adherence to the vascular endothelium, which inhibits margination and increases circulating time. As a result, neutrophils may also become hypersegmented. There may also be increased marrow release of neutrophils. Lymphocytes become redistributed to lymphoid tissues instead of remaining in circulation. This response may be misinterpreted as inflammation, but a left shift is not usually present.

Excitement or Epinephrine Response:

Leukocytosis may occur as a result of exercise or excitement; this response is mediated by increased epinephrine concentration and may be thought of as a transient physiologic response. Epinephrine flushes cells from the marginal to the central pool. The effect may double the total WBC concentration within minutes. In addition, splenic contraction releases WBCs and RBCs into the peripheral circulation. The leukocytosis is usually due to a mature neutrophilia without a left shift. Lymphocytosis may be present, especially in young horses or cats. The effect in cats is often recognized as a prominent lymphocytosis—as much as two times the upper reference value. The excitement response is relatively uncommon in dogs.

Inflammatory Response: The concentration of neutrophils in blood in response to inflammatory disease is highly variable and dynamic. It is best viewed as a balance between tissue demand and bone marrow production at all phases of the response. There are important species differences in this balance that are related to bone marrow storage reserve and proliferative capacity.

At the beginning of an inflammatory process, the bone marrow responds by delivery of its reserve of late-stage maturing neutrophils, including band cells. If consumption exceeds marrow delivery during this acute stage, neutropenia with a prominent left shift will develop. In dogs and cats, this is an indication of severity of the inflammatory lesion.

Subsequently, it takes 2–4 days for the marrow to accelerate neutrophil production by increased stem-cell entry and expansion of proliferative stages that feed the maturation stages and amplify neutrophil delivery to blood. In dogs, the acute stage of the inflammatory response is usually characterized by mild to moderate neutrophilia, with the left shift being somewhat proportional to severity of demand.

After a few days, accelerated bone marrow production adds to the picture. Neutrophilia may increase along with left shift and toxic changes. As the process becomes chronic, the balance between increased marrow output and consumption may favor the development of even higher magnitudes of neutrophilia. The most chronic form, present for weeks or even months, is described as a “closed cavity” inflammatory process. The lesion becomes somewhat walled off and therefore consumes fewer neutrophils, yet it

still stimulates maximal marrow production. Examples of closed cavity processes are pyometra in dogs and traumatic reticuloperitonitis (hardware disease) in cattle. In these conditions, the magnitude of the total WBC concentration, consisting of neutrophilia, may be as high as 100,000/ μ L (100×10^9 /L) of blood in dogs.

Extreme neutrophilia, exceeding upper limits usually seen in inflammation, may be associated with leukemia, *Hepatozoon canis* infections, and rarely other neoplasms that produce colony-stimulating factors.

In contrast, cattle and most other ruminants have a relatively low reserve of bone marrow neutrophils and a lower capacity for accelerating granulopoiesis. This is reflected in the relatively low neutrophil concentration in normal ruminant blood. As a result, acute inflammation in cows is characterized by neutropenia that can be profound. Therefore, neutropenia in cattle does not reveal the degree of inflammatory severity. After several days, the bone marrow response may establish a return of blood neutrophils in modest concentration, characterized by a marked left shift and toxic changes. Chronic, closed cavity inflammatory lesions are associated with magnitudes of neutrophilia that rarely exceed 25,000/ μ L of blood. Cats and horses are intermediate in these responses, with cats being more like dogs and horses being more like cattle. Pigs have an inflammatory leukogram similar to that of dogs.

Bovine leukocyte adhesion deficiency is a lethal, autosomal recessive disorder of Holstein cattle. It is associated with marked neutrophilia; the neutrophils have a deficiency of the glycoproteins (integrins) that are essential for normal leukocyte adherence and emigration from the vasculature. Recurrent bacterial infections, persistent neutrophilia (often $>100,000/\mu$ L [100×10^9 /L]), lymphocytosis, and death (usually between 2 wk and 8 mo of age) are characteristic. Calves often are stunted and have recurrent pneumonia, ulcerative stomatitis, enteritis, and periodontitis. On examination of tissues, there are few neutrophils, except within vessel lumens, because they persist in the circulation and have impaired entry into the tissues. Testing is available to detect carriers. A similar defect has also been reported in some Irish Setter dogs.

Neutropenia may develop because of excessive tissue demand for neutrophils or reduced granulopoiesis. It may be seen with overwhelming bacterial infections, especially gram-negative septicemia or

endotoxemia, in all species. Immune-mediated destruction of neutrophils is diagnosed by exclusion of other consumptive processes. Stem-cell injury may occur from many causes such as certain viral infections (see TABLE 7), chemical injury, and idiosyncratic drug reactions, eg, sulfonamides, penicillins, cephalosporins, and chloramphenicol in cats. These reactions typically affect all bone marrow cell lines but are recognized initially as neutropenia because of the relatively short lifespan of this cell type.

Neutropenia is seen in the now rare **cyclic hematopoiesis syndrome of gray Collie dogs**, also known as canine cyclic neutropenia. It is an inherited, autosomal recessive disease characterized by a profound periodic neutropenia, associated with overwhelming recurrent bacterial infections, bleeding, and coat color dilution. The defect is due to a mutation in a protein that may regulate neutrophil elastase activity. Neutrophil maturation is arrested at regular intervals of 11–14 days; the peripheral blood neutropenia lasts 3–4 days and is followed by neutrophilia. All other hematopoietic cells, including lymphocytes, also have cyclic production that is minimally evident because of the relatively long circulation time of other cell types. Affected puppies often die at birth or during the first week and rarely live >1 yr. Surviving dogs may be stunted and weak and develop serious recurrent bacterial infections during periods of neutropenia.

Monocytosis may be seen in the inflammatory pattern at any stage of its progression. Monocytosis is more likely, and tends to be of greater magnitude, when the process becomes chronic.

Combined Corticosteroid-induced and Inflammatory Response: Inflammatory disease processes commonly induce a concurrent endogenous corticosteroid response, recognized by the presence of

lymphopenia in conjunction with an inflammatory neutrophil response (left shift). The neutrophil response to inflammation overrides and may be additive to the corticosteroid influence on neutrophils.

Lymphocytosis: Mild lymphocytosis and reactive lymphocytes may occur after vaccination. Modest lymphocytosis, in the range of 7,000–20,000/ μ L ($7\text{--}20 \times 10^9/\text{L}$), should prompt consideration of a possible physiologic excitement response, particularly in cats. If that is excluded, then a lymphoproliferative disorder should be considered. If examination of lymphocyte morphology reveals prolymphocytes and/or blast cells, then lymphocytic leukemia is the working interpretation. If the cells are all small with normal appearing chromatin, then chronic lymphocytic leukemia is a consideration requiring further evaluation. Chronic ehrlichiosis may result in lymphocytosis of this magnitude in dogs. At higher concentrations, the lymphocytosis may be regarded as conclusive evidence of leukemia.

Persistent lymphocytosis in cattle is defined by lymphocyte concentrations consistently >7,500/ μ L ($7.5 \times 10^9/\text{L}$). It is due to a B-cell proliferation that occurs in a subset of animals infected with bovine leukemia virus (BLV). Affected cattle are usually asymptomatic. The finding of persistent lymphocytosis is regarded as a positive indication of BLV infection in the individual. A smaller subset of BLV-infected cattle, either with or without lymphocytosis, may progress to develop lymphoma or lymphocytic leukemia.

Lymphopenia: Lymphopenia is a common leukogram abnormality most commonly associated with endogenous (stress) or exogenous corticosteroid administration. The most likely cause is steroid-induced apoptosis of lymphocytes. Lymphopenia also rarely occurs due to

TABLE 7 VIRAL INFECTIONS THAT MAY CAUSE TRANSIENT NEUTROPENIA

Species	Infection
Dogs	Parvovirus, canine distemper (acute phase)
Cats	Panleukopenia (parvovirus), feline leukemia virus
Horses	Equine influenza, equine viral arteritis (acute phase), equine herpesvirus
Cattle	Bovine viral diarrhea virus
Pigs	Classical swine fever virus, African swine fever virus

other causes, such as extravasation of lymph (eg, lymphangiectasia, chylous effusion), some viral infections with tropism for rapidly dividing cells (eg, parvoviral infections), and hereditary immunodeficiency disease (eg, combined immunodeficiency disease of Arabian foals).

Stem-cell Injury and Pancytopenia:

A number of factors may cause reversible or irreversible stem-cell injury. These injuries may affect erythrocyte, platelet, lymphocyte, and/or granulocyte production. Because of short circulating lifespan, neutropenia is often the first abnormality seen. When chronic or irreversible, these injuries result in decreases in all three major blood cell lines, with the hemogram demonstrating leukopenia, nonregenerative anemia, and thrombocytopenia. General causes include 1) overdoses of radiation and antineoplastic drugs, 2) drug or plant toxicities (eg, estrogen toxicity in dogs, bracken fern toxicity in cattle, phenylbutazone toxicity in species other than horses), 3) hematopoietic cell neoplasia involving bone marrow (myelophthisis), and 4) viral infections that injure rapidly dividing cells and may cause transient neutropenia (see TABLE 7).

Eosinophilia and Basophilia: Eosinophilia, or the combination of eosinophilia and basophilia, prompts the consideration of the following processes: allergic-based inflammation, parasitic infestation, subepithelial (skin, respiratory, GI) inflammation that is likely allergic in nature, and less commonly, paraneoplastic induction. Eosinophilia is seen in most dogs with heartworm disease and may be seen in dogs and cats with flea infestation.

Leukemia, canine blood smear; note several atypical large cells of hematopoietic origin with convoluted nuclei. Courtesy of Dr. Darren Wood.

Hypereosinophilic syndrome has been reported in cats, dogs, and ferrets. This poorly understood syndrome is characterized by consistent marked eosinophilia and eosinophil tissue infiltration with associated organ dysfunction. Decreased concentration of these cell types in blood has no pathologic relevance.

Prominent Metarubricytosis: Although typically absent, metarubricytes occasionally become a major component of the total nucleated cell count. The magnitude may be 10%–50% of the nucleated cell population or more, with absolute numbers reaching 5,000–10,000/ μ L ($5\text{--}10 \times 10^9/\text{L}$). This may occur rarely in early phases of an intense regenerative response to anemia. It may also be associated with endothelial injury (eg, heat stroke) resulting in abnormal release rate of nRBCs from marrow. Most nRBCs will be counted as lymphocytes on cell counters with differential capability. This may result in a preliminary result of lymphocytosis being corrected later only by examination of the blood smear.

Hematopoietic Cell Neoplasia and Leukemia:

Most cases of hematopoietic cell neoplasia of either lymphocytic or bone marrow origin will have some abnormal cells in blood. Sometimes, neoplastic cells are present in low numbers and are detected only by scanning the blood smear under low magnification. Finding abnormal hematopoietic precursor cells in blood in small numbers prompts investigation of bone marrow and/or other hematopoietic tissues (such as the spleen) for possible neoplastic disease.

The opposite extreme is marked leukocytosis with a predominance of the abnormal (neoplastic) cell population. In this situation, the blood sample is diagnostic for leukemia. If poorly differentiated, the cells are classified as blasts, with possible cell lineage determined based on morphologic appearance. If well differentiated, the cell lineage is usually more clear, because the cells are mature.

Lymphocytic leukemias are more common in domestic animals than are myeloproliferative disorders (ie, leukemias of granulocytes, erythrocytes, or platelets). Myelodysplasia is a term used to describe peripheral blood cytopenias, a hyperplastic response in bone marrow, and dysplastic features in developing cells. This can occur with a toxic insult to the bone marrow but may also indicate a preleukemic phase, and serial hemograms should be monitored.

A distinction is often made between an “acute” or “chronic” leukemia. The terms

are more in reference to the clinical course of the disease rather than the duration of the tumor. An acute leukemia of leukocytes often causes systemic signs of illness and a poor short-term prognosis. These animals have variable numbers of poorly differentiated blast cells in circulation, as well as cytopenias in other cell lines. In contrast, a chronic leukemia of leukocytes often causes few to no clinical signs, may be discovered incidentally, and can have a long clinical course. These animals usually have

large numbers of well-differentiated cells in circulation and lack cytopenias.

Considerable progress is being made in the use of monoclonal antibody labeling and flow cytometric analysis to better establish cell lineage, particularly when the morphology is equivocal. This is particularly useful for poorly differentiated leukemias, in which morphology alone is unreliable. The distinction between well-differentiated or chronic myelogenous leukemia and extreme neutrophilic leukocytosis can be difficult.

LYMPHADENITIS AND LYMPHANGITIS

CASEOUS LYMPHADENITIS OF SHEEP AND GOATS

Caseous lymphadenitis (CL) is a chronic, contagious disease caused by the bacterium *Corynebacterium pseudotuberculosis*. Although prevalence of CL varies by region and country, it is found worldwide and is of major concern for small ruminant producers in North America. The disease is characterized by abscess formation in or near major peripheral lymph nodes (external form) or within internal organs and lymph nodes (internal form). Although both the external and internal forms of CL occur in sheep and goats, the external form is more common in goats, and the internal form is more common in sheep. Economic losses from CL include death, condemnation and trim of infected carcasses, hide and wool loss, loss of sales for breeding animals, and premature culling of affected animals from the herd or flock. Once established on a farm or region (endemic), it is primarily maintained by contamination of the environment with active draining lesions, animals with the internal form of the disease that contaminate the environment through nasal discharge or coughing, the ability of the bacteria to survive harsh environmental conditions, and lack of strict biosecurity necessary to reduce the number and prevent introduction of new cases. Although CL is typically considered a disease of sheep and goats, it also occurs more sporadically in horses, cattle, camelids, swine, wild ruminants, fowl, and people. Because of its zoonotic potential, care should be taken when handling infected animals or purulent exudate from active, draining lesions.

Etiology and Pathogenesis: *C. pseudotuberculosis* is a gram-positive, facultative, intracellular coccobacillus. Two biotypes have been identified based on the ability of the bacteria to reduce nitrate: a nitrate-negative group that infects sheep and goats, and a nitrate-positive group that infects horses. Isolates from cattle are a heterogeneous group. All strains produce an exotoxin called phospholipase D that enhances dissemination of the bacteria by damaging endothelial cells and increasing vascular permeability. The bacterium has a second virulence factor which is an external lipid coat that provides protection from hydrolytic enzymes in host phagocytes. Replication of bacteria occurs in the phagocytes, which then rupture and release bacteria. The ongoing process of bacterial replication, followed by attraction and subsequent death of inflammatory cells, forms the characteristic abscesses associated with CL.

To establish infection, *C. pseudotuberculosis* must penetrate skin or mucous membranes. The most common site of entry is the skin after an injury that may result from shearing, tagging, tail docking, castration, or other environmental hazards resulting in skin trauma. Contact with purulent material draining from open, active lesions most commonly serves as the source of bacteria through these breaches in the skin. Although less common, entry across mucous membranes from inhalation or ingestion of the bacteria also serves as a means of infection.

Once the bacteria have entered the body, they move to the lymph nodes via the regional draining lymphatic system.

Internally, the bacteria establish infection not only in the lymph nodes but also in the viscera. The incubation period varies from 1 to 3 mo, culminating in development of encapsulated abscesses. *C pseudotuberculosis* is hardy in the environment and can survive on fomites such as bedding and wood for 2 mo and in soil for 8 mo. The presence of organic material, shade, and moisture favor and enhance survival.

Clinical Findings: The hallmark clinical finding in cases of external CL is the development of abscesses in the region of peripheral lymph nodes. Common sites of development include the submandibular, parotid, prescapular, and prefemoral nodes. Less commonly, abscessation of supramammary or inguinal lymph nodes occurs, in addition to an occasional ectopic location along the lymphatic chain. If left untreated, these lesions eventually mature into open draining abscesses. The purulent material from these lesions has no odor and varies in consistency from soft and pasty (more common in goats) to thick and caseous (more common in sheep). Once natural draining occurs, the skin lesion heals with scarring. Recurrence is common, which can be months later. CL should be highly suspected in a sheep or goat with abscessation in these regions. Although other bacteria may also cause abscessation in these locations (and in other animals), because of the ramifications of the presence of this disease within a herd or flock, these cases should be handled as CL until proved otherwise.

The internal form of CL most commonly presents as chronic weight loss and failure to thrive. The presence of other clinical signs depends on the organs of involvement, which may include any of the major organ systems. Lung abscessation is a common site of visceral involvement in internal CL; therefore, signs of chronic ill thrift with cough, purulent nasal discharge, fever, and tachypnea with increased lung sounds may be noted. The internal form is more common in sheep and has been termed the “thin ewe syndrome.”

The incidence of abscesses and development of clinical disease with either the external or internal form increases with age.

Lesions: In sheep, abscesses often have the classically described laminated “onion-ring” appearance in cross section, with concentric fibrous layers separated by inspissated caseous exudate. In goats, the abscesses are less organized, and the exudate is usually soft and pasty.

Diagnosis: The presence of an external abscess on a small ruminant is highly suggestive of CL, especially in locations of peripheral lymph nodes. However, definitive diagnosis is only by bacteriologic culture of purulent material from an intact abscess. Although other pyogenic organisms such as *Trueperella pyogenes* (formerly *Arcanobacterium pyogenes*), *Staphylococcus aureus*, *Pasteurella multocida*, and anaerobes such as *Fusobacterium necrophorum* can cause abscessation, affected animals should be kept isolated pending culture results. Animals with visceral abscesses pose a greater diagnostic challenge. Radiography and ultrasonography can be useful to detect internal lesions. Culture of a transtracheal aspirate obtained from an animal with pneumonia can help determine whether CL is the cause. Excluding other causes of chronic weight loss and ill thrift in the face of proper nutrition and good appetite such as Johne’s disease, parasitism, and poor dentition further raise suspicion.

In the absence of accessible abscesses for bacterial culture, definitive diagnosis of active cases of CL is challenging. Although many diagnostic tools are available, results of these tests must be interpreted with caution and with consideration of herd or flock history, the presence or absence of active infection within the herd or flock, and vaccination status. A synergistic hemolysin inhibition (SHI) test that detects antibodies to the phospholipase D exotoxin is available at many diagnostic laboratories. Positive titers indicate past resolved infections, recent exposure, recent vaccination, or active lesions or their development. Titers of 1:256 or higher have been correlated in past studies with the presence of active, developing abscesses; however, in a recent

Caseous lymphadenitis lesions, external form, submandibular lymph node in a goat. Courtesy of Dr. Kevin Washburn.

study, a high titer was poorly correlated with presence or development of abscesses over an 18-mo period. When the status of an animal with a positive titer is in doubt, the titer should be repeated in 2–4 wk. If the titer is rising and clinical signs of abscesses are noted, then CL can be assumed to be the cause. False-negative results can occur if testing is done in the first 2 wk after exposure before the animal has sero-converted. Also, animals with chronic, walled-off abscesses can have a false-negative result. Colostral titers usually disappear by 3–6 mo of age, so serologic testing of lambs or kids <6 mo old should be interpreted with caution.

Treatment and Control: Once a diagnosis of CL has been established, owner education stressing the persistent, recurrent nature of the disease is necessary. The most practical approach for commercial animals infected with CL is to cull them from the herd or flock. However, animals with draining abscesses should not be sent through sale barns until draining has ceased and the wound has healed. Treatment of individual animals should be undertaken with the understanding that CL is not considered a “curable” disease. Animals with genetic or emotional value are treated mainly for aesthetic reasons and to limit their infectivity to the rest of the herd or flock. Treatment options have included lancing and draining, surgical excision, formalin injection of lesions, systemic antibiotics, and intralesional antibiotics.

If external abscesses are lanced and drained, the cavity should be lavaged with dilute iodine solution and the animal isolated in an area that can be disinfected until the lesion stops draining and heals. Drained purulent material should be carefully collected and disposed of. Dilute bleach and chlorhexidine solutions are effective disinfectants of hard surfaces and fomites, but the presence of organic material on these surfaces inactivates them and drastically reduces or prohibits effectiveness. Intact accessible abscesses can be surgically removed; however, this option is more expensive, and undetected abscesses are often present and continue to develop. Recurrence rates with either lancing or surgical removal are high.

The practice of injecting abscesses with formalin should be strongly discouraged, because the FDA has zero tolerance for extra-label use of a potent carcinogen in food-producing animals. The efficacy of systemic antimicrobial therapy and, more

recently, intralesional antimicrobial therapy has been investigated. However, use of any antimicrobial for treatment of CL is extra-label; therefore, strict adherence to published guidelines on withdrawal times and an established veterinarian-client-patient relationship are mandatory. Longterm administration of procaine penicillin G and rifampin has been efficacious in some cases. Penicillin alone, although efficacious in vitro, is unlikely to effectively penetrate the capsule of developed abscesses, as are many, if not most, of the water-soluble or moderately lipid-soluble antimicrobials. However, recent studies have shown that administration of one dose of tulathromycin at 2.5 mg/kg, either SC directly into the abscess cavity, or two doses at 2.5 mg/kg, administered at the same time, one SC and one intralesionally, can resolve the lesions without lancing the abscess. Further, effective concentrations of tulathromycin can be achieved within walled-off abscesses caused by *C. pseudotuberculosis* after a single dose at 2.5 mg/kg, SC. The highly lipid-soluble property of tulathromycin may be particularly helpful in cases of internal CL, when abscesses are not accessible for other forms of treatment. Despite the efficacy of intralesional and parenteral administration of tulathromycin in many cases, recurrence remains a problem. Therefore, use of these drugs cannot be considered curative but rather an acceptable alternative to manage cases of CL when culling from the herd or flock is not an acceptable option for the owner.

Because of the nature of the causative organism, common means of exposure, chronicity of the disease, and difficulty in completely eliminating the organism from individual animals, control of CL revolves around strict biosecurity measures. The overriding goals of any control program are to eliminate the disease from the herd or flock and to reduce the number of new cases either from the spread of disease or introduction to the farm.

Ideally, animals identified as infected should immediately be culled. If immediate removal is not possible, infected animals should be isolated from the rest of the herd or flock. Diligence in this practice will eventually result in decreased prevalence as animals that develop active cases are identified and removed, and given there are no new animals incubating the disease introduced to the premises.

When elimination through culling is not a viable option for the owner, control of CL is challenging at best. Dividing the herds or flocks into “clean” and “infected” groups

and eliminating older and less genetically valuable animals over time is one control strategy.

Lambs and kids from infected dams can be raised on pasteurized colostrum and milk away from infected animals. However, the internal form of CL and animals incubating the disease can maintain infection within the "asymptomatic clean" group and limit the success of this approach.

Commercial CL vaccines are currently licensed for use in sheep and goats. These vaccines should only be used in the species they are labeled for, because adverse reactions have been reported in goats given vaccine labeled for sheep. Rigidly adhering to vaccination schedules according to the manufacturer's labeling can help reduce the prevalence and incidence of CL within herds or flocks. However, it is important to emphasize that efficacy of these vaccines is not 100%, and vaccination will not clear infected animals. Vaccination of young replacement stock should be considered, and older infected animals should be gradually culled as economics allow. Once the disease is at a low prevalence rate, vaccination should be stopped and all seropositive unvaccinated animals culled. In "clean" herds or flocks that have no history of CL, vaccination is not recommended.

The risks of disease transmission among animals should be recognized when shearing or dipping, and management practices should be adjusted accordingly. Animals with noted lesions should be shorn last, and clipper blades disinfected between animals. Shearers should recognize the hazards associated with contact with purulent material and the possibility of acting as mechanical vectors, either on clothing or via equipment, for spread of the bacteria to new animals. Further, dipping tank solutions should be kept as fresh as possible, because *C pseudotuberculosis* can survive within them and serve as a source of infection of freshly shorn sheep that have skin abrasions.

Owners should remove hazardous items (barbed wire, exposed nails, rough feeders) from the environment to decrease injury and potential CL transmission from the presence of bacteria on these fomites.

One of the most common ways CL can be introduced into a previously "clean" herd or flock, or reintroduced to one in which CL has been reduced or eliminated, is through the addition of replacement stock. Often, animals from other farms that are asymptomatic on arrival are incubating the disease and then manifest infection weeks to

months later. Purchasing animals from sources with unknown histories is hazardous to maintaining a "clean" herd or flock. Newly arrived animals should be examined thoroughly for signs of CL such as abscesses or scars near peripheral lymph nodes. They should remain isolated from the rest of the herd or flock until their serologic status is determined, and only animals that are seronegative with no evidence of present or past CL lesions should be allowed to enter the herd or flock.

CORYNEBACTERIUM PSEUDOTUBERCULOSIS INFECTION OF HORSES AND CATTLE

(Pigeon fever, Dry land distemper)

In horses, *Corynebacterium pseudotuberculosis* causes ulcerative lymphangitis (an infection of the lower limbs) and chronic abscesses in the pectoral region and ventral abdomen. It is one of the most common and economically important infectious diseases of horses in California and Texas and is increasing in prevalence in other western and Midwestern states of the USA. In cattle, the bacteria most commonly cause cutaneous excoriated granulomas. Large, ulcerative skin lesions resembling infected granulation tissue and lymphangitis may occur in 2%-5% of cows. Location on the animal is variable but is often associated with skin trauma. Healing often occurs without treatment or with limited topical treatment in 2-4 wk. Abortion and mastitis may also occur. Rarely, visceral involvement has been reported.

Pathogenesis and Clinical Findings:

The onset of ulcerative lymphangitis in horses is variable and usually manifests as painful inflammation, nodules, and ulcers, especially in the region of the lower limb, or lameness and edematous swelling can extend up the entire limb. The exudate is odorless, thick, tan, and blood tinged. Usually, only one leg is involved. If the animal is not treated aggressively with antimicrobials, lesions and swelling usually progress and become chronic with relapses.

In the southwestern USA, *C pseudotuberculosis* infection in horses is seasonal, with a peak incidence in summer and fall. Infection results in abscessation of the pectoral region or ventral abdominal region with secondary dissemination to internal organs. Clinical signs include diffuse or

localized swellings, ventral pitting edema, ventral midline dermatitis, lameness, draining abscesses or tracts, fever, weight loss, and depression. Leukocytosis and neutrophilia may be present. A marked or prolonged fever, anorexia, or weight loss indicates untoward sequelae such as deep or recurring abscesses, internal abscessation, or systemic infection with abortion. Abscesses can be large, up to 20 cm in diameter before rupturing, and take weeks to months to resolve. Weight loss, colic, splinted abdomen, or lethargy may be signs of internal abscesses. Dermatitis lesions are painful and mildly pruritic with alopecia, exudation, crusting, and ulceration.

The bacteria enter via skin wounds by arthropod vectors such as stable flies, horn flies, and house flies, or by contact with contaminated fomites or soil.

Diagnosis: Isolation of *C pseudotuberculosis* from lesions is necessary for confirmation. In all forms of lymphangitis in horses, samples for culture include aspirates of abscesses, swabs of purulent exudate beneath crusts associated with folliculitis, and punch biopsies. Differential diagnoses include pyoderma, abscesses, lymphangitis from other bacteria (eg, *Staphylococcus aureus*, *Rhodococcus equi*, *Streptococcus* spp, or *Dermatophilus* spp), dermatophytosis, sporotrichosis, equine cryptococcosis, North American blastomycosis, and onchocerciasis.

Abdominal ultrasonography is useful for detection of internal infection of the liver, spleen, or kidneys. Ultrasonography is also useful for detection and drainage of deep

abscesses causing lameness, particularly in the triceps musculature. Transtracheal aspirates are required to confirm pneumonia caused by *C pseudotuberculosis*. Serologic testing with the synergistic hemolysis inhibition test, which detects IgG to the phospholipase D exotoxin, is a useful adjunct for diagnosis of internal infection in the absence of external infection.

Treatment: Lymphangitis and internal infection should be treated with long-term antimicrobials (1 mo duration or as directed by follow-up ultrasonography). The organism is susceptible to most commonly administered antimicrobials; however, antimicrobial treatment of uncomplicated external abscesses may prolong the disease by delaying abscess maturation. External abscess swellings are treated with hot packs, poultices, or hydrotherapy until they rupture or are drained surgically. Abscesses are lanced and flushed with dilute antiseptic solutions. Deep abscesses in the triceps or quadriceps region require ultrasonography to guide placement of an indwelling drain. Phenylbutazone relieves pain and swelling. General supportive and nursing care is indicated.

If treatment is successful, the swelling gradually recedes over days or weeks. Internal infection has a 30%–40% mortality rate, even with appropriate treatment. Severe or untreated lymphangitis cases often become chronic, and fibrosis and induration of the leg occur. Isolation of infected horses, fly control, and good sanitation are recommended for prevention.

CARDIOVASCULAR SYSTEM INTRODUCTION

The cardiovascular system comprises the heart, the veins, and the arteries. The atrioventricular (mitral and tricuspid) and semilunar (aortic and pulmonic) valves keep blood flowing in one direction through the heart, and valves in large veins keep blood flowing back toward the heart. The rate and force of contraction of the heart and the degree of constriction or dilatation of blood vessels are determined by the autonomic nervous system and hormones produced either by the heart and blood vessels (ie, paracrine or autocrine) or at a distance from the heart and blood vessels (ie, endocrine).

Slightly >10% of all domestic animals examined by a veterinarian have some form of cardiovascular disease. Similar to many chronic diseases of other organ systems, cardiovascular diseases generally do not resolve but progress and become more limiting over time, which may ultimately lead to death. Evaluation of the heart is performed via assessment of heart sounds and murmurs, arterial pulses, degree of jugular vein distention, strength and location of the apex beat, electrocardiography, radiography, cardiac biomarkers, echocardiography, and other advanced imaging techniques.

Heart Rate and the Electrocardiogram

The heart beats because of a wave of depolarization that originates in the sinoatrial (SA) node at the juncture of the cranial vena cava and the right atrium. At rest, the SA node discharges ~30 times/min in horses, >120 times/min in cats (typically 180–220 times/min in a hospital setting), and 60–120 times/min in dogs, depending on their size. In general, the larger the species, the slower the rate of SA node discharge and the slower the heart rate. Birds can have a resting heart rate of ~115–130 beats/min, with active heart rates up to 670 beats/min, depending on size and species. Hummingbirds can have an active heart rate of >1,200 beats/min.

The rate of SA nodal discharge increases when norepinephrine is released from the sympathetic nerves and binds to the β_1 -adrenoreceptors on the SA node. This cardioacceleration may be blocked by β -adrenergic blocking agents (eg, propranolol, atenolol, metoprolol, esmolol, carvedilol). The rate of SA nodal discharge decreases when acetylcholine released by the parasympathetic (vagus) nerves binds to the cholinergic receptors on the SA node. This vagally mediated cardiodeceleration may be blocked by a parasympatholytic (vagolytic) compound (eg, atropine, glycopyrrolate). When the SA node discharges and the wave of depolarization traverses the atria, the P wave of the ECG is produced. Subsequently, the atria contract, ejecting a small volume of remaining blood into the respective ventricles (atrial kick).

In quiet, healthy dogs, the variation of the heart rate with respiration is termed **respiratory sinus arrhythmia (RSA)**; it results from decreased vagal activity during inspiration and increased vagal activity during expiration. Therefore, vagolytic compounds, as well as excitement, pain, fever, and congestive heart failure (CHF), usually abolish or diminish RSA. Heart rate variability synchronized with respirations is a good indicator of cardiac health. It is rare to find an animal that has active CHF with RSA; however, comorbid conditions that increase vagal activity (such as primary respiratory or neurologic disease) may cause RSA to persist.

Heart rate is also inversely related to systemic arterial blood pressure. When blood pressure increases, heart rate decreases; when blood pressure decreases, heart rate increases. This relation is known as the **Marey reflex** and occurs by the

following mechanism. When high-pressure arterial baroreceptors in the aortic and carotid sinuses detect increases in blood pressure, they send increased afferent volleys to the medulla oblongata, which increases vagal efferents to the SA node and causes the heart rate to decrease. In heart failure, the baroreceptors (laden with Na^+/K^+ -ATPase) become fatigued, which reduces the afferent signals to the medulla oblongata. This results in less vagal efferent signaling. Thus, dogs in CHF have a decrease in heart rate variability and frequently present with an underlying sinus tachycardia.

Once the wave of depolarization reaches the atrioventricular (AV) node, the speed of conduction is slowed through the nodal tissue, giving the atria time to contract and eject more blood into the ventricles, allowing for atrioventricular synchrony. The depolarization then travels rapidly to the subendocardium of the ventricles and to the ventricular septum. From these points, it travels slowly through the ventricular myocardium, producing the QRS complex of the ECG with subsequent ventricular contraction. The delay between the electrical activity visualized on ECG and mechanical function accounts for transmission of impulses, which allows contraction of myocytes to occur in synchrony. Under rare conditions, there may be depolarization without contraction; this is called **electromechanical dissociation**.

The interval on an ECG between the onset of the P wave and the onset of the QRS complex is termed the PQ or PR interval. It is a measure of the time it takes for the electrical wave of depolarization to begin at the SA node and reach the ventricles (lastly traversing the AV node). Factors that speed or slow the rate of discharge of the SA node (chronotropy) also speed or slow conduction through the AV node (dromotropy). Thus, as the heart rate increases, the PR interval shortens; when heart rate slows, the PR interval lengthens.

The T wave of the ECG represents repolarization of the ventricles. It is affected by electrolyte imbalance (eg, hypo- or hyperkalemia, hypo- or hypercalcemia), myocardial injury, or ventricular enlargement. Repolarization of the atria (Ta wave) is rarely seen, because it occurs during the much larger QRS complex. Occasionally, it can be seen with AV nodal disease (AV block) or in horses with slow heart rates, appearing as a “hammock” after the P wave.

Force of Ventricular Contraction

The force with which the ventricles contract is determined by many factors, including the end-diastolic volume (preload), which is the volume of blood within the ventricles just before they begin to contract, and myocardial contractility (inotropy), which is the rate of cycling of the microscopic contractile units of the myocardium.

The preload is determined by the difference in end-diastolic pressure between the ventricle and the pleural space divided by the stiffness of the ventricular myocardium. The end-diastolic pressure of the ventricle is determined by the ratio of blood volume and the compliance of the myocardium. Preload is regulated predominantly by low-pressure volume receptors in the heart and large veins. When these receptors are stimulated by an increase in blood volume or by distention of the structures the receptors occupy, the body responds by making more urine and by dilating the veins—an attempt to decrease blood volume and lower the pressures in the veins responsible for venous distention. An increase in end-diastolic volume (preload) stretches the ventricular wall, resulting in a more forceful contraction as per the Frank-Starling mechanism, or Starling's law of the heart. Stretching of receptors in the atria and ventricles causes them to release natriuretic proteins: brain natriuretic peptide (BNP) primarily from the ventricles and atrial natriuretic peptide (ANP) from the atria. These peptides are natriuretic, relax smooth muscle, and in general oppose vasopressin and angiotensin II. A correlation between BNP and NT-proBNP levels and degree of stretch of the heart has been identified in dogs.

Myocardial contractility is determined by the availability of ATP and calcium, which allows myosin-actin cross-bridging to occur. The rate of liberation of energy from ATP is determined, in part, by the amount of norepinephrine binding to β_1 -adrenergic receptors in the myocardium. One of the most important factors in heart failure is the down-regulation (decreased number) of myocardial β_1 -receptors.

Oxygen and the Myocardium

Oxygen is essential for the production of energy that permits all body functions. The amount of oxygen available for production of this energy is termed the **tissue oxygen content**. The myocardial oxygen content is a balance between how much oxygen is delivered to the heart minus how much oxygen is consumed by the heart.

The amount of oxygen delivered to the heart depends on how well the lungs function, how much Hgb is present to carry the oxygen, and how much blood carrying the Hgb flows through the heart muscle via the coronary arteries. If pulmonary function is normal and there is sufficient Hgb, coronary blood flow will determine how much oxygen is delivered to the myocardium. Coronary blood flow is determined by the difference in mean pressure between the aorta (normally 100 mmHg) and the right atrium (normally 5 mmHg), into which coronary blood empties. Because coronary flow is greatest during diastole, slower heart rates (which preferentially increase diastolic interval) are associated with improved myocardial oxygen delivery.

The amount of oxygen consumed by the heart is termed **myocardial oxygen consumption**. It is determined, principally, by wall tension and heart rate. Wall tension is expressed by the law of LaPlace, in which tension increases with increases in pressure or diameter of the ventricle, and tension decreases with increases in wall thickness of the ventricle. Tension increases with conditions that increase afterload (pressure), such as pulmonic stenosis, subaortic stenosis, systemic or pulmonary hypertension, or preload (volume), including mitral valve insufficiency, left-to-right shunting defects, and dilated cardiomyopathy. In the absence of a stenotic lesion, afterload is determined by the relative stiffness of the arteries and by the degree of constriction of the arterioles. The tone of vascular smooth muscle depends on many factors, some of which constrict the muscle (eg, adrenergic agonists, angiotensin II, vasopressin, endothelin) and some of which relax the muscle (eg, norepinephrine, atropine, bradykinin, adenosine, nitric oxide). Afterload is often increased in heart failure, and therapy is often directed at decreasing it.

Increases in heart rate result in increasing myocardial oxygen consumption while decreasing time for diastole when coronary blood flow is greatest. The combination can set the stage for an imbalance in myocardial oxygen demand and supply, leading to myocardial ischemia. Cardiac failure is characterized by an increase in sympathetic tone and relative increases in heart rate; the ultimate impact is an inefficient myocardium that can result in deleterious remodeling.

Oxygen is responsible for the production of the vast majority of ATP, which fuels both contraction and relaxation of the

myocardium. Calcium must rapidly be released by intracellular stores (sarcoplasmic reticulum) via calcium-induced calcium release to allow for excitation-contraction coupling, while equally rapid removal of calcium back into the sarcoplasmic reticulum is necessary for relaxation. Both processes of calcium cycling are energy dependent.

In heart failure and cardiomyopathy, inappropriate handling of calcium may result in arrhythmogenesis and may also be the most important factor that leads to both reduced force of contraction and reduced rate of relaxation (ie, reduced systolic as well as diastolic function).

Hindrance to Blood Flow

Blood flow from the heart, termed **cardiac output**, is via both the left and right ventricles. Cardiac output is determined by the heart rate and ventricular stroke volume. Blood flows through the systemic arterial (left ventricular) or pulmonary arterial (right ventricular) trees and is critical to satisfactory function of the heart and consequent perfusion of organs with adequate quantities of blood and the oxygen it contains. Most (>90%) of the hindrance to blood flow is from the degree of constriction of the arterioles, termed **vascular resistance**; however, some interference is from the stiffness of the portion of the great arteries closest to the ventricles, termed **impedance**. The ventricles eject a stroke volume into the proximal portion of the great arteries, which expand to accommodate the stroke volume; when the ventricles are relaxed, the distended great arteries recoil and keep blood moving through the arterioles into the capillaries. The aortic and pulmonic valves close and prevent the stroke volume from returning to the ventricle that ejected it. Systemic vascular resistance is the opposing blood flow that must be overcome to push blood through the peripheral circulation and is calculated by:

$$(\text{mean arterial pressure} - \text{mean venous pressure}) / \text{cardiac output}$$

Pulmonary vascular resistance is similarly calculated and is increased in cases of pulmonary vascular obstruction or pulmonary hypertension.

One of the most important features of heart failure that leads to morbidity is increased resistance of arterial, arteriolar, and venous smooth muscle because of increased angiotensin II, vasopressin, and endothelin. If the left ventricle is unable to eject a normal stroke volume or cardiac

output, it is reasonable that ventricular function might be improved by decreasing vascular resistance. Decreasing afterload (arterial vasodilation) is one therapeutic goal in heart failure therapy.

ABNORMALITIES OF THE CARDIOVASCULAR SYSTEM

The following mechanisms can result in abnormalities of the cardiovascular system:

- 1) the cardiac valves fail to close or open properly (valvular disease); 2) the heart muscle pumps inefficiently or relaxes inadequately (myocardial disease); 3) the heart beats too slowly, too rapidly, or irregularly (arrhythmia); 4) the systemic vessels offer too great an interference to blood flow (vascular disease); 5) there may be abnormal communications between chambers of the left side and right side of the heart (cardiac shunts) or between the systemic and pulmonary circulations (extracardiac shunts); 6) there is too little or too much blood compared with the ability of the blood vessels to store that blood; and 7) there is parasitism of the cardiovascular system (eg, heartworm disease). Cardiac diseases can be either congenital defects or acquired. The diseases of greatest importance, because of their prevalence, are mitral regurgitation in dogs, hypertrophic cardiomyopathy in cats, dilated cardiomyopathy (DCM) in dogs, arrhythmogenic right ventricular cardiomyopathy in Boxers, and heartworm disease.

Valvular Disease: Inadequate closure (coaptation) of valves leads to regurgitation (back flow of blood), which occurs most commonly as mitral regurgitation, or mitral and tricuspid regurgitation (concurrent tricuspid regurgitation occurs in ~30% of cases with mitral regurgitation). Regurgitation through the mitral and/or tricuspid valves due to myxomatous degeneration of the valve leaflets constitutes >75% of all heart disease in dogs. As blood regurgitates through either set of AV valves, a typical holosystolic murmur is heard between the first and second heart sounds. A mid-systolic click, secondary to mitral valve prolapse, may precede development of a murmur in the early stages of disease. When blood regurgitates through the mitral or tricuspid valves, an excessive amount of blood moves back and forth between the ventricle and atrium. Thus, with mitral regurgitation, it is common to see dilation of the left atrium and left ventricle. The degree of left atrial enlargement, documented by

either radiography or echocardiography, may predict disease severity. Mitral or tricuspid regurgitation is most common in older small-breed dogs and older horses that have valve leaflets thickened by myxomatous degeneration (infiltration with glycosaminoglycans). Mitral regurgitation occurs more often in Cavalier King Charles Spaniels, and at a younger age, than in any other breed; however, there is not a significant difference in the time frame of progression to onset of CHF.

Aortic regurgitation occurs most often in older horses due to calcification or noninflammatory degeneration of the aortic valve. It may also develop secondary to aortic endocarditis (infection of the valve leaflets), most often in large-breed dogs. The left ventricle and atrium can become dilated due to the aortic regurgitation, but this is proportional to the degree of regurgitation. The murmur produced by blood regurgitating from the aorta into the left ventricle is always a diastolic murmur, heard immediately after the second heart sound. In horses, the murmur of aortic regurgitation can be described as "blowing" due to the regurgitant blood flow, or as "buzzing" due to the aortic leaflets vibrating as the blood flows past. The buzzing murmur is almost always associated with a relatively small amount of regurgitant flow.

Inadequate opening of valves is termed stenosis. Pulmonic stenosis is most prevalent, valvular aortic stenosis is uncommon, and mitral or tricuspid stenosis is rare. However, subaortic stenosis, produced by a fibrous or fibromuscular band of tissue just beneath the aortic valves, is prevalent, especially in certain breeds (eg, Newfoundlands, Golden Retrievers, Boxers, Rottweilers, and German Shepherds). If a valve opens inadequately, a greater pressure must be generated to maintain the normal volume of blood flowing through it. The ventricle responsible for pumping blood through the stenotic valve concentrically hypertrophies (thickens) proportionally to the degree of tightness of the stenosis. The systolic ejection quality murmurs produced by pulmonic or subaortic stenosis are heard between the first and second heart sound; typically, they are shorter in duration than the holosystolic murmur of mitral regurgitation and are heard best over the left heart base and thoracic inlet (subaortic stenosis). In general, the louder the murmur, the greater the stenosis, although the severity of stenosis is not always predicted by the intensity of the murmur. The velocity of blood flowing through a stenosis

correlates with the severity of the stenosis, which can be estimated by spectral Doppler echocardiography. Medications (β -blockers) or interventional procedures (balloon valvuloplasty) may be recommended in cases of severe subaortic or pulmonic stenosis, respectively.

Myocardial Disease: Impaired force of contraction is termed reduced systolic function (pump failure), which occurs most commonly with DCM—primary DCM in large-breed dogs, DCM-phenotype with Boxer cardiomyopathy, and in cats that are typically either taurine deficient or in the end-stages of other types of cardiomyopathy and in longstanding mitral regurgitation. When this occurs, the cardiac muscle is said to be in a reduced inotropic state, or to have reduced contractile function. In large-breed dogs, this is usually termed idiopathic DCM, because the origin is unknown.

Impaired ventricular relaxation is termed reduced diastolic function, which occurs most commonly when the cardiac muscle suffers oxygen debt and the consequent lack of energy to fuel relaxation. Diastolic dysfunction is seen in most cardiac diseases as they progress to heart failure. The ventricular myocardium also relaxes poorly in hypertrophic cardiomyopathy (ie, when the muscle is too thick), or with pericardial disease when either the thickened pericardium or fluid contained within the pericardial sac interferes with relaxation. Hypertrophic cardiomyopathy is most common in cats. Probably >85% of cats with heart disease have hypertrophic cardiomyopathy. A smaller number of cats will have so-called restrictive cardiomyopathy, in which the heart fills poorly because the walls are stiffer than normal, unclassified cardiomyopathy, or valvular disease. Pericardial disease is most common in older, large-breed dogs with tumors bleeding into the pericardial sac (eg, hemangiosarcoma or chemodectoma).

Arrhythmias: Any cardiac rhythm falling outside the normal sinus rhythm is termed an arrhythmia. An arrhythmia that is too fast, too slow, or too irregular can result in reduced cardiac output, thereby causing clinical signs that could include exercise intolerance, syncope, or exacerbation of CHF. The most common arrhythmias are atrial fibrillation (seen commonly in horses and giant-breed dogs, or in any size dog with advanced cardiac disease and severe left atrial enlargement), ventricular premature depolarizations (seen most commonly in

Boxers and Doberman Pinschers), sick sinus syndrome (seen mainly in aged Miniature Schnauzers), persistent atrial standstill (seen in Labrador Retrievers and English Springer Spaniels), and third-degree AV block.

In atrial fibrillation, depolarization of the atria is not coordinated, stimulation of the AV node is frequent but random, and the heart rate is rapid and irregular. Ventricular premature contractions (also called ventricular premature beats or depolarizations) arise from irritated regions of the ventricles. Such irritations commonly result from chronic stretch of the fibers, as well as from oxygen debt or drug effects. A single premature beat does not typically cause clinical signs and can be relatively benign, but premature beats may evolve into short paroxysms (bursts) or long runs (ventricular tachycardia) that lead to hemodynamic impairment and syncope, or even to a complete loss of coordination of ventricular activity (ventricular fibrillation) and sudden death. Ventricular tachycardia commonly occurs in Doberman Pinschers with DCM and in Boxers with arrhythmogenic right ventricular cardiomyopathy (previously termed Boxer cardiomyopathy) and warrants immediate treatment with antiarrhythmics. With either sick sinus syndrome (ie, transient arrest of discharge of the SA node alternating with periods of tachycardia) or complete heart block (in which no atrial depolarization enters the ventricles), the ventricular rate is exceptionally slow and may lead to hemodynamic impairment (low cardiac output failure, hypoperfusion, hypoxemia), exercise intolerance, syncope, or sudden death. A pacemaker is indicated in all dogs with persistent high-grade AV block or persistent atrial standstill and in dogs that are symptomatic for sick sinus syndrome.

Vascular Disease: Interference to blood flow through systemic arterioles (systemic hypertension) is most common in aging animals with impaired renal function (dogs and cats), hyperadrenocorticism (dogs), or hyperthyroidism (cats). The exact underlying cause is usually unknown, but suspected causes include sodium retention and plasma volume expansion, hyperaldosteronism, increased sympathetic tone, and possibly increased angiotensin II. Regardless of the cause, a loss in arteriolar compliance may persist even with adequate treatment of the associated clinical condition. Arterial vasodilators, such as angiotensin-converting enzyme (ACE)

inhibitors and amlodipine, are a mainstay of antihypertensive therapy.

Cardiac Shunts: Abnormal communications between the left and right side of the circulation are termed cardiovascular shunts. These take the form of (in decreasing prevalence) patent ductus arteriosus (between the aorta and pulmonary trunk), ventricular septal defect (between the left and right ventricles), or atrial septal defect (between the left and right atria). When blood crosses these defects from the left side to the right side, which is most common, these defects are termed left-to-right shunts. They result in overcirculation of the lungs and dilatation of the cardiac chambers required to pump or to carry the shunted blood. Chronic dilatation ultimately leads to myocardial failure. *See also* CONGENITAL AND INHERITED ANOMALIES OF THE CARDIOVASCULAR SYSTEM, p 76.

Tetralogy of Fallot (*see* p 83) is a complex congenital anomaly that consists of a hypoplastic right ventricular outflow tract and/or pulmonary trunk, an aorta that overrides the interventricular septum (therefore arising from both ventricles), ventricular septal defect, and right ventricular hypertrophy. Poorly oxygenated blood enters the systemic circulation (right-to-left shunt) and produces a bluish tinge (cyanosis) to the mucous membranes and increased numbers of RBCs (polycythemia). Tetralogy of Fallot is the most common form of a right-to-left shunt, although any large atrial or ventricular septal defect can result in right-to-left shunting (Eisenmenger physiology) secondary to pulmonary hypertension from chronic pulmonary overcirculation. Right-to-left shunting patent ductus arteriosus is also seen infrequently and typically results from persistent pulmonary hypertension from birth. Any cardiac or extracardiac shunt can also originate as a left-to-right shunt and reverse in direction if the pressure within the pulmonary circulation or right heart becomes greater than the pressure in the aorta or left heart.

Heartworm Disease: Heartworm disease (*see* p 127) is seen predominantly in dogs but also in cats and is transmitted via mosquitoes. In heartworm disease, adult heartworms in the pulmonary vessels and the pulmonary arterial changes they induce impede flow through the lungs. Severe, persistent pulmonary hypertension may result in right ventricular hypertrophy, increased right side filling pressure, and eventual development of rightside CHF

(cor pulmonale). The disease progresses at a varying rate in dogs but usually lasts <2 yr in cats. Both species may develop syncope or cor pulmonale from pulmonary hypertension or may develop pulmonary thromboembolism from in situ thrombus formation or adult worm death. Antigenic stimulation from the heartworms may also cause changes in the lungs, resulting in eosinophilic pneumonitis. The death of adult worms secondary to adulticide therapy always results in some degree of pulmonary thromboembolism. Strict cage rest is necessary in the month after adulticide therapy, and pretreatment with doxycycline and ivermectin to kill *Wolbachia* organisms before adulticide treatment may also mitigate the pulmonary pathology resulting from worm death.

Common Endpoints of Heart Disease

Signs associated with any of the above diseases are due either to inadequate organ perfusion (eg, exercise intolerance, weakness, syncope, azotemia) or to blood damming up in organs in which the venous effluent is emptied inadequately (eg, pulmonary edema, ascites, pitting edema, other effusions). An animal showing signs due to relative inadequacy of the cardiovascular system to deliver enough blood to sustain normal function is said to be in low output, or forward heart failure. An animal showing signs caused by blood damming up in poorly drained organs is said to be in CHF. When inadequate amounts of oxygen are present in systemic arterial blood and there is too much unoxygenated Hgb, the mucous membranes appear cyanotic and polycythemia may develop.

Animals with heart failure may deteriorate gradually, due most often to pulmonary edema, or they may die suddenly, due to arrhythmias, chordal rupture, or left atrial tear.

Heart Failure, Congestive Heart Failure, and the Failing Heart

Systolic myocardial failure is described as reduced myocardial contractile function, characterized by a reduced force of contraction from any given preload. More objectively, a failing heart can be described as one with a reduced rate of liberation of energy from the breakdown of ATP, or with a reduced velocity of fiber shortening when the heart contracts during the imaginary situation of contracting against no load. It is difficult to directly measure myocardial

contractility and to identify myocardial failure. Almost any animal with heart disease leading to chamber enlargement or increased wall thickness has a degree of myocardial failure on the cellular level, but such animals may remain compensated without clinical signs of heart failure for a prolonged time.

Low output heart failure and CHF (see p 87) are clinical syndromes in which an animal manifests signs referable to a complex interaction between a failing heart and the blood vessels. In low output heart failure, cardiac output is insufficient to perfuse organs with enough oxygenated blood for the organs to function properly either at rest or during periods of exertion. In CHF, blood dams up in or around organs—usually the lungs but occasionally in the systemic organs—and causes the congested organs to function abnormally, become edematous, or both. The functional classification of heart failure is expressed when, during graded exercise, the animal shows signs (eg, dyspnea, cough, collapse) due to the heart disease. There are several classifications of heart failure, the most recent and perhaps most practical of which is based on the course of heart disease expressed in four basic stages (A, B1, B2, C, D) described in the ACVIM Consensus Statement on canine chronic valvular heart disease.

DIAGNOSIS OF CARDIOVASCULAR DISEASE

Diagnosis of cardiovascular disease is based on history and signalment, physical examination (eg, inspection, auscultation, palpation), cardiac biomarkers (NT-proBNP, BNP, ANP, troponin I), radiography, electrocardiography, and echocardiography. Clear images must be obtained for radiography, electrocardiography, and echocardiography, or accurate, valid interpretation will not be possible. Most cardiovascular diseases (eg, mitral regurgitation, dilated cardiomyopathy) can be highly suspected based on the results of physical examination and radiography. Electrocardiography is specific for diagnosis of rhythm disturbances (eg, atrial fibrillation, sick sinus syndrome). Echocardiography is excellent to confirm tentative diagnoses, assess severity of valvular regurgitations and stenotic lesions, evaluate chamber enlargement and quantify systolic and diastolic myocardial function, characterize the form of cardiomyopathy in cats, detect cardiac tumors or pericardial

disease, diagnose pulmonary hypertension or heartworm caval syndrome, and identify congenital cardiac defects. Thoracic radiographs are the best diagnostic tool to evaluate the lungs for evidence of active CHF. Heartworm disease is diagnosed best by detecting antigens of mature, female heartworms circulating in the blood (dogs). In cats, diagnosis of heartworm disease may entail heartworm antigen and antibody testing, supplemented by thoracic radiographs and echocardiography.

Many heart diseases have specific breed prevalences. Any older Cavalier King Charles Spaniel with a cough, labored breathing, and exercise intolerance should be suspected to have left side CHF due to mitral regurgitation; however, chronic obstructive pulmonary disease with fibrosis may produce nearly identical signs and thoracic radiographs; echocardiography and NT-proBNP testing may be needed to differentiate. Any middle-aged, depressed, coughing, exercise-intolerant Doberman Pinscher with a rapid, irregular heart rate likely has dilated cardiomyopathy. Any middle-aged to older Miniature Schnauzer with fainting likely has sick sinus syndrome. Any Boxer who faints intermittently should be suspected to have arrhythmogenic right ventricular cardiomyopathy; however, Boxers can also develop neurocardiogenic syncope or sick sinus syndrome, and Holter monitoring may be needed to diagnose the underlying cause of syncope and to formulate the best treatment plan. A middle-aged cat with labored breathing and reluctance to lie down probably has myocardial disease (most commonly hypertrophic cardiomyopathy), whereas an older cat with weight loss and behavioral changes is likely to have hyperthyroidism, which can result in systemic hypertension and exacerbate cardiac disease.

Heart disease should be considered if any of the following are identified on physical examination: 1) the heart rate is rapid, slow, or irregular (and not due to respiratory sinus arrhythmia); 2) respiratory sinus arrhythmia is absent even when the animal is at rest (this also occurs due to pain, fever, or excitement); 3) more than two heart sounds are heard (eg, producing a "gallop" rhythm) in any animal but a horse (most common in cats with cardiomyopathy); 4) a loud murmur is heard; 5) heart sounds are muffled in the absence of obesity (may indicate pericardial or pleural effusion); 6) arterial pulsations are rapid, feeble, or irregular with more heart beats than arterial pulsations (pulse deficits); 7) the animal faints or has reduced exercise tolerance in

the absence of skeletal muscle disease or obesity; 8) the mucous membranes are acutely cyanotic in the absence of primary pulmonary disease.

Echocardiography is more effective than radiography, which is more effective than electrocardiography, to detect enlargement of chambers of the heart and great vessels. In general, the degree of chamber enlargement parallels disease severity. The degree of pulmonary infiltrates detected radiographically, or the degree of impairment of left ventricular wall motion or thinning of the left ventricular walls, may predict the severity of heart failure. Unfortunately, the correlation between hemodynamic or echocardiographic measurements and either signs or likelihood of death is not always good. There appears to be a better correlation between increase in heart and respiratory rates and exercise incapacity to severity of heart disease. NT-proBNP testing may also help in the prognostication of heart disease and heart failure.

Diagnosis of specific cardiovascular diseases are discussed in their respective chapters.

PRINCIPLES OF THERAPY

See also SYSTEMIC PHARMACOTHERAPEUTICS OF THE CARDIOVASCULAR SYSTEM, p 2525.

Although therapy is disease-specific, there are some general goals of therapy for heart disease: 1) Chronic stretch on myocardial fibers should be minimized, because chronic stretch injures and irritates fibers, causes them to consume excess quantities of oxygen, and leads to their death and replacement by fibrous connective tissue (remodeling). 2) Edema fluid should be removed because it makes the lungs wet, heavy, and stiff and causes ventilation perfusion inequalities, impairs oxygen diffusion, and fatigues muscles of ventilation. 3) Cardiac output should be improved, and the amount of regurgitation (most often mitral regurgitation) decreased. Improved cardiac output enhances blood flow to important organs, and reducing mitral regurgitation decreases stretch and reduces pressures in the left atrium and pulmonary veins, thus reducing pulmonary capillary pressure and edema formation. 4) Heart rate and rhythm should be regulated. A heart beating too slowly fails to eject enough blood, whereas a heart beating too rapidly does not have time to fill adequately and consumes too much oxygen at a time when there is too little coronary blood flow. A heart beating too irregularly may deteriorate into ventricular fibrillation and

sudden death. 5) Oxygenation of the blood should be improved. Inadequate oxygenation leads to inadequate energy to fuel both contraction and relaxation of the myocardium. Inadequate oxygenation of the myocardium may also lead to myocardial fibrosis and arrhythmia. 6) The likelihood of thromboembolism should be minimized. Cats with hypertrophic cardiomyopathy may shed emboli from the enlarged left atrium, which may block major arterial branches and lead to ischemia and death. 7) Mature heartworms and microfilariae should be killed. Mature heartworms may initiate severe changes in the pulmonary arteries that ultimately impede blood flow through the lungs.

The ultimate goals of therapy for cardiovascular disease are achieved when treatment resolves the presenting clinical signs, the respiratory and heart rates are not increased at rest, and quality of life is good for both pet and owner.

Common Therapeutic Agents

Furosemide is a loop diuretic that decreases resorption of sodium, chloride, and potassium in the thick ascending limb of the loop of Henle. It is also a venodilator when used IV. It is the most important and effective means to remove edema fluid from animals with heart failure and frequently is lifesaving in the short term. Diuresis with furosemide may be augmented by using thiazide diuretics (eg, hydrochlorothiazide). Thiazides suppress resorption of sodium and water at the distal renal tubules. When using a loop diuretic and a diuretic that works at the distal tubules, the ability of the kidneys to conserve water is reduced dramatically, so dehydration and hypokalemia may develop. This may be signaled by worsening azotemia, and renal values must be monitored closely in animals on multiple diuretics. Torsemide is a loop diuretic that is 10 times more potent than furosemide; it is reserved for refractory CHF or in cases of suspected diuretic resistance to furosemide.

Spirolactone is a potassium-sparing diuretic that blocks the effects of aldosterone. Like thiazides, it exerts its effect principally at the distal convoluted tubule. Although spironolactone effectively maintains potassium levels, data suggest that it does not induce a significant diuretic effect. However, spironolactone minimizes remodeling of both blood vessels and the heart, and like angiotensin-converting enzyme (ACE) inhibitors and β -blockers, has been shown to decrease symptoms and to prolong the lives of people and perhaps

dogs with heart failure. Aldactazide, a combination diuretic consisting of spironolactone and hydrochlorothiazide, may be used in cases of refractory CHF. Renal values should be monitored closely because of the risk of worsening azotemia and renal failure with aldactazide therapy. Amiloride and triamterene are also potassium-sparing diuretics; however, these drugs are not typically used in veterinary medicine.

Digitalis glycosides exert their effects by inhibiting membrane Na^+/K^+ -ATPase. This increases intracellular sodium, which activates the sodium-calcium pump that increases intracellular calcium. Digoxin increases the force of myocardial contraction (to a minor degree), slows the heart rate, and improves baroreceptor function. Digoxin has a narrow therapeutic index; thus, serum levels should be monitored, and animals should be watched for signs of toxicosis (vomiting, diarrhea, inappetance, arrhythmogenesis).

Enalapril, benazepril, lisinopril, and ranipril are ACE inhibitors commonly used in heart failure management in dogs. They are all equally effective at blocking the conversion of angiotensin I to angiotensin II. They minimize remodeling of both blood vessels and myocardium. They are part of the mainstay treatment regimen for advanced cardiac disease and heart failure.

Amrinone and milrinone, analogues of theophylline that deactivate other forms of phosphodiesterase, are potent IV inodilators. That is, they are both positive inotropes and vasodilators. However, they have been associated with worse outcomes in people with CHF and are not commonly used. Pimobendan, a calcium-sensitizing agent and phosphodiesterase inhibitor, is another inodilator shown to improve the quality of life and improve survival in dogs with CHF. Pimobendan is not approved for use in cats but may be beneficial in cats with heart failure (that do not have evidence of outflow tract obstruction). Sildenafil is a potent phosphodiesterase inhibitor used to treat moderate to severe pulmonary hypertension in dogs. Sildenafil has been shown to improve exercise intolerance and quality of life in people and dogs with pulmonary hypertension via pulmonary arterial vasodilation. There may also be additional beneficial effects on vascular remodeling and cardiac function.

Both procainamide and quinidine, class IA antiarrhythmics used formerly to manage ventricular arrhythmias, have been superseded by the class III antiarrhythmics

sotalol and amiodarone, and the class IB antiarrhythmic mexiletine for treatment of malignant ventricular arrhythmias. Sotalol is used to treat both supraventricular and ventricular tachyarrhythmias, and it is particularly effective in treatment of Boxers with arrhythmogenic right ventricular dysplasia, either alone or in combination with mexiletine. Amiodarone is useful to manage all forms of arrhythmias, including ventricular arrhythmias, and rate control or conversion of atrial fibrillation. Increased liver enzymes and hepatotoxicity are potential adverse effects of amiodarone; thus, liver enzymes and serum amiodarone levels should be monitored periodically throughout therapy. Lidocaine, a class IB antiarrhythmic, is used only IV for emergency ventricular arrhythmias such as sustained ventricular tachycardia or R-on-T morphology.

Atenolol, propranolol, and metoprolol are oral β -blockers, and esmolol is an IV β -blocker, that slow the heart rate, suppress arrhythmias, and up-regulate adrenergic receptors. Carvedilol is a β - and α -adrenergic blocker that scavenges oxygen free radicals. Like ACE inhibitors and spironolactone, carvedilol has been shown to both prolong life and decrease symptoms in people with heart failure; however, β -blockers are not generally advised for use in animals with active CHF. β -blockers are often used to treat dogs with subaortic stenosis, and for dynamic outflow obstruction in cats with hypertrophic cardiomyopathy.

Diltiazem is a calcium-channel blocker used to slow ventricular rate in animals with atrial fibrillation or supraventricular tachycardia. It is also used occasionally in cats with hypertrophic cardiomyopathy and outflow tract obstruction.

Atropine and glycopyrrolate block the effects of the vagus nerve on the SA node. Because the vagus nerve slows discharge of the SA node and heart rate, these compounds speed heart rate and may be useful when the heart beats too slowly. Nitroglycerin is a venodilator usually applied in a paste form to the skin inside the earflap or the mucous membranes; venodilation causes blood to pool in the dilated peripheral veins and splanchnic organs, decreasing left ventricular preload and pulmonary edema. Sodium nitroprusside is another nitrate that is a veno- and arterial dilator. Nitroprusside can be administered IV to treat acute fulminant CHF. These two medications should never be given simultaneously. Aspirin, clopidogrel, dalteparin, enoxaparin, and coumadin are antithrombotics that may prevent thromboembolism in cats with cardiomyopathy. Rivaroxaban is an oral factor Xa inhibitor that may prove useful for thromboprophylaxis in cats and dogs, although further studies are needed to evaluate its dosing and safety. Taurine and L-carnitine are amino acids used to prevent dilated cardiomyopathy in cats and in a limited number of dogs, respectively. Melarsomine is used to kill mature heartworms; ivermectin, milbemycin, and selamectin are used to kill microfilariae. Doxycycline should be administered to target *Wolbachia*, an intracellular bacteria that has a symbiotic relationship with heartworms.

Pimobendan and ACE inhibitors have been proved to be safe and effective to treat dogs with heart failure. Furosemide and digoxin are approved but without data proving either safety or efficacy. Use of other agents to manage heart failure or rhythm disturbances is based on anecdotal evidence or unblinded, uncontrolled reports and clinical experience.

CONGENITAL AND INHERITED ANOMALIES OF THE CARDIOVASCULAR SYSTEM

Congenital anomalies of the cardiovascular system are defects that are present at birth and can occur as a result of genetic, environmental, infectious, toxicologic, pharmaceutical, nutritional, or other factors or a combination of factors. For several defects, an inherited basis is suspected based on breed predilections and breeding studies. Congenital heart defects are significant not

only for the effects they produce but also for their potential to be transmitted to offspring through breeding and thus affect an entire breeding population. In addition to congenital heart defects, many other cardiovascular disorders have been shown, or are suspected, to have a genetic basis. Diseases such as hypertrophic cardiomyopathy, dilated cardiomyopathy, and

degenerative valvular disease of small breeds of dogs may have a significant heritable component.

In dogs, the prevalence of congenital heart disease is estimated at <1%. In multiple large studies of congenital heart disease in dogs, the three most common defects are aortic stenosis, pulmonic stenosis, and patent ductus arteriosus (PDA). Less common defects include ventricular septal defect, atrial septal defect, mitral valve dysplasia, tricuspid valve dysplasia, tetralogy of Fallot, cor triatriatum, and persistent right aortic arch. However, because of regional differences, the most common congenital cardiac defects in dogs in the USA vary from those reported in the UK and may likely differ from those in Europe and other regions.

In cats, the prevalence of congenital heart disease has been estimated to be 0.2%–1% and includes atrioventricular (AV) septal defects (including ventricular septal defect, atrial septal defect, and endocardial cushion defects), AV valve dysplasia, endocardial fibroelastosis, PDA, aortic stenosis, and tetralogy of Fallot.

The most common defects in other species are as follows: cattle—ventricular septal defect, ectopic heart, and ventricular hypoplasia; sheep—ventricular septal defect; pigs—tricuspid valve dysplasia, atrial septal defect, and subaortic stenosis; horses—ventricular septal defect, PDA, tetralogy of Fallot, and tricuspid atresia. Arabian horses have a relatively higher incidence of congenital defects than other breeds; a variety of defects have been reported for this breed.

Detection, Diagnosis, and Clinical Significance:

The early detection of a congenital heart defect is critical for several reasons. Certain defects are surgically correctable, and treatment should be performed before the onset of congestive heart failure (CHF) or irreversible cardiac damage; recently purchased animals may be returned to avoid economic loss; pets with congenital heart defects are likely to die prematurely, causing emotional distress; and animals purchased for performance have limited potential and will likely be unsatisfactory. Early detection also prevents incorporation of genetic defects into breeding lines.

The evaluation of most animals with a congenital cardiac defect usually consists of a physical examination, electrocardiography, radiography, and echocardiography. This allows for a definitive diagnosis and an assessment of the severity of the defect. The

use of Doppler echocardiography has supplanted the use of invasive cardiac catheterization studies in the evaluation of most cardiac defects. Once the diagnosis has been made and severity determined, treatment options can be developed and a prognosis given.

The clinical significance of congenital heart disease depends on the particular defect and its severity. Mildly affected animals may exhibit no ill effects and live a normal life span. Defects causing significant circulatory derangement will likely cause neonatal death. Such defects, many incompatible with life, also cause fetal death and reduced litter size. Medical or surgical management is most likely to benefit animals with congenital cardiac defects of moderate or greater severity. Left-to-right shunting PDA is one notable exception in which surgical correction is indicated in nearly all affected animals.

Pathophysiology: Congenital heart defects produce signs of cardiac failure through a variety of pathophysiologic mechanisms. Defects such as pulmonic stenosis and subaortic stenosis cause ventricular outflow obstruction and may result in right- and left-side failure, respectively. Outflow obstruction also leads to concentric hypertrophy of the respective ventricle, increasing the risk of ischemia-induced arrhythmias and sudden death. PDA and septal defects are examples of abnormal communications between the systemic and pulmonary circulatory systems and typically result in left-to-right shunting of blood. The recirculation of blood through the pulmonary circulation and into the left-side chambers often precipitates signs of left-side CHF (eg, pulmonary edema, cough, fatigue). Larger defects typically result in a greater degree of volume overcirculation to the left-side chambers. PDA is a possible exception, with very large defects sometimes contributing to pulmonary hypertension and right-to-left shunting (*see* p 83), also called a reversed PDA. Animals with right-to-left shunting defects (tetralogy of Fallot, reversed PDA) may develop right heart failure but more often have clinical signs associated with polycythemia (*see* p 43), which develops subsequent to renal perfusion with deoxygenated blood. This results in an increase in erythropoietin production by the kidneys and consequent polycythemia.

Innocent Murmurs: It is imperative to appreciate that the presence of a heart murmur in a young animal is not

pathognomonic for a congenital heart defect. Many young animals will have a low-grade systolic murmur (often grade II/VI or less) that is the result of mild turbulence and is not associated with a congenital heart defect. These murmurs usually disappear by 6 mo of age in dogs and cats. Innocent murmurs are heard in the absence of any other demonstrable evidence of cardiovascular disease. High-grade systolic murmurs (grade IV/VI or greater) and diastolic murmurs are indicative of cardiac disease and should prompt further investigation.

OUTFLOW TRACT OBSTRUCTIONS

This group of congenital cardiac defects includes aortic stenosis, pulmonic stenosis, and coarctation of the aorta. All involve obstruction to either right or left ventricular outflow.

AORTIC STENOSIS

Aortic stenosis impedes normal left ventricular emptying and is caused by a narrowing at one of three locations:

- 1) below the aortic valve (subvalvular or subaortic),
- 2) at the aortic valve (valvular), or
- 3) above the aortic valve (supravalvular).

The most common form of aortic stenosis in dogs is subaortic stenosis, caused by fibrous nodules or a ridge or ring of fibrous tissue within the left ventricular outflow tract just below the aortic valve. Subaortic stenosis is generally seen in large-breed dogs. Predisposed breeds include Boxers, Golden Retrievers, Rottweilers, German Shepherds, and Newfoundlands.

Pathophysiology: Aortic stenosis induces left ventricular concentric hypertrophy, the degree of which depends on the severity of the stenosis. In severe cases, left ventricular output may be decreased, especially during exercise. The major ramification of left ventricular hypertrophy is the risk of myocardial ischemia secondary to inadequate perfusion. Myocardial ischemia is a major factor in the development of life-threatening ventricular arrhythmias.

Clinical Findings and Treatment: Clinical signs do not consistently parallel the severity of stenosis. Inadequate output can result in lethargy, exercise intolerance, and syncope. Animals with no history of illness may die suddenly, with the defect first detected at necropsy. Affected animals have

an ejection-type systolic murmur heard best at the aortic valve area. The intensity of the murmur correlates fairly well with the degree of stenosis and may increase as animals mature, reflecting progressive stenosis. Puppies without detectable murmurs should not be considered free of disease until they reach maturity (~1 yr of age). In moderate to severe cases, femoral pulse strength is diminished. Electrocardiography may show left ventricular enlargement (tall R waves in lead II) and ventricular premature complexes that may increase in frequency with exercise. Holter monitoring is indicated in syncope animals or in animals with severe disease to define the presence of any arrhythmias, assess arrhythmia severity, and help determine the risk of sudden death. A recheck Holter monitor may be considered after initiation of antiarrhythmic therapy to assess efficacy. Radiographically, there is variable left ventricular enlargement and poststenotic dilatation of the aorta. Doppler echocardiography can generally provide a definitive diagnosis of aortic stenosis and exclude other cardiac abnormalities. A visible subaortic ridge or ring may be visible, and the velocity of systolic blood flow through the defect determines the severity of the stenosis. Dogs with more significant stenosis may show left ventricular concentric hypertrophy and hyperechoic areas within the myocardium consistent with myocardial ischemia and fibrosis.

Treatment options include medical management, balloon valvuloplasty, and open surgical correction. Medical management generally consists of the use of a β -blocker (eg, atenolol) for its potential to decrease myocardial oxygen demand, prolong diastole, and reduce left ventricular wall stress. Antiarrhythmic therapy is indicated in dogs with significant ventricular ectopy. Balloon valvuloplasty, although potentially effective short term, is unlikely to offer consistent longterm benefits. Open surgical resection is costly, limited to facilities offering cardiopulmonary bypass, and associated with higher morbidity/mortality. Mildly affected animals commonly require no treatment, and the prognosis can be fair to good in animals very mildly affected. Affected animals should not be bred.

PULMONIC STENOSIS

Pulmonic stenosis is common in dogs and infrequent in cats. It results in obstruction to right ventricular outflow due, in most cases, to dysplasia of the pulmonic valve

cusps. Although the valvular form is most common, stenosis can also occur in the subvalvular region (infundibulum) or in the supravalvular area. Breed predilections for valvular pulmonic stenosis include English Bulldogs, Boxers, Beagles, Boykin Spaniels, and terriers. Supravalvular pulmonic stenosis is uncommon and may be most often seen in Giant Schnauzers.

Pathophysiology: The right ventricle must generate increased pressure during systole to overcome the stenosis, which in moderate to severe cases can lead to dramatic right ventricular concentric hypertrophy and dilatation. As the right ventricle hypertrophies, ventricular compliance diminishes, leading to increased right atrial pressure and venous congestion. The turbulent jet of blood flow across the stenosis deforms the wall of the main pulmonary artery, resulting in a poststenotic dilatation. In severe cases, right-side congestive failure may be noted. Concurrent tricuspid valve dysplasia is sometimes noted in animals with pulmonic stenosis. Anomalous coronary artery development has been documented in some affected animals with pulmonic stenosis such as English Bulldogs and Boxers. Most commonly, the left main coronary artery originates from the right coronary artery and encircles the right ventricular outflow tract.

Clinical Findings and Treatment:

Affected animals may have a history of exercise intolerance and failure to thrive. Right-side CHF may be present and is characterized by ascites or peripheral edema. A prominent ejection-type systolic murmur is present and heard best at the pulmonic valve area (left base). A corresponding precordial thrill may be present. Jugular distention and pulsations may also be present. Electrocardiography will demonstrate evidence of right ventricular enlargement (deep S waves in lead II) in many cases. Radiographic abnormalities include right ventricular enlargement, dilatation of the main pulmonary artery, and diminished pulmonary perfusion. Echocardiography is indicated to obtain a definitive diagnosis and may demonstrate right ventricular hypertrophy and dilatation, thickened and relatively immobile pulmonic valve cusps, and turbulent blood flow across the stenosis. In a few cases, supravalvular or discrete subvalvular stenosis can be noted. Pulmonic insufficiency can sometimes be seen in dogs with pulmonic stenosis. The velocity of blood flow across the stenosis is used to assess the

severity of disease and determine the need for intervention. Animals with moderate or severe pulmonic stenosis can benefit from balloon valvuloplasty or surgical intervention (valvulotomy, patch grafting, partial valvectomy, or conduits). Balloon valvuloplasty is a minimally invasive and highly effective treatment option. Some animals are medically managed with a β -blocker (eg, atenolol) alone or in conjunction with balloon valvuloplasty. Congestive heart failure should be medically managed if present. Similarly, the presence of supraventricular or ventricular arrhythmias warrants therapy with the appropriate antiarrhythmic drug(s).

COARCTATION OF THE AORTA

This rare condition of dogs and cats involves narrowing of the aorta distal to the subclavian artery, typically in the area of the ductus arteriosus. Similar to other stenotic lesions, this leads to increased pressure proximal to the narrowing, resulting in concentric hypertrophy of the left ventricle. Other uncommon congenital abnormalities of the aorta include tubular hypoplasia of the ascending aorta and aortic interruption. Surgical correction has been reported.

LEFT-TO-RIGHT SHUNTS

PATENT DUCTUS ARTERIOSUS

In fetal life, blood entering the right heart largely bypasses the nonfunctional lungs through either the foramen ovale or the ductus arteriosus. The ductus arteriosus effectively shunts blood from the pulmonary artery into the descending aorta (right-to-left shunt). At birth, several factors mediate closure of the ductus to separate the systemic and pulmonary circulatory systems. Inflation of the lungs and remodeling of the fetal pulmonary vasculature allows the pulmonary circulation to change from a high-pressure, high-resistance system to a low-pressure, low-resistance system. Closure of the ductus occurs shortly after birth, leading to formation of the ligamentum arteriosum.

Pathophysiology: Persistence or patency of the ductus with an otherwise normal systemic and pulmonary circulatory system results in significant shunting of blood from the descending aorta to the pulmonary artery (left to right). Because systolic and diastolic aortic pressures normally exceed pulmonary artery pressures, shunting is

continuous throughout the cardiac cycle. The result is a continuous murmur and volume overload of the pulmonary arteries and veins, left atrium, and left ventricle. Left atrial and left ventricular dilatation may result in cardiac arrhythmias. Diastolic flow (also called diastolic run-off) through the ductus leads to a decrease in diastolic and mean systemic blood pressures. The widened difference between systolic and diastolic pressures creates an increased pulse pressure and bounding femoral pulses. Chronic volume overload and dilatation of the left-side cardiac chambers usually result in development of left-side CHF in most untreated cases within the first 1–2 years of life. Animals with a small ductus and minimal shunting may reach adulthood, although most affected dogs have evidence of volume overload even at a young age. In some animals with a large PDA, increased pulmonary blood flow may induce pulmonary vasoconstriction and development of pulmonary hypertension. In cases of severe pulmonary hypertension in which pulmonary pressures exceed systemic pressures, blood flow through the ductus can reverse and result in right-to-left shunting. This “reverse PDA” causes disappearance of the classic machinery murmur and results in caudal hypoxemia. Delivery of oxygenated blood to the head and neck results in pink mucous membranes cranially, while delivery of hypoxemic blood caudally results in cyanotic mucous membranes caudally (vulva and prepuce). Differential cyanosis is a characteristic examination finding in animals with reverse PDA. In addition, perfusion of the kidneys with deoxygenated blood causes excessive release of erythropoietin and subsequent polycythemia.

Clinical Findings and Treatment:

In animals with a left-to-right PDA, a prominent, continuous, machinery-like murmur is present. The murmur is usually loudest at the left base of the heart and is often associated with a precordial thrill. In some cases, the ductus remains open for several days after birth, so a continuous murmur may be detected during examination of the neonate. Femoral pulses are typically bounding. Most young animals do not demonstrate clinical signs. Those with a large shunt and older animals often have signs of left-side CHF. Electrocardiography frequently demonstrates tall R waves in lead II, indicative of left ventricular enlargement. A spectrum of cardiac arrhythmias may also be seen, including both atrial and ventricu-

lar premature complexes. Radiographic abnormalities depend on the size of the ductus and may demonstrate left atrial and left ventricular enlargement, prominent pulmonary vessels, aortic and pulmonic aneurysmal dilatations (ductal bump), and variable degrees of pulmonary edema. Echocardiography is valuable in excluding concurrent congenital cardiac defects, as well as documenting presence of the PDA. Continuous turbulence in the main pulmonary artery is characteristic of a left-to-right shunting PDA. Left ventricular and left atrial dilatation are typically noted, and mild mitral regurgitation may be present secondary to annular dilation.

Because of the high risk of CHF early in life for animals with a PDA, closure is generally recommended. There are two major treatment options for PDA closure: interventional transcatheter occlusion and surgical ligation. Catheter-based occlusion is minimally invasive and typically involves placement of an occlusion device through a peripheral vessel (most commonly the femoral artery). The Amplatz canine ductal occluder is used most often and is highly successful with minimal complications. The use of other occlusion devices such as Gianturco coils and vascular plugs has also been described. The major limitations to a transcatheter approach are ductal size and patient size. Surgical ligation of the ductus is also usually curative and considered most often for small dogs and cats. If present, CHF should be medically managed before anesthesia and surgery are performed.

In animals with a reverse PDA, there is usually a history of lethargy, exercise intolerance, and collapse that relates to severe pulmonary hypertension and venous admixture. Careful examination may reveal differential cyanosis. The second heart sound may be split, and there may be a soft diastolic murmur of pulmonic insufficiency. A continuous murmur is not present, and femoral pulses are not bounding. The finding of polycythemia in a young animal with the above clinical signs should prompt further diagnostic evaluation of the heart. Electrocardiography demonstrates severe right ventricular enlargement and occasional arrhythmias. In reverse PDA, right ventricular enlargement and aneurysmal dilatation of the descending aorta can be noted on radiographs. Echocardiography is indicated in these cases and will demonstrate abnormalities associated with pulmonary hypertension (right ventricular dilatation and hypertrophy, septal flattening, pulmonary artery dilatation). Contrast

echocardiography using agitated saline can be used to confirm the diagnosis. After the injection of agitated saline into a peripheral vein, microbubbles will be seen within the right heart, pulmonary artery, and abdominal aorta, suggesting a right to-left shunt between the pulmonary artery and the aorta. Occlusion or ligation of the ductus is contraindicated with reverse PDA, because this results in an increase in pulmonary hypertension (by causing an increase in flow through the pulmonary arteries), right heart failure, and death. Therapy in these cases involves medical management of pulmonary hypertension and control of polycythemia through periodic phlebotomy. Longterm prognosis is poor.

VENTRICULAR SEPTAL DEFECTS

Ventricular septal defects are most commonly located in the perimembranous portion of the septum, high in the ventricular septum immediately beneath the right and noncoronary aortic valve cusps on the left and just below the cranioseptal tricuspid valve commissure on the right. They vary in size and hemodynamic significance. Doubly committed juxta-arterial septal defects (located beneath the aortic valve on the left and beneath the pulmonic valve on the right) and muscular septal defects (located at any site along the muscular septum) may also be seen. Ventricular septal defects may be seen with other congenital cardiac anomalies. This defect is heritable in miniature swine.

Pathophysiology: Shunting of blood from the left ventricle into the right ventricle or right ventricular outflow tract occurs in most animals because of the pressure gradient between the two ventricles. The magnitude of the shunt depends on the size of the defect, the ratio of pulmonary to systemic vascular resistance, and the relative compliance of the two ventricles. Blood shunted into the right ventricle is recirculated through the pulmonary vessels and left cardiac chambers, which causes dilatation of these structures. The right ventricle may dilate as well, especially in animals with large ventricular septal defects (which are rare). Small defects limit the volume of shunted blood and minimize hemodynamic effects, whereas large defects usually result in severe circulatory derangements and clinical signs. Most ventricular septal defects are restrictive, in which the degree of shunting is small, allowing the left and right ventricles to maintain normal

pressures and a normal pressure gradient. Significant shunting through the pulmonary arteries can induce vasoconstriction and pulmonary hypertension. As resistance rises, the shunt may reverse and result in right-to-left shunting of blood, cyanosis, and polycythemia. The reversal of shunt flow (right-to-left) through a septal defect as a consequence of pulmonary hypertension is referred to as Eisenmenger syndrome.

Clinical Findings and Treatment: Clinical findings depend on the severity of the defect and the shunt direction. A small, restrictive defect usually causes minimal or no signs. Larger defects may result in left-side CHF. Cattle are prone to developing signs of right-side failure. The development of Eisenmenger syndrome is indicated by cyanosis, fatigue, and exercise intolerance. Most animals with a restrictive ventricular septal defect have a loud holosystolic murmur heard best over the right thorax that may be accompanied by a palpable thrill. This murmur is often absent or faint when a very large defect is present or when shunting is right to left. On occasion, aortic valvular insufficiency develops secondarily, because the defect may disrupt aortic valve apposition. In these cases, a concurrent diastolic murmur may be present, and the combination systolic/diastolic murmur ("to-and-fro" murmur) may be mistaken as that of a PDA. Thoracic radiographs can demonstrate generalized cardiomegaly with overcirculation of the pulmonary vessels. The defect can usually be visualized by echocardiography, although small defects may be missed. Doppler echocardiography can often confirm the presence of a shunt.

Therapy depends on use of the animal, severity of clinical signs, and direction of the shunt. Animals with small ventricular septal defects do not typically require therapy and have a good longterm prognosis if significant aortic insufficiency is not present. Animals with a moderate to severe ventricular septal defect and secondary volume overload to the left heart more commonly develop clinical signs, and treatment should be considered. Surgical closure of the defect requires cardiopulmonary bypass and is often limited by expense and availability. Percutaneous transcatheter closure can be considered for muscular septal defects and involves placement of an occluder or coil. Pulmonary artery banding to increase right ventricular outflow tract resistance, and thus decrease left-to-right shunting, can be considered. Medically, the use of drugs to reduce systemic vascular resistance (eg, vasodilators) may help to

decrease the degree of left-to-right shunting. With right-to-left shunting, surgical closure of the defect is generally contraindicated. Phlebotomy to relieve the effects of polycythemia or use of hydroxyurea may be considered to relieve clinical signs; however, the prognosis is poor to guarded. Animals diagnosed with a ventricular septal defect should not be bred; the defect has been demonstrated to be heritable in at least one breed (English Springer Spaniels).

ATRIAL SEPTAL DEFECTS

A communication between the atria may be the result of a patent foramen ovale or a true atrial septal defect. During fetal life, the foramen ovale, a flapped oval opening of the interatrial septum, allows shunting of blood from the right atrium to the left atrium to bypass the nonfunctional lungs. This flapped oval opening develops between two septa that make up the interatrial septum: the septum primum and septum secundum. At birth, the drop in right atrial pressure and rise in left atrial pressure cause the foramen ovale to close and shunting to cease. Increased right atrial pressure may prevent closure of the foramen ovale and lead to persistent shunting through a patent foramen ovale. This does not represent a true atrial septal defect, because the septa have formed normally. A true atrial septal defect is an opening or hole within the interatrial septum, which allows blood to shunt from the atrium with the greater pressure. Septum secundum defects occur high in the interatrial septum, near the foramen ovale, and are the most common type. Septum primum defects are located in the most apical portion of the interatrial

septum, near the AV junction, and are often a component of AV septal (AV canal) defects. Sinus venosus defects are most often located at the junction of the right atrium and cranial vena cava.

Pathophysiology: In most cases, blood shunts from the left atrium to the right atrium, causing a volume overload of the right-sided chambers. The magnitude of shunting depends on the size of the defect, the ratio of pulmonary to systemic vascular resistance, and the relative compliance of the two ventricles. Excessive blood flow through the right-side chambers results in their dilation and hypertrophy. Pulmonary vasoconstriction and development of pulmonary hypertension may occur as a consequence of excessive pulmonary blood flow and may precipitate right-side CHF. In conditions associated with high right atrial pressure (eg, pulmonic stenosis), shunting may occur from right-to-left across a patent foramen ovale or atrial septal defect, potentially resulting in cyanosis and polycythemia.

Clinical Findings and Treatment: Signs of right heart failure (eg, ascites, jugular venous distention) may be present. A soft ejection-type systolic murmur is usually present over the pulmonic valve area, reflecting increased blood flow through the pulmonic valve. Blood flow through the defect itself does not produce a murmur due to the low velocity of shunt flow. Prolonged ejection time of the right ventricle may result in a split second heart sound. Electrocardiography may reveal evidence of right ventricular or right atrial enlargement (right axis shift, deep S waves, tall P waves). Right bundle-branch block and arrhythmias can also be noted. Radiographically, there are variable degrees of right ventricular enlargement and prominence to the pulmonary vessels indicating pulmonary overcirculation. Echocardiography is indicated and demonstrates varying degrees of right atrial and right ventricular dilation, as well as identification of the defect as a loss of echogenicity at the interatrial septum. The normal loss of echogenicity of the fossa ovale (artifactual drop out) should not be interpreted as an atrial septal defect. Doppler evaluation confirms shunting through the defect and increased ejection velocities across the pulmonic valve. Surgical correction may be attempted but is associated with high expense and mortality. Animals with small or medium-sized septum secundum defects

Echocardiographic image of a secundum-type atrial septal defect (ASD) in a dog. RA = right atrium, LA = left atrium, RV = right ventricle, LV = left ventricle. Courtesy of Dr Sandra Tou.

can tolerate the defects well, and many of these defects are noted as an incidental finding in older animals. Larger defects, such as noted with septum primum defects or endocardial cushion defects, are more likely to cause right-side CHF. The prognosis is guarded to poor in these cases, although many dogs show no clinical signs for years. For dogs with large defects and significant volume overload, surgical or interventional correction is possible. Surgical closure of the defect requires cardiopulmonary bypass and is often limited by expense and availability. Transcatheter closure using a septal occluder has been reported for secundum and muscular defects.

RIGHT-TO-LEFT SHUNTS

TETRALOGY OF FALLOT

Tetralogy of Fallot is the most common defect that produces cyanosis. It results from a combination of four components: pulmonic stenosis, large ventricular septal defect, right ventricular hypertrophy, and dextropositioning (overriding) of the aorta. A single conotruncal malformation (cranially displaced formation of the upper portion of the interventricular septum) is believed to result in narrowing of the right ventricular outflow tract (pulmonic stenosis), overriding of the aorta, and the ventricular septal defect. The right ventricular concentric hypertrophy is simply a consequence of the pulmonic stenosis. The pulmonic stenosis may be valvular, infundibular, or both. Breeds predisposed to tetralogy of Fallot include Keeshonds, English Bulldogs, and Wirehaired Fox Terriers. The trait is inherited in Keeshonds and presumably in other breeds. This defect has been recognized in other breeds of dogs and in cats.

Pathophysiology: The hemodynamic consequences of tetralogy of Fallot depend primarily on the severity of the pulmonic stenosis, the size of the ventricular septal defect (which is typically large and nonrestrictive), and the ratio of pulmonary to systemic vascular resistance. The direction and magnitude of the shunt through the septal defect depends in large part on the relative resistances to flow between the pulmonic circulation (obstructed by the pulmonic stenosis) and the systemic circulation. Consequences include reduced pulmonary blood flow

(resulting in fatigue, shortness of breath) and generalized cyanosis (resulting in polycythemia and weakness) caused by the mixing of deoxygenated blood from the right ventricle with oxygenated blood from the left ventricle. Because of venous admixture, the kidneys release erythropoietin, resulting in polycythemia (*see* p 43). The increased blood viscosity associated with polycythemia can lead to sludging of blood and poor capillary perfusion. Consequences of polycythemia include ocular changes, bleeding diathesis, and neurologic abnormalities (ataxia, seizures).

Clinical Findings and Treatment:

Typical historical features include stunted growth, exercise intolerance, cyanosis, collapse, and seizures. A precordial thrill may be felt in the area of the pulmonic valve, and in most cases, a murmur of pulmonic stenosis is present. The intensity of the murmur is attenuated when severe polycythemia is present, and in some affected animals, a cardiac murmur is not present. Electrocardiographically, a pattern of right ventricular enlargement is usually seen (deep S waves in lead II, right axis shift), and arrhythmias are infrequent. Radiographs demonstrate variable right heart enlargement and undersized pulmonary vessels. Echocardiography confirms the diagnosis. Overriding (rightward displacement) of the aortic root, right ventricular hypertrophy, and a ventricular septal defect are evident. The left-side chambers may be small as a result of decreased pulmonary venous return. Routine contrast echocardiography demonstrates right-to-left shunting at the level of the ventricular septal defect. Flow through the defect can also be detected by Doppler echocardiography.

β -adrenergic blockade has been used to reduce the dynamic component of right ventricular outflow obstruction and to attenuate β -adrenergic-mediated decreases in systemic vascular resistance. Increases in systemic vascular resistance lower the magnitude of shunting. Polycythemia should be controlled by periodic phlebotomy to resolve clinical signs of polycythemia. The prognosis is guarded, but animals with mild to moderate shunting may reach adulthood.

Treatment options include surgical and medical management. Corrective surgery has been reported in dogs but is rarely performed. Palliative surgical techniques to relieve clinical signs associated with tetralogy of

Fallot are also rarely performed and include techniques to produce systemic to pulmonary anastomoses such as a modified Blalock-Taussig shunt. These procedures increase blood flow to the lungs to reduce signs of pulmonary hypoperfusion and systemic hypoxia. In some cases, reducing pulmonic stenosis is palliative. Surgical valvuloplasty or balloon valvuloplasty of the pulmonic stenosis are also options.

OTHER CYANOTIC HEART DISEASES

PDA, ventricular septal defect, and atrial septal defect with Eisenmenger syndrome are described previously. Other cyanotic heart diseases, including truncus arteriosus, ventricular septal defect with pulmonary atresia, double-outlet right ventricle, and D-transposition of the great arteries, are rare in dogs and cats.

CONDITIONS OF THE ATRIOVENTRICULAR VALVES

MITRAL VALVE DYSPLASIA

Congenital malformation of the mitral valve complex (mitral valve dysplasia) is a common congenital cardiac defect in cats. Canine breeds predisposed are Bull Terriers, German Shepherds, and Great Danes. Mitral valve dysplasia results in mitral insufficiency and systolic regurgitation of blood into the left atrium. Any component of the mitral valve complex (valve leaflets, chordae tendineae, papillary muscles) may be malformed, and often more than one component is defective.

Pathophysiology: Malformation of the mitral valve complex results in significant valvular insufficiency. Chronic mitral regurgitation leads to volume overload of the left heart, which results in dilatation of the left ventricle and atrium. Severe mitral regurgitation can subsequently result in pulmonary venous congestion and left-side CHF. Dilatation of the left-side chambers predisposes affected animals to arrhythmias. When mitral regurgitation is severe, cardiac output decreases and signs of poor cardiac output may occur (weakness, syncope). In some cases, malformation of the mitral valve complex causes a degree of valvular stenosis as well as insufficiency (see p 85).

Clinical Findings and Treatment: Clinical signs correlate with the severity of the defect. Affected animals may display signs of left-side CHF. A holosystolic murmur of mitral regurgitation is prominent at the left cardiac apex. A diastolic heart sound (gallop rhythm) is present in some cases. Affected animals may have a precordial thrill over the left cardiac apex. Electrocardiography may demonstrate atrial arrhythmias (atrial premature complexes, atrial fibrillation), especially in severely affected animals with left atrial dilatation. There may also be evidence of both left atrial (widened P waves) and left ventricular enlargement. Thoracic radiographs may demonstrate severe left atrial enlargement. Left ventricular enlargement and pulmonary venous congestion can also be noted. Echocardiography demonstrates malformation of the mitral valve complex (fused chordae tendineae and thickened, immobile valve leaflets, abnormal appearance to the papillary muscles) and left atrial and ventricular dilatation. Doppler echocardiography demonstrates severe mitral regurgitation. Evidence of mitral stenosis can be identified on the echocardiogram (see p 85).

Prognosis for animals with clinical signs and severe disease is poor. Mildly affected animals may remain free of clinical signs for several years. Animals with CHF should be treated medically. For therapy of progressive left-side CHF, see MANAGEMENT OF HEART FAILURE, p 103.

TRICUSPID VALVE DYSPLASIA

Congenital malformation of the tricuspid valve complex is seen in dogs and cats. Breeds predisposed are Labrador Retrievers and German Shepherds. Tricuspid dysplasia results in tricuspid insufficiency and systolic regurgitation of blood into the right atrium. Rarely, tricuspid valve stenosis can be noted. Chordae tendineae are commonly shortened or absent, and tricuspid valve leaflets may be thickened or adhered to the ventricular or interventricular septal wall. Other concurrent congenital anomalies such as mitral valve dysplasia, septal defects, subaortic stenosis, or pulmonic stenosis may be present. In Ebstein anomaly, a variant of tricuspid dysplasia, the tricuspid valve is displaced toward the cardiac apex.

Pathophysiology: Malformation of the tricuspid valve results in significant valvular insufficiency. Chronic tricuspid regurgitation leads to volume overload of the right heart,

dilating the right ventricle and atrium. Pulmonary blood flow may be decreased, resulting in fatigue and tachypnea. As the pressure in the right atrium increases, venous return is impaired, causing signs of right heart failure (ascites, jugular venous distention, and possibly pleural effusion).

Clinical Findings and Treatment: Clinical signs correlate with the severity of the defect. Affected animals may display signs of right-side CHF. A holosystolic murmur of tricuspid regurgitation is prominent at the right cardiac apex. Atrial arrhythmias, especially paroxysmal atrial tachycardia, are common. Electrocardiography and radiography typically demonstrate right ventricular and right atrial enlargement. The caudal vena cava may be significantly enlarged. Echocardiography demonstrates malformation of the tricuspid valve and varying degrees of right atrial and ventricular dilatation. Doppler echocardiography demonstrates tricuspid regurgitation.

Prognosis for animals with clinical signs is highly dependent on the severity of disease and the degree of tricuspid regurgitation. For dogs with right heart failure, CHF therapy and periodic abdominocentesis may be needed to control peritoneal effusion.

MITRAL VALVE STENOSIS

Mitral valve stenosis is a narrowing of the mitral valve orifice caused by abnormalities of the mitral valve, resulting in obstruction to left ventricular inflow. This congenital abnormality is rare in dogs and cats and can occur together with other congenital defects such as subaortic stenosis, mitral valve dysplasia, and pulmonic stenosis.

Pathophysiology: The disease results in increased resistance to left atrial outflow, creating a pressure gradient between the left atrium and left ventricle. This leads to left atrial enlargement and increases in pulmonary venous and capillary wedge pressures. Pulmonary edema can develop as a consequence, and syncope occurs in some cases.

Clinical Findings and Treatment: Mitral stenosis can result in a diastolic heart murmur that is typically low-grade (I-II/VI). If concurrent mitral valve dysplasia is present, a systolic murmur with maximum intensity at the left cardiac apex may be heard. Radiographs demonstrate varying degrees of left atrial enlargement and pulmonary edema in animals with left-side CHF. Electrocardiography may demonstrate

widened P waves (indicating left atrial enlargement) and supraventricular arrhythmias. Echocardiography provides a definitive diagnosis. Doming of the mitral valve leaflets toward the left ventricle during diastole, left atrial enlargement, and thickening of the mitral valve leaflets can be noted. Doppler echocardiography demonstrates turbulent diastolic flow across the mitral valve, beginning at the mitral valve and extending into the left ventricle. A pressure gradient is documented between the left atrium and left ventricle in early diastole.

Medical management of animals with mitral valve stenosis involves use of diuretics and dietary sodium restriction. Excessive diuresis should be avoided, because this can reduce cardiac output severely. Surgical or interventional therapy options include closed commissurotomy (disruption of the stenosis without the use of bypass), open commissurotomy, mitral valve replacement, and balloon valvuloplasty.

VASCULAR RING ANOMALIES

Pairs of embryonic aortic arches exist during early fetal development and subsequently give rise to the carotid arteries (third arches), the aortic arch (left fourth arch), and the pulmonary arteries and ductus arteriosus (sixth arches). The other aortic arches regress, although the first aortic arches also become part of the maxillary arteries. Congenital defects may arise if development or dissolution of the aortic arches is disrupted. Multiple vascular ring anomalies have been reported in dogs, including persistent right aortic arch, double aortic arch, left aortic arch with right ligamentum arteriosum, and retroesophageal subclavian arteries.

PERSISTENT RIGHT AORTIC ARCH

Persistent right aortic arch is the most common vascular ring anomaly in dogs (German Shepherds and Irish Setters in particular) and has also been reported in cattle, horses, and cats. The right aortic arch fails to regress normally, resulting in entrapment of the esophagus and trachea at the level of the heart base. The structures are encircled by the persistent arch on the right, by the ligamentum arteriosum on the left and dorsally, and by the base of the heart ventrally. The esophagus is typically compressed, leading to the most common clinical sign of regurgitation (often noted at weaning). Aspiration pneumonia is

common in affected animals. Surgery is recommended to transect the ligamentum arteriosum to free the esophagus from entrapment. Radiographically, right-ward deviation of the trachea on dorsoventral or ventrodorsal view is highly sensitive and specific for the diagnosis of persistent right aortic arch. CT can confirm the diagnosis before surgery and assist surgical planning.

MISCELLANEOUS CONGENITAL CARDIAC ABNORMALITIES

Peritoneopericardial diaphragmatic hernia is the most common congenital pericardial disease in dogs and cats. It results from abnormal development of the dorsolateral septum transversum or from failure of the lateral pleuroperitoneal folds and the ventromedial pars sternalis to unite. The result is herniation of abdominal viscera into the pericardial sac. The liver is the most commonly herniated organ, followed by the small intestine, spleen, and stomach. Clinical signs are highly variable, with many animals remaining asymptomatic and the defect being discovered on postmortem examination. Thoracic radiographs can demonstrate lack of a visible diaphragmatic border and small-intestinal loops or liver crossing the diaphragm into the pericardial sac. The suspicion of peritoneopericardial diaphragmatic hernia is heightened when abdominal organs are seen adjacent to the heart on echocardiogram. A contrast radiographic examination using oral barium may also identify small-intestinal loops or stomach in the pericardial sac. CT can usually confirm the diagnosis before surgery. In animals with respiratory signs or signs relatable to organ entrapment, the hernia should be surgically reduced.

Cor triatriatum sinister and dexter result from a fibrous membrane dividing the left or right atrium, respectively. Cor triatriatum sinister is a rare defect of cats. It occurs when the common pulmonary vein fails to regress normally; as a result, a fibrous membrane persists within the left atrium, dividing the left atrium into two subchambers. There are commonly one or more perforations in the separating membrane, allowing communication between the two portions of the atrium. The proximal, high-pressure subchamber receives pulmonary venous return, while the distal, low-pressure subchamber is adjacent to the mitral valve and contains the left auricular appendage. Affected cats can present in left heart failure, with pulmonary edema, pleural

effusion, or both. Surgical resection and balloon dilation of the membrane using a surgical approach have been reported.

Cor triatriatum dexter is a rare defect of dogs. It is caused by persistence of the right valve of the sinus venosus. The remaining fibrous membrane partitions the right atrium into two subchambers; the cranial vena cava and tricuspid valve are associated with the low-pressure subchamber (true right atrium), whereas the caudal vena cava and coronary sinus are typically associated with the high-pressure subchamber. The membrane may contain one or more perforations, or be imperforate. The degree of blood flow between the subchambers determines the severity of disease. Dogs with more severe septation often present with right heart failure (typically ascites). Surgical resection and transcatheter balloon dilation of the membrane are treatment options. CHF should be medically managed before surgery.

Double chamber right ventricle is an uncommon defect in which an anomalous muscle bundle divides the right ventricle into two chambers. The muscle bundle leads to obstruction of the right ventricular outflow tract, creating a high-pressure proximal subchamber (receiving inflow through the tricuspid valve) and a low-pressure distal subchamber distal to the obstruction. Increased pressure in the proximal subchamber leads to left atrial dilatation and subsequent right heart failure. A systolic ejection murmur is often evident on auscultation. Definitive therapy requires open-heart surgery to resect the muscle bundles, which requires cardiopulmonary bypass. Balloon valvuloplasty has not proved to be a successful treatment option.

Anomalous pulmonary venous connection is a congenital abnormality in which varying numbers of pulmonary veins (from one to all) attach to the right atrium or a systemic vein.

Endocardial cushion defects (AV canal defects, persistent AV ostium, AV septal defects) involve abnormalities of endocardial cushion development and can produce septum primum defects, AV valve abnormalities, and ventricular septal defects.

Dextrocardia, positioning of the heart in the right hemithorax, can be seen as a congenital cardiac defect and by itself is typically benign. It can also be seen in combination with **situs inversus** (an abnormal orientation of the organs of the body). The combination of these defects is typically noted in animals with other concurrent abnormalities such as sinusitis, bronchitis, and bronchiectasis.

HEART DISEASE AND HEART FAILURE

Heart disease is defined as any functional, structural, or electrical abnormality of the heart. It encompasses a wide range of abnormalities, including congenital abnormalities (see p 76) as well as anatomic and physiologic disorders of varying causes. Heart disease can be classified by various characteristics, including whether the disease was present at birth or not (eg, congenital or acquired), cause (eg, infectious, degenerative, genetic or heritable), duration (eg, chronic or acute), clinical status (eg, left heart failure, right heart failure, or biventricular failure), by anatomic malformation (eg, ventricular septal defect), or by electrical disturbance (eg, atrial fibrillation, ventricular premature complexes).

Heart failure is usually the end result of severe, overwhelming systolic and/or diastolic cardiac dysfunction that most commonly results in the formation of edema or effusion (eg, pulmonary edema, pleural effusion, ascites) severe enough to cause clinical signs (eg, tachypnea, dyspnea, abdominal distension). It may also produce signs referable to poor perfusion (low cardiac output). This most commonly happens in late stage chronic heart failure; rarely, it may be due to acute heart failure (eg, ruptured chorda tendineae). The most common abnormalities in systole that lead to heart failure are decreased contractility (eg, dilated cardiomyopathy), severe valvular regurgitation (eg, mitral regurgitation), and left-to-right shunting cardiac defects (eg, ventricular septal defect, patent ductus arteriosus). Myocardial fibrosis is the most common abnormality that causes severe diastolic dysfunction, as seen in cats with hypertrophic cardiomyopathy. Heart disease can be present without ever leading to heart failure. Heart failure, however, can occur only if severe heart disease is present.

DIAGNOSIS OF HEART DISEASE

The diagnosis of heart disease typically involves evaluating the signalment, history, and physical examination findings, as well as results of diagnostic tests such as radiography, electrocardiography, and echocardiography. Rarely, more specialized tests such as cardiac catheterization, CT, MRI, or nuclear studies are necessary.

History and Signalment

For animals with suspected heart disease, the signalment (age, breed, sex) helps formulate a differential diagnosis list. The signalment influences the relative importance of possible heart diseases (eg, endocarditis is rare in cats and small dogs but more common in cows and large dogs) as well as many specific abnormalities (eg, breed predispositions for certain congenital defects, dilated cardiomyopathy (DCM), myxomatous valve degeneration, etc).

Animals presenting with heart disease may have no clinical signs or have a history of tachypnea, dyspnea, abdominal distention (ascites), subcutaneous edema, weakness, syncope (fainting), cyanosis, exercise intolerance, or weight loss. A few historical findings are more species specific, including peripheral or ventral (subcutaneous) edema in horses and cattle. Cats rarely cough with heart failure and more commonly present with a history of tachypnea/dyspnea (which may be subtle and go unnoticed by the owner) and anorexia. In dogs, coughing can occur due to pulmonary edema, but many more dogs that cough do so because of lung disease (eg, chronic bronchitis), so extreme care must be taken when evaluating dogs (especially older, small-breed dogs) with a cough and a heart murmur because most are not in heart failure.

Physical Examination

A complete physical examination should be performed on any animal being evaluated for heart disease or that presents with signs that could be attributable to heart disease. The cardiac physical examination should start with auscultation of the heart. Auscultation should be done in as quiet of an environment as possible. In all cats, small dogs, and small mammals, a pediatric stethoscope should be used and only the diaphragm of the stethoscope needs to be used, because heart sounds, including gallop sounds, in animals this size are not low enough in frequency to require the bell. In large dogs and large animals, the bell should also be used. In general, the left apex beat should first be located by palpation, then the head of the stethoscope placed over it (mitral area). The stethoscope head then should be inched forward and upward to the left base (pulmonic and aortic area).

In any young animal, care should also be taken to place the stethoscope head farther forward (left axillary region) to listen for a continuous murmur (patent ductus arteriosus). Then the right apical region should be ausculted. In a young animal suspected of having congenital heart disease, the right base and along the neck should also be ausculted.

In addition to auscultation of the thorax, palpation of the ventral thorax should be performed to assess for the presence of a thrill (vibration created by turbulent blood flow that can be palpated with the fingertips) and alterations in intensity or location of the apex beat. Concurrent auscultation and palpation of the pulse should also be performed to identify pulse deficits (premature beats, atrial fibrillation) and to assess the strength and character of the systemic arterial pulse. Pulmonary auscultation should be performed (*see below*). Mucous membrane color and refill time should be assessed but are often normal even in animals with severe heart failure. Cyanosis may be present if the animal is severely hypoxemic. Limbs should be examined for the presence of edema, and the abdomen should be assessed for presence of ascites (palpation and ballottement). The jugular veins should be examined with the animal in a standing or sitting position for presence of abnormal distention and pulsation. A normal jugular vein will be distended and may pulsate when an animal is laterally recumbent.

Heart Sounds: Heart sounds are generated by the rapid acceleration and deceleration of blood and secondary vibrations in the cardiohemic system and are associated with valve closure. Four heart sounds can potentially be ausculted. The first heart sound (S_1) is associated with closure of the atrioventricular (mitral and tricuspid) valves, and the second heart sound (S_2) with closure of the semilunar (aortic and pulmonic) valves. The third heart sound (S_3) occurs in early diastole and is a result of the ventricles vibrating at the frequency heard at the time of rapid cessation of ventricular filling, and the fourth heart sound (S_4) is in late diastole and associated with atrial systole (atrial contraction). All four sounds can be heard in a healthy horse. In healthy cattle, typically only S_1 and S_2 are audible, although S_3 or S_4 can sometimes be heard. IV fluid administration in cattle can be used to accentuate S_3 and/or S_4 . In dogs, cats, and ferrets, S_1 and S_2 are the only heart sounds normally audible. Less is known about heart

sounds in goats, sheep, and pigs; however, only S_1 and S_2 are believed to be audible in these species.

Three-Heart-Sound Rhythms (Gallop Heart Sounds and Systolic Clicks): A gallop heart sound (rhythm) is the presence of S_1 and S_2 accompanied by an interceding sound or sounds in diastole (between S_2 and S_1) that is either an accentuated third heart sound (S_3) or fourth heart sound (S_4), or both. These are classified as protodiastolic (S_3), presystolic (S_4), or sununation gallop heart sounds (fusion of S_3 and S_4). The most common gallop heart sound noted in dogs is a result of an accentuated S_3 and typically occurs secondary to a normal quantity of blood “dumping” into a stiff left ventricle (eg, DCM), or a massive amount of blood “dumping” into a normal left ventricle in early diastole (eg, mitral regurgitation and patent ductus arteriosus). An S_4 gallop heart sound is caused by atrial contraction pushing blood into a stiff left ventricle. In cats with cardiomyopathy, especially hypertrophic cardiomyopathy, the left ventricle is stiff, so both third and fourth heart sounds can be heard. However, because the heart rate commonly exceeds 160–180 bpm in cats in an examination room, it is usually impossible via auscultation to determine whether the gallop sound is due to an S_3 or S_4 gallop; often, it is a summation of the two.

Gallop rhythms are not the only three-heart-sound rhythms that can be ausculted. Systolic clicks also occur in dogs and cats and are much more common than gallop rhythms in dogs. A systolic click is a short, sharp sound that occurs during mid to late systole. In dogs, they occur mostly in middle-aged to older small-breed dogs and are thought to be evidence of early myxomatous AV valve degeneration causing mitral valve prolapse (as they are in people). A systolic murmur may or may not also be present. Although systolic clicks are reasonably easy to distinguish from a gallop sound in a dog (they are usually relatively loud and high pitched whereas a gallop sound is soft and low-pitched), they often sound identical to a gallop sound in a cat. Thoracic radiographs can be used to help make the distinction between the two. In cats, gallop sounds are heard only in those with severe heart disease. Systolic clicks are usually heard in cats with an otherwise normal heart. So if the heart is not enlarged, the sound is more likely a systolic click. Systolic clicks usually are single but may be multiple and can vary in intensity (even

completely disappearing) depending on cardiac loading conditions. Rarely, a three-heart-sound rhythm can be caused by a bigeminal rhythm.

Splitting of S_1 or S_2 : Splitting of S_1 is caused by discordant closure of the mitral and tricuspid valves, which can occur when there is asynchronous contraction of the ventricles as in left or right bundle-branch block, cardiac pacing, and ectopic premature ventricular beats. Splitting of S_1 can also occur in healthy, large-breed dogs and in large animals. Delayed closure of the pulmonic valve (in relation to the aortic valve) results in splitting of S_2 . Splitting of S_2 can be a normal finding in horses during respiration. Abnormal splitting of S_2 has been associated with pulmonary hypertension, as in pulmonary emphysema of horses and severe heartworm disease in dogs. Other possible causes include a large atrial septal defect, right bundle-branch block, or premature ventricular ectopic beats of left ventricular origin. Delayed closure of the aortic valve (paradoxical splitting of S_2) might be heard with left bundle-branch block or premature ventricular ectopic beats of right ventricular origin. A split second heart sound is a subtle finding that usually must be heard several times before it can be appreciated.

Heart Murmurs: Heart murmurs are audible vibrations (sound) emanating from the heart or major blood vessels. The vast majority are due to turbulent blood flow brought on by high velocity blood flow that produces a mixed-frequency murmur. Much less commonly, they are due to vibrations of cardiac structures such as part of a valve leaflet or chordal structure that produces a single frequency (musical) murmur. Murmurs are typically defined relative to timing (systole, diastole, continuous), intensity (grade I–VI), and location (eg, left apex, left base) but can also be characterized by frequency (pitch), quality (eg, musical), and configuration (eg, crescendo-decrescendo).

A systolic murmur is classically described as either ejection (crescendo-decrescendo) or regurgitant (holosystolic, plateau). However, making this distinction is often difficult, even for an experienced examiner, especially when the heart rate is fast. Ejection-quality systolic murmurs typically demonstrate the greatest intensity during mid-systole and appear diamond-shaped on phonocardiography. They are most commonly produced by stenotic lesions at the semilunar valves (eg,

pulmonic stenosis or subaortic stenosis). A classic regurgitant systolic murmur demonstrates a constant intensity throughout systole and is commonly caused by mitral or tricuspid regurgitation (eg, myxomatous degeneration of the mitral valve) or a ventricular septal defect. However, these murmurs may also change intensity during systole. Diastolic murmurs are typically decrescendo (decreasing in intensity through diastole) and usually the result of aortic insufficiency (such as that caused by aortic valve infective endocarditis in dogs or degenerative disease in horses). In horses, the murmur of aortic insufficiency is most commonly musical, although “musical” in this context is a technical term (single frequency). They may sound like a dive-bomber or grunting. A continuous murmur is most commonly the result of patent ductus arteriosus and occurs throughout systole and diastole. A continuous murmur varies in intensity over time, typically being most intense at the end of ventricular ejection (second heart sound) and then decreasing in intensity through diastole. A to-and-fro murmur describes a murmur that occurs both in systole and in diastole (eg, in an animal with subaortic stenosis and aortic insufficiency).

In horses, early systolic and diastolic murmurs can be noted in the absence of heart disease or anemia. The point of maximal intensity is typically located over the left heart base. A short, high-pitched, squeaking, early diastolic cardiac murmur is sometimes heard in healthy, young horses. Often, a systolic heart murmur is heard in a cat without cardiac disease. Some of these systolic murmurs are due to an increase in right outflow tract flow velocity (dynamic right ventricular outflow tract obstruction). Innocent cardiac murmurs are also sometimes noted in immature cats and dogs (<3 mo old) and may be the result of a relative increase in stroke volume (stroke volume/aortic cross-sectional area).

Heart murmur intensity is classified as follows: Grade I—the lowest intensity murmur that can be heard, typically detected only while auscultation is performed in a quiet room; Grade II—a faint murmur, easily audible, and restricted to a localized area; Grade III—a murmur immediately audible when auscultation begins; Grade IV—a loud murmur immediately heard at the beginning of auscultation but not accompanied by a thrill; Grade V—a very loud murmur with a palpable thrill; and Grade VI—an extremely loud murmur with a thrill and that can be

heard when the stethoscope is just removed from the chest wall.

Arrhythmias: Arrhythmias are abnormalities of the rate, regularity, or site of cardiac impulse formation and are noted during auscultation. Other terms such as dysrhythmia and ectopic rhythm are also used to describe arrhythmias. The presence of a cardiac arrhythmia does not necessarily indicate the presence of heart disease; some arrhythmias are normal, such as sinus arrhythmia in a dog and second-degree AV block in a horse; many cardiac arrhythmias are clinically insignificant and require no specific therapy. Some arrhythmias, however, may cause severe clinical signs, such as syncope, or lead to sudden death. Numerous systemic disorders may be associated with abnormal cardiac rhythms. (For discussion of specific arrhythmias, *see* p 94.) Common auscultatory findings in animals with an arrhythmia are a rate that is too slow (bradycardia), a rate that is too fast (tachycardia), premature beats (a beat is heard too early), an irregular rhythm, and pauses in the rhythm. Whenever an abnormal rhythm is heard, an ECG should be performed.

Pulses: The arterial pulse is the rhythmic expansion of an artery that can be digitally palpated (or visualized) during physical examination. Physiologically, the pulse pressure is the systolic pressure minus the diastolic pressure. The arterial pulse can be felt best in several different locations. For example, in dogs and cats, the arterial pulse is typically palpated at the femoral artery. In horses, the facial artery is usually used. To feel the maximum pulse, an examiner must first occlude the artery with his or her fingers and then gradually decrease the digital pressure until the maximum pulse is felt. A weak pulse (a reduction in pulse pressure) is usually caused by a decrease in systolic pressure and can be noted with decreased stroke volume in animals in heart failure, hypovolemic shock, or cardiac tamponade, as well as with subaortic stenosis. However, a weak pulse can also be felt in a healthy animal if the artery is not palpated appropriately or in an obese or heavily muscled animal. A bounding pulse (an increase in pulse pressure) is usually caused primarily by a reduced diastolic pressure and can be noted with aortic insufficiency and patent ductus arteriosus. However, the pulse in a thin, athletic dog may also feel stronger than expected. The pulse felt with mitral regurgitation is often normal but at times may be termed “brisk.”

A pulse deficit is an absent pulse despite auscultation of a heart beat and is thus detected during simultaneous auscultation and pulse palpation. This often occurs as the result of a premature beat that occurs so early that the ventricles are unable to fill sufficiently, resulting in a reduced stroke volume that produces either a weak pulse or no pulse. Atrial fibrillation also produces pulse deficits as well as alternating pulse strength.

Dogs with severe subaortic stenosis may have a pulse pressure that slowly increases during ventricular systole and reaches a peak pressure late in systole called *pulsus parvus et tardus*. *Pulsus paradoxus* is a decrease in pulse pressure during inspiration and an increase in pulse pressure during expiration. This is a normal occurrence in animals, but it is too subtle to observe on physical examination. Animals with cardiac tamponade (severe pericardial effusion), however, demonstrate an exaggeration of this finding, so it becomes detectable. *Pulsus alternans* is an alternating strong and weak pulse while the animal is in sinus rhythm; it can be noted (albeit rarely) in animals with severe (usually terminal) myocardial failure or tachyarrhythmias. *Pulsus bigeminus* is an alternating strong and weak pulse caused by an arrhythmia such as ventricular bigeminy. The weaker pulse (during the ventricular premature contraction) typically follows a shorter time interval than the stronger pulse.

Jugular venous pulsation can be noted in normal animals but typically does not extend beyond the thoracic inlet.

Respiratory Sounds: Pulmonary edema may develop as a result of congestive heart failure (CHF). Animals with pulmonary edema will be hyperpneic (increased rate and depth of respiration) and may be dyspneic. The increased depth of respiration may increase bronchovesicular sounds. Fine, and less commonly, coarse crackles might be auscultated in animals with pulmonary edema, but fine crackles are usually heard only at the end of a deep inspiration. Coarse crackles in dogs are most commonly heard with chronic bronchitis. Pulmonary edema is often silent (no auscultatory abnormality). Respiratory sounds may be absent in animals with pleural effusion, especially ventrally.

Ascites: Abdominal distention may occur as a result of gas, soft tissue, or fluid accumulation. Animals with right heart failure (eg, due to severe heartworm

disease, severe tricuspid valve dysplasia, cardiac tamponade) can develop ascites. Because there are many causes of ascites, it is important to evaluate the jugular veins in every case in which ascites is present. If right heart failure is the cause of the ascites, the jugular veins may be distended (but often are not in dogs and cats) by the increase in right atrial pressure. If the jugular veins are not distended in a dog or cat with ascites, a hepatojugular reflux test should be performed. To do this, one person examines the jugular veins with the animal standing or sitting, while another places firm and steady pressure on the abdomen. In a dog or cat in right heart failure, the jugular veins should distend well up the neck with this maneuver. If ascites is present without jugular venous distension and with a negative hepatojugular reflux test, then extracardiac causes of the ascites should be considered.

Synchronous Diaphragmatic Flutter:

The diaphragm may contract synchronously with the heart to produce loud thumping noises on auscultation and usually visible contraction in the flank area. The syndrome results from stimulation of the phrenic nerve by atrial depolarization and occurs primarily when there is a marked electrolyte or acid-base imbalance, particularly with hypocalcemia. It is most common in horses and dogs. It is seen most commonly in dogs in association with hypocalcemia and electrolyte disturbances induced by GI disease. Similarly, in horses it is seen with hypocalcemia and in endurance horses that are dehydrated and electrolyte depleted.

Radiography

Thoracic radiographs frequently provide valuable information in the assessment of animals with or suspected of having heart disease. However, thoracic radiography is rarely performed in horses or cows to evaluate heart disease because of the animal's large size and body conformation, which reduces the quality of the images. In dogs, in which numerous different body types must be dealt with, chest conformation must always be assessed before attempting to evaluate cardiac size. On the lateral view, dogs can be normal, shallow-chested, or deep-chested. On the dorsoventral (DV) or ventrodorsal (VD) views, they can be normal, narrow-chested, or barrel-chested. Many small breeds of dogs are shallow-chested. This makes the cardiac silhouette appear to be enlarged on the lateral view and often necessitates relying on the DV view to

obtain an accurate assessment of size and shape. In deep-chested breeds, even severe cardiomegaly can look normal on the lateral view and, because the heart sits more upright in the chest, can also mask its presence on the DV view (eg, in Doberman Pinschers with DCM). Obesity also interferes with accurate reading of cardiac size by the presence of intrapericardial fat or by pushing the diaphragm forward, reducing the size of the thoracic space and pushing the heart into the cranial and narrower aspect of the thoracic cavity. Because of the marked variation in chest conformation, the changes seen between inspiration and expiration, and the changes seen between systole and diastole, only relatively dramatic changes in overall cardiac size can be identified in most dogs. Consequently, conditions such as mild generalized cardiomegaly cannot be identified on thoracic radiographs. The one chamber where mild, moderate, and severe enlargement can be relatively accurately identified is the left atrium. Finding enlargement of specific cardiac chambers and great vessels makes the presence of heart disease more likely and may also provide clues as to the specific disease present.

Cardiogenic pulmonary edema is a common finding in animals with CHF and may be associated with pulmonary venous congestion. However, the identification of pulmonary edema is often difficult and may not be possible in some dogs and even some cats. Cardiogenic pulmonary edema in dogs is typically found in the caudodorsal aspects of the lungs. In many cases, this region has an interstitial density that is enhanced by age and by expiration, giving a false impression that pulmonary edema is present or masking the presence of pulmonary edema. Digital radiography units, especially if not set up perfectly (to match analog units), have made the diagnosis even harder in many cases. In animals with chronic left heart failure, the left atrium is usually severely and always at least moderately enlarged. In acute heart failure (eg, chorda tendineae rupture), the left atrium may not be enlarged. Pleural effusion can usually be readily identified radiographically. In most species, this is seen with right or biventricular heart failure. However, in cats it is seen most commonly with left heart failure. Resolution of these abnormalities on subsequent thoracic radiographs can be used as one indication of efficacy of therapy. The presence of pulmonary edema or pleural effusion does not definitively confirm a cardiogenic origin or exclude another origin.

Overall cardiac size can be assessed using the vertebral heart scale or score. This is most commonly done using the lateral projection. The maximal diameter of the cardiac silhouette from cranial to caudal is measured, as well as the distance from the carina to the apex of the cardiac silhouette (dorsal to ventral). These lengths are added together and measured in terms of thoracic vertebral bodies, so they are normalized for the size of the animal. The vertebral bodies are measured from the fourth thoracic vertebra caudally. The normal range is 8.5–10.5 vertebral bodies in dogs and 6.9–8.1 in cats. In many cases, it is more important to try to accurately assess the size of the left atrium than the overall size of the cardiac silhouette.

Electrocardiography

Electrocardiography is the recording of cardiac electrical activity from the body surface (surface ECG). It should primarily be used to identify cardiac arrhythmias. It can also identify conduction disturbances that do not alter rhythm and has been used to identify chamber enlargement in dogs and cats. However, its inaccuracy in identifying chamber enlargement and the advent of diagnostic ultrasound have diminished this role. As opposed to small animals in which the Purkinje fibers penetrate only $\sim 1/3$ of the way into the myocardium, Purkinje fibers in horses and cattle penetrate throughout the myocardium, resulting in “burst” depolarization of the ventricles and reduced waveform production and complexes on the surface ECG. Consequently, there is no relationship between complex height on a surface ECG and chamber enlargement. The most common ECG lead used in large animals is a base-apex that produces large deflections and is used for rhythm analysis. ECGs should be used only to characterize an arrhythmia in an animal with an auscultatory arrhythmia and to monitor rhythm during anesthesia; they should never be used as screening tools, as they are in human medicine (primarily for changes secondary to coronary artery disease).

Waveform Abnormalities: Chamber enlargement can be indicated by waveform abnormalities in dogs and cats, but these abnormalities are commonly absent when there is chamber enlargement and are sometimes present when the heart is normal. In lead II in dogs and cats, wide or notched P waves suggest left atrial enlargement, whereas tall P waves suggest right atrial

enlargement. Tall R waves in leads that have the positive electrode on the left and/or caudal aspect of the body (leads I, II, aVF, CV6LL, and CV6LU) are evidence of left ventricular enlargement. Deep S waves in the same leads in which the positive electrode is on the left side of the heart or the presence of a right-axis deviation suggest right ventricular enlargement. Wide QRS complexes can be seen in animals with either right or left ventricular enlargement; however, they can also be due to conduction disturbances (*see* p 93). The ECG is very insensitive at identifying mild to moderate changes in chamber size and unacceptably insensitive for detecting severe enlargement. Although false-positive findings are less frequent than false-negative findings, they do occur. Consequently, the accuracy is unacceptable, especially when compared with echocardiography and even with thoracic radiography.

Sinus Rhythm and Sinus Node

Abnormalities: The sinus node initiates depolarization of the rest of the heart in a healthy animal, sets the normal rate and rhythm, and is called the normal pacemaker of the heart. It functions as the pacemaker because it is automatic (depolarizes on its own) and does so at a rate faster than the other automatic sites in the heart (AV node and Purkinje fibers). Normal sinus rhythm is regular and originates at the sinus node, indicated on the ECG by a P wave that precedes each normal QRS complex. The rate at which the sinus node fires varies tremendously from species to species and situation to situation. For example, a healthy horse can have a heart rate of 30 bpm at rest and 250 bpm during maximal exercise. Similarly, a healthy dog can have a heart rate in the teens when asleep and ≥ 250 bpm during maximal exercise. A healthy cat can have a heart rate of 240 bpm at rest in an examination room.

Sinus bradycardia is a regular sinus rhythm that is slower than expected for that species and for the situation the animal is in. Sinus bradycardia may be noted in animals overdosed with anesthesia or agents that can result in increased vagal tone (primary or secondary) or reduced sympathetic tone (eg, xylazine, β -adrenergic blocker), hypothermic animals, hypothyroid animals, animals with sick sinus syndrome, or in animals with increased vagal tone secondary to systemic disease (such as respiratory, neurologic, ocular, GI, or urinary tract disease). Treatment for sinus bradycardia is typically not needed unless clinical signs associated with the bradycardia, such as

exercise intolerance, weakness, or collapse, are noted. In dogs and cats, atropine (0.04 mg/kg, IV, IM, or SC) may be considered for treatment of bradycardia. The initiating cause should also be corrected.

Sinus tachycardia is the finding of a regular sinus rhythm at a rate faster than normal but generally appropriate for the situation the animal is in (eg, stress, exercise, heart failure). If the rate is inappropriately high (eg, 200 bpm in an otherwise healthy dog at rest at home), another form of tachycardia (eg, atrial or ventricular) should be considered. Causes include stress (resulting in high sympathetic drive), exercise, hyperthyroidism, fever, pain, hypovolemia, cardiac tamponade, heart failure, or administration of agents that can increase the rate of sinus node discharge (eg, catecholamines). Treatment involves resolving the underlying cause.

Sinus arrhythmia occurs as a result of irregular discharge of the sinus node most commonly associated with the respiratory cycle. The site of impulse formation remains the sinus node; however, the frequency of the discharge varies. Sinus arrhythmia is a normal finding in dogs and horses; it is abnormal in cats in the hospital setting, although it appears to be more common in cats in their home environment. Respiratory sinus arrhythmia is characterized by an increase in heart rate with inspiration and a decrease with expiration. In dogs, sinus arrhythmia can also be seen that is not in sync with respiration. The variation in heart rate is associated with variation in the intensity of vagal tone. It is abolished by reduced vagal tone resulting from excitement, exercise, or administration of vagolytic drugs such as atropine. It may be associated with a wandering pacemaker, which is characterized on the ECG by taller P waves during faster rates and smaller P waves during slower rates.

Sinoatrial (SA) block occurs when the impulse from the SA node fails to be conducted through the surrounding tissue to the atria and ventricles. Thus, no P waves or QRS complexes are noted on the ECG, and the P-P interval surrounding the break in sinus rhythm is an exact multiple of the normal P-P interval. This is often difficult to diagnose in dogs because sinus arrhythmia is common, resulting in a variable normal P-P interval.

Sinus arrest (sinoatrial arrest, sinus pause) is the absence of P waves on the ECG for a short period (typically accepted as a pause exceeding twice the normal P-P interval). Sinus arrest is caused by excessive vagal tone, inherent sinus node

disease, or both. This is usually due to some form of sick sinus syndrome (*see below*).

Atrial standstill is characterized as the complete absence of P waves on the ECG and occurs as a result of the atria being unable to be depolarized from the SA node discharge. This occurs either because the atrial myocardium is functionally unable to be depolarized (usually due to hyperkalemia), or because it has been destroyed by a cardiomyopathy or myocarditis (persistent atrial standstill). In hyperkalemia, the sinus node continues to depolarize, and the electrical tracts from the sinus node to the AV node (internodal tracts) continue to function, so the sinus node controls the rate (albeit at a slower rate). With persistent atrial standstill, the sinus node is destroyed, so the animal usually has an AV nodal (junctional) escape rhythm with a heart rate in the 40–65 bpm range (dog).

Sick sinus syndrome is a constellation of abnormalities, including ECG changes (sinus arrest, junctional or ventricular escape complexes, and possibly supraventricular tachycardia) and possible weakness or syncope from the bradycardia (usual) or tachycardia (rare). With this clinical syndrome, the principal problem either lies within the SA node or perinodal tissue, or is due to increased vagal tone, or both. In some instances, other portions of the specialized conduction tissue of the myocardium, including the AV node, can also be affected. Therefore, evidence for AV block may also be seen (*see below*). This condition is commonly noted in geriatric dogs, including Miniature Schnauzers and American Cocker Spaniels. Medical therapy consisting of parasympatholytics (eg, propantheline bromide, 0.25–0.5 mg/kg, PO, bid-tid) or sympathomimetics (eg, extended-release theophylline, 10 mg/kg, PO, bid; terbutaline, 0.14 mg/kg, PO, bid-tid in dogs) to increase heart rate can be tried, but these are often ineffective or are effective for only a relatively short time or with unacceptable adverse effects. These drugs may also worsen supraventricular tachyarrhythmias that can occur with sick sinus syndrome. The most effective treatment for the bradycardia is pacemaker implantation.

AV Conduction Disturbances: Atrioventricular (AV) block refers to alteration of impulse conduction through the AV node from the atria to the ventricles. In first-degree AV block (prolonged conduction), the conduction time is increased and is recognized on an ECG as an increased PR interval. This is clinically silent. In second-degree AV block (intermittent conduction),

occasional impulses fail to be conducted through the AV node, bundle of His, or both bundle branches and is characterized by occasional P waves not followed by QRS complexes. During the block, there is no S_1 or S_2 and no arterial pulse. In horses, the sound associated with atrial contraction (S_1) is commonly heard, and the occurrence of S_1 not followed by other heart sounds is diagnostic for second-degree heart block. S_1 may also be audible in dogs with second-degree AV block, but this is much less common. When the PR intervals preceding the dropped beat progressively lengthen, the condition is known as Mobitz type I second-degree AV block or Wenckebach phenomenon. This is usually due to high vagal tone and is the most common type of second-degree AV block seen in horses and puppies. No treatment is indicated. If the PR intervals do not change, the condition is known as a Mobitz type II second-degree AV block. Again, no treatment is indicated, but closer surveillance may be warranted to see whether the block progresses to a more severe form. A third type of second-degree AV block, high-grade second-degree AV block, refers to the situation when the block occurs with every other beat (2:1 [ie, two P waves for every QRS complex]) or more (3:1, 4:1, etc). High-grade second-degree AV block is distinguished from third-degree AV block by identifying an association between the QRS complexes and the P wave preceding each one (same PR interval for each). Dogs with high-grade second-degree AV block can have signs the same as dogs with third-degree AV block (eg, syncope) and are also at increased risk of sudden death.

In third-degree AV or complete heart block, none of the impulses is conducted from the atria to the ventricles. The atrial rhythm (P waves) occurs more rapidly and independently from the ventricular rhythm (QRS complexes; a form of AV dissociation), which originates from subsidiary pacemakers (AV node or Purkinje fibers in the ventricles; nodal and ventricular escape beats, respectively). The heart and pulse rates are usually regular but slow and generally unresponsive to factors or agents that usually increase heart rate (eg, exercise, excitement, atropine). The difference in timing between atrial and ventricular contractions results in variation in ventricular filling and consequent variation in intensity of S_1 (bruit de canon) and possibly arterial pulse pressure. Periodically, the atria contract when the ventricle is in systole, which results in a pulsation in the jugular vein (cannon A wave).

The significance of the AV block varies by species. Both first- and second-degree AV block may be present without outward evidence of cardiac disease. First-degree AV block may result from excessive vagal tone and usually is not significant in dogs or horses unless other evidence of heart disease or pathologic cause of increased vagal tone (eg, CNS or pulmonary disease) or AV nodal disease is present. In all species, second-degree AV block may be indicative of heart disease. However, in horses, Mobitz type I is common and is a normal physiologic response resulting from increased vagal tone. Mobitz type II second-, high-grade second-, and third-degree (complete) AV blocks are always abnormal in all species.

Second- and third-degree AV blocks may be caused by fibrosis, neoplasia, or injury to the AV node, or by hypoxia, increased vagal tone, or electrolyte abnormalities. The ideal treatment would be to correct the underlying cause, although this is not usually possible. High-grade second-degree AV block and third-degree AV block can cause exercise intolerance or, more commonly, weakness, collapse, and syncope. Oral therapy with extended-release theophylline (10 mg/kg, PO, bid), terbutaline (0.14 mg/kg, PO, bid-tid in dogs), or propantheline bromide (0.25–0.5 mg/kg, PO, bid-tid) may occasionally be useful in animals with second-degree AV block, but more aggressive therapy (pacemaker implantation) is usually indicated in symptomatic (eg, syncopal) animals. Third-degree heart block is usually associated with irreversible lesions; the only effective treatment in dogs is pacemaker implantation. Dogs with third-degree AV block are at risk of sudden death and so should have a pacemaker implanted regardless of clinical signs. In cats, third-degree AV block often produces no clinical signs and so requires no therapy. However, problems can arise if it is not identified before anesthesia, and some cats will faint and thus require pacemaker implantation. Third-degree AV block is rare in horses and other species. Pacemakers have been implanted successfully in species other than dogs and cats but has rarely been done.

Common Tachyarrhythmias: Tachyarrhythmias can be divided into supraventricular and ventricular based on their site of origin. Supraventricular premature complexes are premature complexes (as seen on an ECG) that originate from ectopic (nonautomatic) sites above the ventricles (eg, atrial myocardium and AV node). They may also be called atrial or nodal premature

complexes/depolarizations/contractions/beats. Possible sites for ectopic depolarizations include the SA node (rare), atrial myocardium (very common), and AV node (AV junction). Electrocardiographically, supraventricular premature complexes are identified by a QRS complex that usually appears relatively normal but occurs earlier than the next expected normal QRS complex. Variable P wave morphologies may be noted before or after the supraventricular premature complex or may be hidden in the preceding sinus complex or within the premature complex. Supraventricular premature complexes are most commonly a result of atrial enlargement or disease, stress, or other causes of increased sympathetic tone. Supraventricular tachycardia (SVT) is a series of supraventricular premature complexes occurring consecutively. It may be short (nonsustained) or occur for prolonged periods (called sustained when >30 sec). SVT most commonly ranges in rate from 200–350 bpm in dogs. At rates closer to 200 bpm, it may be indistinguishable from sinus tachycardia on a surface ECG. Vagal maneuvers (ocular pressure, carotid sinus massage), precordial blow (chest thump), and IV drug administration (eg, diltiazem) often “break” an SVT into sinus rhythm and either do not change or more gradually slow a sinus tachycardia. Diltiazem (0.5–4 mg/kg, PO, tid) is the most common drug used to treat SVT long-term, but it can also be used IV to break the SVT into sinus rhythm (0.25 mg/kg, IV bolus administered over 2 min, followed 15 min later by up to 0.35 mg/kg, IV bolus administered over 2 min, if needed). Digoxin and β -blockers are also used. An accessory pathway (bypass tract) is a congenital abnormality that forms an electrical connection between an atrium and a ventricle outside the normal connection (AV node/bundle of His). These pathways have been recognized in dogs and cats and may result in supraventricular tachycardia (eg, orthodromic reciprocating tachycardia). Treatment may include radiofrequency catheter (heat) ablation of the bypass tract or, more commonly, oral medications such as procainamide, sotalol, or diltiazem.

Atrial flutter is a rare arrhythmia that often progresses to atrial fibrillation. It is most commonly caused by a reentrant loop within the atria and is classically characterized on the ECG by a “saw-toothed” baseline with relatively normal QRS complexes that can appear in a regular or irregular rhythm. The atrial rate of discharge is very rapid (>400 bpm). Only intermittent atrial impulses are conducted through the AV

node because of its normal long refractory period, so the ventricular rate is slower than the atrial rate.

In dogs and cats, atrial fibrillation is an even more rapid (>600–700 atrial depolarizations/min) atrial rhythm that results in a slower (in the 80–300 bpm range in dogs) and always irregular ventricular rhythm. As in atrial flutter, the AV node is bombarded by frequent atrial depolarizations. The AV node acts as a filter, allowing only some of the depolarizations to reach the ventricles but always in an irregular fashion. In dogs and cats, atrial fibrillation is characterized on the ECG by a supraventricular (normal-appearing QRS complexes) and an irregular ventricular rhythm that is most commonly fast. Once those characteristics are identified, the next thing to look for is the absence of P waves and an undulating baseline that can appear almost flat (fine) or very rough (coarse). The irregular rhythm results in variation in the diastolic filling period of the ventricles, resulting in variability in stroke volume and thus variability in pulse character, including pulse deficits. This also causes variation in the intensity of the heart sounds, especially the second heart sound, creating a heart that sounds like “tennis shoes in a dryer” on auscultation in dogs. In dogs, atrial fibrillation is most commonly associated with underlying cardiac disease. The notable exception occurs in some giant dog breeds, such as Irish Wolfhounds, Scottish Deerhounds, Great Danes, and others, in which the rhythm can develop with an otherwise normal heart (so-called lone or primary atrial fibrillation). Lone atrial fibrillation is the most common form seen in horses (*see below*). All cats in atrial fibrillation have severe underlying heart disease.

The goal of treatment of atrial fibrillation in most dogs and all cats is control of the ventricular rate, ie, the frequency with which QRS complexes are generated from the fibrillatory depolarization waves. Rate control is usually accomplished with digoxin alone, diltiazem alone, or a combination of the two. Diltiazem alone is generally more effective than digoxin alone, and the combination is generally more effective than either alone. A β -blocker, such as atenolol, may also be used but never in combination with diltiazem. These drugs prolong the refractory period of the AV node and slow AV nodal conduction, resulting in fewer atrial depolarizations crossing the AV node to the ventricles. Amiodarone has also been used to control the ventricular response rate, but its adverse effects

(hepatic and thyroid toxicities) limit its use to second-line therapy in animals refractory to the digoxin and diltiazem/atenolol protocol. In rare instances, electrical cardioversion (defibrillation of the heart that is synced to the ECG to prevent causing ventricular fibrillation) is used to convert atrial fibrillation to sinus rhythm. This is generally more rational in a dog with lone atrial fibrillation but has also been done in dogs with severe cardiac disease. In those instances, sinus rhythm commonly reverts back to atrial fibrillation within weeks to months, necessitating reconversion or rate control. Cardioversion is frequently combined with amiodarone administration in an attempt to prolong the time until reversion to atrial fibrillation.

In ruminants, atrial fibrillation is usually paroxysmal and associated with GI tract disorders (eg, vagal indigestion), but it also may be persistent and occur as a sequela of cor pulmonale or with other cardiac diseases.

In horses, atrial fibrillation can usually be diagnosed by identifying an undulating baseline. It most often occurs in the absence of underlying cardiac disease (primary or lone atrial fibrillation) and is associated with the normally high vagal tone found in horses that most likely have some predisposition for the arrhythmia. However, it may also occur secondary to cardiac disease such as mitral insufficiency, aortic insufficiency, myocarditis, pericarditis, or untreated congenital cardiac defects. The resting heart rate is usually within the normal range when there is no underlying cardiac disease, whereas it is typically increased with underlying disease; this may help identify the cause of the arrhythmia on physical examination. Most horses with primary atrial fibrillation exhibit no clinical signs at rest or with moderate exercise or work; however, more strenuous exercise or work may result in evidence of reduced cardiac output. This can be seen in racehorses who are evaluated for a sudden reduction in race performance. In this setting, the clinical signs could also be due to paroxysmal atrial fibrillation, which can be identified only during the exercise period. In horses with primary atrial fibrillation, conversion to sinus rhythm with quinidine at a dosage of 22 mg/kg, PO, every 2 hr until conversion, is still the treatment of choice. The success rate for conversion is greatest in horses with atrial fibrillation of shorter duration. The chance for success is considered excellent if the duration is <4 mo and relatively good if >4 mo, although conversion may take longer and quinidine

toxicity is more likely to develop. Horses with atrial fibrillation can also be successfully converted to sinus rhythm electrically (cardioversion). This requires the careful placement of electrode catheters in a pulmonary artery and the right atrium (via the jugular vein) of an awake horse followed by anesthesia and then delivery of electrical shocks of increasing intensity through the catheters. This method is very successful but is time-consuming and expensive. Most horses can return to successful racing performance after conversion. However, some will revert to atrial fibrillation over time. Conversion to sinus rhythm is not indicated in horses with severe underlying cardiac disease, because the likelihood of conversion, or maintenance of sinus rhythm if converted, is very low.

Ventricular premature complexes arise from a site within the ventricular myocardium or specialized conduction system. On the ECG, the QRS complex usually appears wide and is followed by a large T wave that is opposite in polarity to the QRS complex. This produces a large, bizarre complex when compared with normally sinus-driven QRS complexes, occurs earlier than the next expected sinus-driven QRS complex (ie, premature), and does not have an associated preceding P wave, although unassociated P waves going at a slower rate (AV dissociation) may be seen. Most commonly, these complexes occur from noncardiac causes such as anesthesia, age, electrolyte abnormalities, acute toxicities, neoplasia (eg, splenic hemangiosarcoma in dogs), gastric distention (eg, gastric dilation and volvulus syndrome in dogs), or trauma. They may also be associated with ventricular myocardial diseases such as DCM, arrhythmogenic right ventricular cardiomyopathy (Boxer cardiomyopathy), and myocarditis.

Ventricular tachycardia is the occurrence of three or more sequential ventricular premature complexes. These can again be nonsustained or sustained (>30 sec). They can also be divided into slower, benign ventricular tachycardias and faster, malignant ones. A slower, benign ventricular tachycardia is called an accelerated idioventricular rhythm (AIVR) and is commonly seen in dogs in the intensive care unit secondary to systemic (often intra-abdominal) disease or trauma. It is characterized on the ECG by the presence of a ventricular tachycardia that is relatively slow (usually <200 bpm). Sinus rhythm may be interspersed with the AIVR, with one rhythm taking control of the rhythm whenever it is slightly faster than the other.

Fusion beats (hybrid sinus beat and premature ventricular contraction [PVC]) can also be seen. This arrhythmia does not result in sudden death and usually dissipates on its own within 48–72 hr. As such, it only needs to be treated (eg, lidocaine) if it is causing hemodynamic instability.

Malignant ventricular tachycardia is most commonly found in dogs with severe underlying cardiac disease, usually either a cardiomyopathy (eg, DCM or arrhythmogenic right ventricular cardiomyopathy) or severe semilunar valve stenosis (eg, subaortic stenosis, pulmonic stenosis). Malignant ventricular tachycardia predisposes the animal to sudden death due to the tachycardia degenerating into ventricular fibrillation. Frequently, this arrhythmia is not identified, so the first clinical sign seen is sudden death. Some dogs (especially Boxers and Doberman Pinschers) will experience syncope as the result of a very fast (often >400 bpm) ventricular tachycardia that spontaneously reverts back to sinus rhythm within seconds (must last >6 sec and usually lasts no more than 1 min) of its onset. Sotalol or a combination of atenolol and mexiletine effectively controls the arrhythmia in Boxers and usually stops the syncope and presumably prevents sudden death. β -blockers are frequently administered to dogs with severe subaortic stenosis and to some with severe pulmonic stenosis in an attempt to prevent sudden death. Proof of efficacy is lacking. Sotalol may be a more logical choice. Ventricular tachycardia must be distinguished from ventricular escape rhythm, as seen with third-degree AV block, and from idioventricular rhythm, a terminal ventricular escape rhythm. A ventricular escape rhythm is a slow rhythm (20–40 bpm) that occurs because higher pacemakers (SA and AV nodes) have failed. Suppression of a ventricular escape rhythm by drug therapy (eg, lidocaine) results in cessation of all cardiac electrical activity (ie, death).

Ventricular fibrillation is a result of microreentrant circuits within the ventricular myocardium, resulting in the absence of effective ventricular contractions; thus, it is a terminal rhythm. The only effective treatment is electrical defibrillation.

Antiarrhythmics: A detailed discussion of antiarrhythmic therapy is covered elsewhere (*see* p 2535). Most antiarrhythmic drugs are administered to suppress ectopic premature depolarizations (eg, atrial and

ventricular premature complexes, atrial and ventricular tachycardia) or to slow the ventricular rate in animals with atrial flutter or fibrillation. Many of these drugs are being supplanted by automatic implantable defibrillators in human medicine, so the manufacture of these drugs is waning. Some of the antiarrhythmics have negative inotropic effects, with the potential to worsen active CHF. This is most likely to occur with the use of β -blockers in the treatment of supraventricular tachyarrhythmias and with sotalol.

Atrial fibrillation is one of the most commonly treated tachyarrhythmias; it is imperative to decrease the ventricular rate to ≤ 160 bpm if the rate is faster than that in the clinic. In experimental situations, pacing the heart of a dog at a rate ≥ 180 bpm results in myocardial failure severe enough to cause CHF within weeks. Consequently, leaving the rate this high will cause further cardiac disease and decompensation. There are no firm data to suggest that keeping the heart rate even lower than 160 bpm is beneficial in dogs. Diltiazem (0.5–2 mg/kg, PO, tid) or a combination of diltiazem and digoxin are generally the preferred methods of controlling the ventricular rate in dogs with atrial fibrillation. A low dose of a β -blocker, such as atenolol (0.25 mg/kg, PO, bid), may also be used instead of diltiazem, but its use is uncommon. (*See also* ANTIARRHYTHMICS, p 2535.)

Ventricular tachycardia can degenerate into ventricular fibrillation and cause sudden death. Fast ventricular tachycardia (>250 bpm) and ventricular tachycardia in animals with severe underlying cardiac disease, such as subaortic stenosis, DCM, and arrhythmogenic right ventricular cardiomyopathy ([ARVC] Boxers), are most vulnerable to dying suddenly from ventricular tachycardia. In Boxers with ARVC, sotalol (0.5–3 mg/kg, PO, bid; most commonly 80 mg/dog, PO, bid) or a combination of mexiletine (5–8 mg/kg, PO, tid) and atenolol (0.5–1 mg/kg, PO, bid) can effectively reduce or, more commonly, stop the syncope (usually due to a ventricular tachycardia firing at a rate of >400 bpm) seen in these dogs. It also obviously decreases the incidence of sudden death and so commonly results in years of survival. A minority of Boxers with ARVC develop true DCM and are also prone to sudden death. Doberman Pinschers with DCM also commonly die suddenly due to ventricular tachycardia. In these instances, the negative inotropic effects of sotalol can either push a dog into heart failure or make

existing heart failure worse. Consequently, if sotalol is to be used in either of these patient populations, the dose must be started low and titrated upward carefully, with pimobendan administered concurrently. Mexiletine can also be used alone but, at least in theory, is not as effective at preventing sudden death. Amiodarone (12–15 mg/kg/day, PO, for 2 wk [loading dose] followed by 5–7 mg/kg/day, PO) is probably more efficacious at preventing sudden death than mexiletine but has many more adverse effects. Doberman Pinschers appear to be particularly susceptible to the hepatotoxic effects of the drug.

Animals with chronic bradyarrhythmias as seen with AV block (high-grade second or third degree) or sick sinus syndrome most commonly present with weakness, episodic weakness/collapse, and syncope. Pacemaker implantation is the treatment of choice. If pacemaker implantation is not a viable option, anticholinergics, phosphodiesterase (PDE) inhibitors, or sympathomimetics may be administered. Propantheline is a mild anticholinergic dosed at 0.25–0.5 mg/kg, PO, bid-tid. The parenteral formulation of atropine may be administered PO but must be diluted 10:1 with corn syrup at a dosage of 0.04 mg/kg, PO, tid-qid. Adverse effects include mydriasis, dry mucous membranes, tachycardia, and GI stasis. Theophylline is a nonselective PDE inhibitor with modest positive chronotropic effects. Extended-release tablets or capsules can be given at 10 mg/kg, PO, bid. If no adverse effects are seen and the desired clinical effect is not achieved, the dosage in dogs can be increased to 15 mg/kg, PO, bid, while monitoring for adverse effects, and in cats to 20 mg/kg, PO, every 24–48 hr. Adverse effects may include restlessness, excitability, tachycardia, or GI upset. Terbutaline is a β -agonist that has more potent positive chronotropic effects but with similar adverse effects to those seen with theophylline. It is dosed to effect at 1.25–5 mg/dog (not per kg), PO, tid, and 0.625 mg/cat, PO, bid. Attempts to overcome clinically significant bradyarrhythmias with oral therapy are often unrewarding, although overall clinical signs may improve in some animals.

Echocardiography

Echocardiography, the use of diagnostic medical ultrasound to evaluate the heart and proximal great vessels, complements other diagnostic procedures by quantifying chamber dimensions, wall thicknesses, and the dynamic events of the cardiac cycle; it also allows visualization of the anatomy

and motion of valves and visualization of congenital abnormalities ranging from a defect in the interventricular septum to a stenotic pulmonary valve. Blood flow velocity is also commonly measured, and turbulent blood flow is identified using Doppler echocardiography. Pressure gradients, blood flow volumes, and several indices of cardiac function can be calculated. Echocardiography can also identify changes in myocardial tissue texture indicative of ischemia and fibrosis and delineate masses, valvular vegetations, pericardial effusion, and many other features previously verifiable only with cardiac catheterization or at necropsy.

There are four main types of echocardiography: three-dimensional, two-dimensional, M-mode (one-dimensional), and Doppler. Two-dimensional echocardiography provides a wedge-shaped, two-dimensional image of the heart in real-time. Several standard long-axis and short-axis views obtained from standard imaging windows on the thorax have been developed for dogs, cats, horses, and cows. M-mode echocardiography is produced by a one-dimensional beam of ultrasound that penetrates the heart, providing an “ice-pick view” over time. The tissue interfaces that are encountered by the beam are then plotted on a screen. This mode of evaluation has been typically used to measure chamber dimensions, wall thickness, valve motion, and great vessel dimensions but, as frame rate of two-dimensional echocardiography has improved, this mode has lost some of its usefulness. Three-dimensional echocardiography is the newest modality and is still in its infancy. Doppler echocardiography uses the principle of changing frequency of the ultrasonic beam after it contacts a moving structure (eg, RBCs, cardiac wall) to measure velocity. Doppler echocardiography is further divided into spectral (pulsed and continuous wave), color flow, and tissue Doppler echocardiography. Color flow Doppler echocardiography is a form of pulsed Doppler echocardiography prone to aliasing when high velocity flow is encountered, allowing high velocity (and therefore turbulent) flow in the heart and great vessels to be detected. Continuous wave Doppler is used to quantitate high velocity flow and thus used to calculate pressure gradients, most commonly across the regions of valves, using the modified Bernoulli equation ($4 \times \text{velocity}^2$). Tissue Doppler imaging is used to measure the lower velocity motion of cardiac structures, most commonly ventricular walls, in an attempt to quantitate regional myocardial

function. Variations include measuring strain and strain rate.

Cardiac Catheterization

Cardiac catheterization involves the placement of catheters into cardiac chambers and surrounding great vessels to measure pressure, inject contrast agents, and place devices. The latter is commonly termed interventional cardiology. Indications include diagnostic evaluation (eg, when other diagnostic tests are insufficient to identify specific cardiac abnormalities or are unable to identify the severity of a lesion), presurgical evaluation (eg, to help diagnose constrictive pericarditis before surgery), therapeutic intervention, and clinical research. Diagnostic and presurgical cardiac catheterization, however, have largely been replaced by echocardiography. Currently, most cardiac catheterizations are interventional procedures to address cardiac defects (eg, closure of a patent ductus arteriosus).

HEART FAILURE

Heart failure is a clinical syndrome that occurs secondary to severe, overwhelming cardiac disease. It occurs because the heart is no longer able to maintain normal venous/capillary pressures, cardiac output, and/or systemic blood pressure. It is most commonly caused by a chronic disease that results in a severe decrease in myocardial contractility, severe regurgitation or shunting, or severe diastolic dysfunction. However, it is common to have all three abnormalities present simultaneously (but with one predominating). By far, the most common clinical manifestations seen with heart failure are directly due to edema and effusion (congestive or backward heart failure). Much less commonly, animals present because of signs referable to a decrease in cardiac output (forward heart failure). Very rarely, they present in cardiogenic shock (low blood pressure due to decreased cardiac output). This occurs because the cardiovascular system operates under a system of priorities. Its three primary functions are to maintain a normal blood pressure and normal cardiac output, both at a normal venous/capillary pressure. When the system is overwhelmed, it allows venous/capillary pressure to increase first (and so allows edema or effusion to form) and then allows cardiac output to fall. Only after cardiac output has fallen remarkably does cardiogenic shock occur. In acute heart failure, before any compensation has

occurred, cardiogenic shock may predominate, but even in this situation, acute chordal rupture is the most common cause of acute heart failure in animals and results in an increased left atrial pressure and thus pulmonary edema.

Initial changes in cardiac chamber dimension (volume) or wall thickness that occur are best understood in relation to preload (the tension imposed by venous return on the ventricular walls at end-diastole) and afterload (the tension imposed on the ventricular walls at end-systole). Alterations in preload or afterload may be caused by structural cardiac abnormalities, systemic compensatory mechanisms, or both. Volume overload states, such as those that occur with chronic valvular disease/valvular insufficiencies, patent ductus arteriosus, atrial or ventricular septal defects, peripheral left-to-right shunts, anemia, or hyperthyroidism, cause an increase in preload that leads to ventricular growth and chamber enlargement (euphemistically called dilation) via eccentric myocyte hypertrophy. Pressure overload states, such as those that occur with pulmonary or systemic hypertension, and pulmonic or aortic stenosis, cause an increase in afterload (systolic intraventricular pressure) that leads to ventricular wall thickening via concentric hypertrophy. Neither volume nor pressure overload is synonymous with heart failure; either state may result in heart failure, depending on the severity of the overload and the degree of compensation.

Systolic Dysfunction

Systolic function is a broad classification of cardiac function that encompasses all of the entities in systole that are capable of altering blood flow into the aorta. It includes (but is not limited to) heart rate, myocardial contractility, preload, afterload, hypertrophy (volume and pressure overload), leaks, and shunts. Diseases that alter systolic cardiac function can become severe enough to overwhelm the ability of the cardiovascular system to compensate for the systolic dysfunction (primarily renal sodium and water retention, leading to hypervolemia, leading to increased venous return to the heart, leading to increased stretch on the myocardium, leading to myocardial growth and a larger left ventricular chamber [eccentric or volume overload hypertrophy]) and thus cause heart failure. The most common disease that alters systolic function is mitral regurgitation. Here, in systole, a portion of

the blood flow that should be ejected into the aorta is ejected backward through the mitral valve from the left ventricle into the left atrium. When the regurgitation is mild (<50% of the blood flow goes backward) to moderate (50%–75% goes backward), the left ventricle is able to compensate for the leak by growing larger (volume overload hypertrophy) and increasing the total stroke volume it ejects. When regurgitation is severe (>75% backward flow), the compensatory mechanisms may become overwhelmed, resulting in an increase in left atrial pressure and so pulmonary edema. The classic example of systolic dysfunction is dilated cardiomyopathy (DCM), in which an inherent myocardial disease results in a decrease in myocardial contractility (myocardial failure). The decrease in myocardial contractility results in an increase in the end-systolic diameter/ volume of the left ventricular chamber (muscle is weaker and cannot contract down as far in systole) and a decrease in myocardial contraction (the amount of wall motion [shortening fraction or fractional shortening] seen on an echocardiogram). Again, the left ventricle grows larger to compensate for this disease, but when the myocardial failure is severe, compensation can no longer maintain a normal diastolic pressure in the left ventricle (kidneys continue to retain sodium and water) and this increased pressure backs up into the left atrium, pulmonary veins, and pulmonary capillaries, creating pulmonary edema.

Diastolic Dysfunction

Diastole can be roughly divided into early myocardial relaxation and late filling that is altered primarily by compliance (1/stiffness). Most ventricular diastolic dysfunction severe enough to cause heart failure is due to myocardial fibrosis, thus due to a decrease in ventricular compliance (an increase in stiffness). When a ventricle is less compliant or stiffer than normal, for any given volume of blood that fills the chamber in diastole, the pressure is higher. This increase in diastolic pressure (when the AV valves are open) is transmitted back up into the atrium, veins, and capillary beds behind the affected ventricle, resulting in transudation of fluid and signs referable to edema or effusion. The classic example of a disease that primarily causes heart failure due to diastolic dysfunction is hypertrophic cardiomyopathy. Diastolic function is compromised to some degree by the thickening of the myocardium itself but

more so by the myocardial fibrosis that builds up over time when severe disease is present. Restrictive cardiomyopathy is another classic example of diastolic dysfunction, but it is much less common. Diastolic dysfunction also occurs in pericardial diseases that cause cardiac compression (pericardial effusion, constrictive pericarditis). With pericardial disease, right heart failure (eg, ascites) predominates because systemic (eg, hepatic) capillaries leak more easily (leak profusely at a pressure of 10 mmHg) than pulmonary capillaries (which can generally withstand a pressure up to 20 mmHg without leaking).

CHF may also occur if a tumor or other anatomic obstruction impedes venous return to one or both atria. Pericardial disease or effusion leading to decreased ventricular filling may also be thought of as an extracardiac cause of CHF. Iatrogenic volume overload (ie, aggressive IV fluid therapy) can lead to edema formation in the absence of primary heart disease.

Compensatory Mechanisms

Systemic blood pressure and blood flow (and thus oxygen delivery to peripheral tissues and organs) is under strict neuroendocrine control. Compensatory mechanisms act rapidly to correct any decreases in blood flow and/or pressure. Acute compensatory mechanisms, such as increased sympathetic tone, are generally short-lived and useful only for situations that demand an acute change in cardiac function (eg, hypovolemia). Chronic mechanisms of cardiac compensation generally take over within days of the onset of a cardiac disease and are viable for years. They are responsible for the heart's ability to compensate for chronic disease. These remarkable mechanisms allow for an animal to compensate for mild, then moderate, and then even severe disease, often for years. Only at the very end of a chronic disease do they contribute to the formation of heart failure and require medical intervention.

When a decline in stroke volume occurs secondary to cardiac dysfunction, cardiac output decreases. The acute response is an increase in sympathetic tone leading to peripheral vasoconstriction, increased heart rate, and increased cardiac contractility that serve to restore cardiac output and maintain systemic blood pressure. This effect fades within days as events such as β -receptor down-regulation occur. Chronically, the renin-angiotensin-aldoste-

rone system (RAAS) is activated. Activation is initiated by events such as decreased renal perfusion, leading to decreased sodium delivery to the macula densa (which interacts with the juxtaglomerular apparatus). The juxtaglomerular cells release renin, which converts angiotensinogen (synthesized in the liver) to angiotensin I. Angiotensin-converting enzyme (ACE) converts angiotensin I to angiotensin II, chiefly in the lungs. A separate tissue RAAS exists in the brain, vascular, and myocardial tissues, which can generate angiotensin II independently of the renal, or systemic, RAAS.

Angiotensin II has widespread effects, including stimulation of aldosterone synthesis and release from the adrenal glands, increased thirst via stimulation of antidiuretic hormone (ADH) release, increased norepinephrine and endothelin release, and stimulation of cardiac hypertrophy. Aldosterone forces the renal distal tubules to retain sodium and water. This, plus the effect of ADH, causes an increase in circulating blood volume. The increased blood volume leads to an increase in venous return to the affected ventricle. This chronic increase in preload stimulates the myocytes to add in new sarcomeres (contractile elements), leading to the growth of longer myocytes. This creates a larger ventricle (larger chamber with normal wall thickness [volume overload or eccentric hypertrophy]).

In response to these compensatory mechanisms, counter-regulatory systems are in place such as the release of atrial natriuretic peptide (ANP) from the atria, and B-type natriuretic peptide (BNP) from the atria and ventricles. ANP and BNP are released in response to stretch of the atrial and ventricular chambers. Both hormones serve to increase natriuresis (with subsequent diuresis) and decrease systemic vascular resistance, thus countering the effects of the RAAS. The effects of ANP and BNP are greatly outweighed by those of the RAAS and other systems in animals with chronic disease. Again, this is beneficial up until the end, when the RAAS continues to force sodium and water retention despite the presence of edema and effusion.

In situations when the heart must deal with higher than normal systolic intraventricular pressures (eg, subaortic stenosis, pulmonic stenosis, systemic arterial hypertension), the affected ventricle must contract against a greater force. Much like skeletal muscle when it is forced to lift a heavier weight, cardiac muscle undergoes

concentric or pressure overload hypertrophy. In this situation, sarcomeres again replicate within cardiac myocytes but in parallel (side by side), to grow a wider myocyte and a thicker ventricular wall.

Cardiac Biomarkers

A biomarker is a measurable characteristic that reflects the severity or presence of some disease state. Blood pressure, cholesterol, gamma-glutamyl transferase, and BUN are all biomarkers. Studies in dogs and cats have shown that increased blood concentrations of BNP (most commonly N-terminal pro-B-type natriuretic peptide [NT-proBNP]), ANP, and endothelin-1 are indicators of cardiac disease that increase proportionately with progressive cardiac disease and CHF. Cardiac troponin I (cTnI), which is released after cardiomyocyte death, has also been evaluated as a biomarker for cardiac disease but found to be less sensitive than those mentioned above. ANP, BNP, and cTnI have also been evaluated as screening tools for occult DCM (before onset of CHF) in dogs. Increased levels of BNP were found to be highly sensitive for the detection of occult DCM, whereas ANP and cTnI were relatively less sensitive. NT-proBNP is cleaved from BNP in equal amounts in response to increased cardiac filling pressures (myocardial stretch) and ischemia, and its greater stability and longer half-life make it more suitable for use as a diagnostic biomarker. Several studies have demonstrated the usefulness of NT-proBNP in differentiating between cardiac and primary respiratory causes of dyspnea in dogs and cats. A rapid assay is available for this use in cats. Biomarkers such as NT-proBNP and troponin I should never be evaluated in isolation, because they are not 100% accurate. Instead, they should be used in concert with other diagnostic modalities.

Clinical Manifestations

The hemodynamic changes that occur in heart failure are relatively limited, as are the clinical syndromes resulting from these changes. Much depends on the location(s) of cardiac chamber failure, as well as on species differences.

Left Heart Failure: The pulmonary veins drain into the left atrium. Left atrial pressure increases as left heart diseases worsen (eg, from regurgitant blood flow and increased circulating blood volume). An increase in left atrial pressure is transmitted

to the pulmonary veins and to the pulmonary capillaries. Pulmonary capillary hydrostatic pressure continues to increase, promoting the transudation of fluid out of the capillaries and first into the lung interstitium and then into the alveoli as the pressure increase becomes more severe. Simply put, pulmonary edema develops and becomes worse as heart failure progresses. In animals, this first causes tachypnea and then dyspnea. Most owners do not notice the tachypnea and so do not seek veterinary attention until dyspnea is present. This often makes it look like the onset of the heart failure was acute, when, in fact, it was chronic.

Some dogs and a few cats and horses will cough with cardiogenic pulmonary edema. Cough is a much more common manifestation of primary lung disease in all species. Coughing is always present in dogs with chronic bronchitis. One manifestation of chronic bronchitis is airway collapse (tracheomalacia and bronchomalacia) on radiographs. Bronchomalacia appears to be evidence of chronic bronchitis in dogs. When the left atrium is enlarged, a collapsed left mainstem bronchus can often be seen above the left atrium, because the large left atrium highlights this finding. It does not appear that the large left atrium actually compresses this bronchus.

Animals with heart failure may also be exercise intolerant due to lower than normal cardiac output during exercise and/or hypoxemia, which is caused by pulmonary edema or pleural effusion. This is a rare presenting complaint in cats, because they usually do not exercise. The same is true for many dogs. In dogs, most true exercise intolerance (fatigue with marked tachypnea or dyspnea) is due to respiratory failure rather than heart failure. However, most "exercise intolerance" ends up being due to something else and is not true exercise intolerance. Instead, it is frequently an unwillingness to exercise because of other conditions, such as orthopedic disease or obesity. A dog that is truly exercise intolerant looks and sounds "out of breath." A severe decrease in cardiac output results in cold extremities (paws, ears) and can lead to total body hypothermia, especially in cats. Although syncope (transient loss of consciousness due to a transient decrease in cerebral metabolic substrate, most commonly oxygen) is not a sign of or directly due to heart failure, it may also be noted in dogs in heart failure, especially in small-breed dogs with chronic valvular disease. In many instances, the cause is unknown. However, syncope often

improves once pulmonary edema is treated. In some, it is associated with coughing and is most likely a vagally mediated event (transient asystole). The syncope is frightening to the owner, but sudden death is rare unless associated with DCM or subaortic stenosis.

The diagnosis of congestive left heart failure (cardiogenic pulmonary edema) in dogs is classically made radiographically. However, the inability to take a radiograph during a deep inspiration is a diagnostic obstacle. Consequently, the caudodorsal lung fields on a lateral radiograph, where cardiogenic pulmonary edema is usually identified, often have an interstitial density that is either mistaken for pulmonary edema or hides pulmonary edema. This is exacerbated in older dogs. Most dogs with severe pulmonary edema can be identified radiographically, but those with mild to moderate edema are often problematic. In these dogs, it is often beneficial to send the dog home (if it is stable) to have the owner count the dog's sleeping respiratory rate (SRR). The owner must be taught how to count respiratory (breathing) rate and then count the rate preferably while the dog is sound asleep and in a cool environment. A normal dog has an SRR <30 breaths/min, so a rate greater than that is abnormally high (ie, the dog has tachypnea). All dogs with pulmonary edema have an increased SRR (are tachypneic). However, dogs with respiratory disease/failure can also have an increased SRR. Therefore, once an increased SRR is documented, the dog should be started on furosemide at a dosage of at least 2 mg/kg, PO, bid. If the SRR decreases, then the diagnosis of left heart

Lateral radiograph of a dog with cardiogenic pulmonary edema due to severe mitral regurgitation. Note the large body of the left atrium almost touching the spine.

Courtesy of Dr. Mark D. Kittleson.

failure is confirmed. The same can be done in cats for both pulmonary edema and pleural effusion. All healthy cats have an SRR <40 breaths/min, with most <30 breaths/min. Once the diagnosis is established, the owner should continue to count the SRR daily and titrate the furosemide dosage to keep the SRR within the normal range. In dogs thought to be in an impending stage of heart failure (large left atrium but no pulmonary edema), the owner can also be instructed to count the SRR daily to weekly in an attempt to identify heart failure at an early stage. Owners should also always be instructed to keep a log and bring it with them at each recheck.

In cats, left heart failure also commonly manifests as pleural effusion. The visceral pleural veins (veins on the surface of the lung) drain into the left heart rather than the right heart. This also occurs in people and dogs. The exact reason for this phenomenon is not fully understood. The pleural effusion may be a modified transudate, pseudochylous, or chylous in cats with left heart failure. A small volume of pericardial effusion can also be seen in cats with heart failure and is generally of no hemodynamic consequence (pericardiocentesis is not required). Cats also often stop eating and may stop drinking when in heart failure.

Right Heart Failure: The right atrium receives systemic and cardiac venous and lymphatic drainage via the cranial and caudal vena cavae and the coronary sinus. Right atrial pressure increases as right heart disease worsens due to diseases such as tricuspid valve insufficiency and pulmonary hypertension. Clinical manifestations of right heart failure include jugular venous distention, hepatomegaly, pleural effusion, pericardial effusion, ascites, and peripheral edema. Dogs and cats are more likely to develop ascites (although right heart failure is uncommon in cats). Horses and cows more commonly develop subcutaneous edema ventrally. In dogs and cats, jugular venous distention may not be evident without intervention. A hepatojugular reflux test is often useful (see p 91).

Management

Management of heart failure is primarily directed at controlling clinical signs related to the presence of organ edema and cavity effusion (eg, pulmonary edema, pleural or pericardial effusion, and ascites). In some animals, decreased cardiac output, and even cardiogenic shock, need to be

addressed. These are accomplished through reducing preload and/or afterload (diuretics and vasodilators), improving cardiac performance (positive inotropes, positive lusitropes, antiarrhythmics), and using neurohormonal modulators (ACE inhibitors, and potentially β -blockers, aldosterone antagonists, and angiotensin II receptor blockers).

Diuretics: The **loop diuretics** are the single most effective agents used to decrease circulating blood volume and reduce signs referable to edema and effusion in animals in heart failure. They act via inhibition of the $\text{Na}^+/\text{K}^+2\text{Cl}^-$ cotransporter in the thick ascending loop of Henle. This leads to increased renal sodium and chloride excretion, with subsequent free water loss. Furosemide is the most widely used loop diuretic. When administered IV, it also directly reduces pulmonary capillary wedge pressure (before onset of diuresis) via local prostaglandin synthesis, which has a vasodilatory effect. The onset of action after IV administration is 5 min, with effects peaking at 30 min and lasting ~2 hr. The onset of action after oral administration is 60 min, with peak effects seen at 1–2 hr and lasting ~6 hr.

Emergency therapy of pulmonary edema often requires high doses of IV or IM furosemide (4–8 mg/kg for dogs; 2–4 mg/kg for cats), repeated at 60- to 120-min intervals until clinical signs, usually referable to pulmonary edema (ie, tachypnea, dyspnea), are controlled. Because of the concern for dehydration, azotemia, and significant electrolyte disturbances with overzealous furosemide administration, tapering to a lower dosage as soon as the respiratory rate decreases is mandatory. Once the pulmonary edema is controlled, the dosage that keeps the sleeping respiratory rate (SRR) normal is recommended. Mild to moderate prerenal azotemia and electrolyte and acid-base disturbances (hyponatremia, hypokalemia, and a hypochloremic metabolic alkalosis) are common and are generally well tolerated, so can be safely ignored (albeit monitored carefully) as long as the animal is eating and drinking. Oral doses used to manage chronic CHF may vary significantly between animals; in theory the lowest possible dosage should be used, but care must be exercised, again via monitoring SRR, not to lower the dosage too far. In dogs, CHF is often initially controlled at dosages of 1–2 mg/kg, bid; cats are more sensitive to the development of adverse effects and generally require lower dosages

(0.5–2 mg/kg every 12–24 hr). The maximal dosage in dogs is generally 4 mg/kg, PO, tid. In cats, it may be closer to 2 mg/kg, PO, tid, but dosages as high as 4 mg/kg, tid, may be required. Use of furosemide or other diuretics as sole therapy in long-term management of CHF increases RAAS activation; thus, combination with an ACE inhibitor is generally recommended.

Furosemide resistance, typically defined by persistent signs of heart failure despite dosages of 4 mg/kg, PO, tid, often develops in advanced cases of CHF. There are many causes of diuretic resistance, including remarkably severe cardiac disease, decreased delivery of the drug to the nephron (low cardiac output), activation of the RAAS (which counteracts the effects of diuresis), and hypertrophy of the distal convoluted tubular cells with consequent increases in ion transport in this region of the nephron. GI edema secondary to right CHF may decrease absorption of orally administered diuretics and contribute to diuretic resistance. Animals with resistance to chronic high doses of oral furosemide may thus have an improved diuretic response from parenteral (eg, SC) administration of the drug or from addition of other diuretic agents ("diuretic stacking"). In other cases, switching to torsemide (see below) may be the best option.

Adverse effects seen with furosemide administration are generally related to dehydration from volume depletion, reduced cardiac output and glomerular filtration rate (GFR), and electrolyte and acid-base abnormalities. Less common adverse effects include vomiting, pancreatitis, and idiosyncratic deafness with rapid IV administration. Animals with preexisting renal disease are more likely to develop adverse effects, and furosemide therapy should be reduced or temporarily withdrawn accordingly. Renal values should be monitored frequently when starting diuretic therapy (on initiation and at least 1 wk later) and should be reassessed at least every 3–6 mo during chronic administration. Some animals may remain mild to moderately azotemic (usually with a greater increase in BUN than in creatinine), which is generally tolerated provided they are eating and drinking adequately.

Torsemide is a newer loop diuretic that has better and more consistent bioavailability (better and more consistent GI absorption), has a longer duration of action (can be administered less frequently), and is more potent (requires a lower dose) than furosemide in dogs. Although there is less experience with this agent, it can be useful

in management of refractory heart failure in which furosemide resistance has been documented or when furosemide is not tolerated. The starting dosage is approximately one-tenth that of the current furosemide dose (take total daily current dose of furosemide, multiply times 0.1, and divide that dose bid). Most commonly that translates into a dosage of 0.1–0.3 mg/kg, bid. However, dosages as high as 1 mg/kg, bid, have been used in a few dogs with ascites but only using careful upward titration.

Thiazide diuretics (eg, hydrochlorothiazide, chlorothiazide) decrease sodium resorption via inhibition of the Na^+/Cl^- cotransporter in the distal convoluted tubule. This results in increased sodium and water delivery to the collecting ducts and subsequent increased hydrogen and potassium excretion. Although the thiazides are relatively weak diuretics, they do exert a synergistic effect when administered with loop diuretics and can cause profound electrolyte abnormalities (particularly hypokalemia) and dehydration when used in combination if not used judiciously. Hydrochlorothiazide is more commonly used, with a recommended dosage of 1–4 mg/kg, PO, 1–2 times/day. It is also used as a combination product with the potassium-sparing diuretic spironolactone (see below), which may be dosed at 1–4 mg/kg, PO, 1–2 times/day. Many animals do not tolerate dosages at the higher end of this range, and the lowest effective dosage should be used. Chlorothiazide is dosed at 20–40 mg/kg, PO, 1–2 times/day. Thiazide diuretics are generally reserved for those cases in which resistance to furosemide has developed.

Potassium-sparing diuretics are the weakest of the diuretic class, exhibiting little to sometimes undetectable diuretic effect at standard dosages, especially when used alone in healthy dogs. Although they may produce more diuresis in a dog in heart failure, they should never be relied on to produce diuresis in an animal in heart failure. They should also never be used to replace a loop diuretic; they are used only as adjunctive (add-on) agents. Drugs in this class include the aldosterone inhibitors spironolactone and eplerenone and those that block sodium resorption at the distal tubules, triamterene and amiloride. Spironolactone is currently the only one used clinically in veterinary medicine. A large-scale clinical trial in people with heart failure in the 1990s demonstrated significant improvement in morbidity and mortality in patients with myocardial infarction administered spironolactone versus

placebo, in addition to standard heart failure therapy. It was subsequently shown that the beneficial effect was all due to spironolactone's antifibrotic effects in the myocardium, not its diuretic properties. Only one **discredited** study from Europe has suggested benefit in dogs in heart failure. In theory, spironolactone may be of benefit in dogs with DCM, because myocardial fibrosis is a component of this disease. It is unlikely that myocardial fibrosis and diastolic dysfunction are important components of the pathophysiology of primary mitral regurgitation. In one study, spironolactone had no benefit in cats with hypertrophic cardiomyopathy before the onset of heart failure, another disease with myocardial fibrosis. Eplerenone has demonstrated a myocardial protective effect in dogs with experimentally induced myocardial infarction and heart failure.

Spironolactone is used by many veterinary cardiologists for its theoretical benefits. It may be beneficial in some dogs with refractory ascites or in those in which clinically significant hypokalemia has developed. It is dosed at 1–3 mg/kg, PO, 1–2 times/day.

Positive Inotropes: Pimobendan is a novel inodilator (inotropic drug and vasodilator) approved by the FDA in 2007 for use in dogs with CHF related to atrioventricular valve insufficiency or DCM. It is classified as a calcium sensitizer and a phosphodiesterase (PDE) III inhibitor. The parent compound (pimobendan) is responsible for the calcium sensitization, while an active metabolite (desmethylpimobendan) is a PDE III inhibitor (~100 times more potent than pimobendan). Pimobendan sensitizes cardiomyocyte contractile proteins (mostly troponin C) to calcium, and desmethylpimobendan increases cyclic AMP and calcium cycling within the cell. Myocardial oxygen consumption is increased, as for any positive inotropic agent, in healthy dogs. Vasodilation occurs via vascular PDE III inhibition, leading to endothelial smooth muscle relaxation and calcium efflux. Vasodilation includes coronary artery vasodilation, which leads to increased coronary blood flow and increased myocardial oxygen delivery. Additional beneficial effects may include improved myocardial relaxation, anti-inflammatory and anticytokine effects, and neurohumoral modulation.

Pimobendan is not approved for use in dogs before the onset of heart failure. With regard to mitral regurgitation due

to myxomatous mitral valve degeneration, a study in Beagles with mild, naturally occurring mitral regurgitation demonstrated increased valvular lesions in dogs treated with pimobendan compared with dogs treated with benazepril. Preclinical studies by the manufacturer suggest the same thing might occur in healthy dogs. A clinical study is nearing completion that looks at pimobendan vs placebo in small dogs with mitral regurgitation before onset of heart failure to determine whether it prolongs the time to onset of heart failure. A study in Doberman Pinschers with DCM but no heart failure suggested that low-dose pimobendan administration may prolong the time until the onset of heart failure or sudden death. Neither of these disparate endpoints was statistically significant on its own, but the combined endpoint was.

The combination of increased inotropy with mild afterload reduction results in improved cardiac output and reduced cardiac filling (diastolic) pressures in dogs in heart failure due to either mitral regurgitation or DCM. Clinical improvements seen with pimobendan may include improved quality of life, improved clinical scores, and a longer survival time. It is not unusual for a dog to improve clinically more than expected, and it is theorized that the drug may also have nonspecific phosphodiesterase-inhibiting properties (possibly similar to those of caffeine). Consequently, the clinical improvement seen may not always be because of improvement in heart failure. No studies to date have investigated the effects of combining pimobendan with an ACE inhibitor, but most veterinary cardiologists feel that this combination may confer additional clinical benefits. The inotropic effect of pimobendan is significantly greater than that seen with digoxin, and pimobendan has supplanted digoxin for inotropic support in CHF in dogs.

Pimobendan effectively decreases calculated pulmonary artery systolic pressure (tricuspid regurgitant jet velocity) in dogs with pulmonary hypertension secondary to mitral regurgitation. Whether this decrease is due to the expected decrease in left atrial pressure, pulmonary arterial vasodilation, or both, is unknown. There are no studies that have shown that pimobendan is beneficial in dogs with pulmonary hypertension due to causes other than left heart failure.

There is ongoing debate regarding the use of pimobendan in cats. Pimobendan is not approved for use in cats, and the package insert states that it is contraindicated in cats with hypertrophic cardiomyopathy,

although several studies have suggested that the drug is safe in cats, even those with hypertrophic cardiomyopathy, when administered at the same dosage as in dogs. However, a pharmacokinetic study showed that the serum concentration of pimobendan in cats given a canine dose results in a serum pimobendan concentration 10 times that seen in dogs. Cardiac pathology is found in dogs administered 3–5 times the recommended dose. It is unlikely any species that experienced a similar calcium sensitization effect as dogs could survive a dose 10 times the recommended dose, which suggests that cats are somehow very different. This requires more investigation before rational recommendations can be made with regard to using pimobendan in cats. However, anecdotally and in one retrospective study, pimobendan has been used in cats with CHF from any cause and has been beneficial clinically. Consequently, if a cat is no longer responding to conventional heart failure drug therapy, pimobendan (1.25 mg/kg/cat, bid) may be tried.

Pimobendan is dosed at 0.2–0.3 mg/kg, PO, bid, in dogs. With progression of heart failure, many veterinary cardiologists increase the dosing frequency in dogs to tid or double the dose. Adverse effects are rare and generally seen at high dosages but may include GI upset (anorexia, diarrhea). There is no clinical evidence supporting a significant increase in arrhythmias in animals treated with pimobendan; although some studies demonstrated such a trend, others refuted this. There clearly was no increase in the incidence of sudden death in the aforementioned study of Doberman Pinschers with subclinical DCM.

The **sympathomimetic amines** (eg, dobutamine, dopamine) improve contractility and cardiac output via β -adrenergic agonist effects and can be valuable in the acute management of cardiogenic shock or CHF secondary to myocardial failure. Stimulation of the membrane-bound β receptor activates adenylyl cyclase, leading to the production of cAMP and subsequent phosphorylation of membrane-bound calcium channels on both the sarcolemma (myocyte membrane) and sarcoplasmic reticulum. These cellular actions increase myocardial contractility and relaxation, as well as oxygen consumption. Effects on ion channels in cardiac pacemaker cells and conduction fibers lead to decreased depolarization threshold, increased heart rate, and increased conduction velocity, all of which predispose to cardiac arrhythmias. In the peripheral vasculature, mixed β_1 and β_2 stimulation has a negligible effect on

vascular resistance, although α -adrenergic stimulation (as occurs with dopamine at higher doses) can lead to vasoconstriction.

Dobutamine is administered IV as a continuous-rate infusion at 2.5–20 mcg/kg/min diluted in 5% dextrose. Dosages >15 mcg/kg/min are rarely required and can be associated with increased tachyarrhythmias. Starting at a lower dosage with uptitration every 15–30 min as required is recommended. Concurrent ECG monitoring is strongly recommended, and if arrhythmias worsen, the dosage of dobutamine should be reduced or dobutamine should be discontinued. Because dobutamine increases conduction through the AV node, additional caution is advised in atrial fibrillation. Dobutamine may preferentially increase myocardial flow, as compared with dopamine, which tends to increase renal and mesenteric flow. Dobutamine also tends to cause less tachycardia than dopamine. Dopamine is administered as a continuous-rate infusion at 2–8 mcg/kg/min; higher dosages (>10 mcg/kg/min) are associated with vasoconstriction and tachycardia. Gradual uptitration is recommended, as with dobutamine. Both dopamine and dobutamine may cause GI upset. These agents are less commonly used in cats, although the same general treatment strategy may be followed, but starting at more conservative infusion doses (~1 mcg/kg/min) for both dobutamine and dopamine.

The **bipyridine compounds** (milrinone, amrinone, or inamrinone) are PDE III inhibitors. Inhibition of PDE III reduces the degradation of cAMP, with subsequent effects similar to those seen with sympathomimetic amines. These agents are generally reserved for animals with severe refractory myocardial failure, because their use is associated with a higher level of mortality than that seen with the sympathomimetic amines. Because of lack of dependence on β -receptor stimulation, PDE III inhibitors are unaffected by β -receptor downregulation or uncoupling that may occur with progressive cardiac disease and may be useful in clinical situations when benefits of sympathomimetic therapy are less than expected. Additionally, vascular PDE III inhibition and lack of α -adrenergic stimulation results in vasodilation. Adverse effects noted with PDE III inhibitors include tachycardia, tachyarrhythmias, thrombocytopenia, GI upset, and hypotension at higher dosages. Amrinone is dosed at 1–3 mg/kg, IV, or as a constant-rate infusion at 10–80 mcg/kg/min. Milrinone is dosed at 30–300 mcg/kg (loading dose), followed by 1–10

mcg/kg/min constant-rate infusion (start low and titrate).

Cardiac Glycosides: The **digitalis glycosides** (eg, digoxin) are relatively weak positive inotropes (inhibit sodium-potassium ATPase pumps on cell surface membrane) that increase vagal tone to the heart (primarily to supraventricular regions), have a narrow therapeutic range, and are associated with significantly more adverse effects than pimobendan when administered in doses that produce toxicity. Digitoxin is no longer commercially available. Although used infrequently for its inotropic effects since the introduction of pimobendan, digoxin still plays an important role in cardiac disease, particularly in atrial fibrillation or supraventricular tachycardia with concurrent CHF, because it is the only available pharmacologic agent that slows AV nodal conduction without concurrent negative inotropic effects. (For a complete discussion, *see* p 2529.)

Rapid (IV) digitalization commonly results in toxicity and is not recommended. Digoxin may be administered at a conservative starting dosage of 0.003–0.005 mg/kg, PO, bid. Adequate serum concentration is not achieved until the second day of administration, and a serum digoxin concentration should be checked 4–7 days after initiation of therapy, 6–8 hr after the last dose is given. The therapeutic serum concentration is in the range of 0.5–2 ng/mL. There is no added benefit to a higher serum concentration within that range, so trying to keep it in the lower end of the range is recommended. Dosage adjustments should be based on the animal's serum digoxin concentration and clinical response. If digoxin is used in cats, it may be started at one-fourth of a 0.125-mg tablet every third day for cats <5 kg and every other day for cats >5 kg. Some larger cats may ultimately tolerate doses as high as one-fourth of a 0.125-mg tablet daily. An alcohol-based elixir form is available, although cats generally dislike the taste.

Adverse effects are increasingly likely at higher serum concentrations and generally occur in order of GI (anorexia, vomiting), cardiac (bradycardia, AV block, premature ventricular contractions), and CNS derangements. Because of its ability to slow electrical conduction as well as increase intracellular calcium, digoxin can cause almost any cardiac arrhythmia, and it is contraindicated in cases of AV block, significant bradycardia, and rapid ventricular tachycardia. If adverse effects are noted, the drug should be temporarily

discontinued (usually for at least 1–2 days) and the dosage subsequently reduced by at least 50%.

Angiotensin-Converting Enzyme (ACE) Inhibitors: ACE inhibitors competitively inhibit ACE, which converts angiotensin I to angiotensin II. This blunts the increase in systemic vascular resistance, hypertrophy, and aldosterone release caused by angiotensin II. ACE inhibitors are mild balanced vasodilators. They may reduce systemic vascular resistance up to 25%, improving cardiac output and reducing regurgitant fraction in mitral regurgitation, although these effects are rarely clinically apparent. Additional benefits include a reduction in left ventricular filling pressure and thus pulmonary edema. It is thought that the beneficial effects of ACE inhibitors are primarily due to neurohormonal modulation, in addition to hemodynamic benefits. Studies in dogs with CHF have demonstrated improved clinical scores when an ACE inhibitor was added to standard therapy (diuretics with or without digitalis glycoside), although those benefits have generally been mild and apparent only for short times. Improvements have generally been more apparent in dogs with DCM than in those with myxomatous mitral valve degeneration. A trend toward prolonged survival has been seen in some studies.

In general, veterinary cardiologists agree that an ACE inhibitor is indicated in dogs with CHF. The benefit of ACE inhibitor therapy before the onset of CHF is more controversial, although two prospective studies and one retrospective study have shown no benefit in dogs with mitral regurgitation due to myxomatous mitral valve degeneration. One retrospective study has suggested mild benefit in Doberman Pinschers with DCM. Studies of ACE inhibition in cats are limited, and none has shown a true statistical benefit of ACE inhibition beyond what is gained from standard diuretic therapy in cats with CHF. These studies had low patient numbers, however, and most cardiologists do prescribe an ACE inhibitor in addition to appropriate background therapy for cats with CHF. No benefit has been shown in delaying the progression of occult hypertrophic cardiomyopathy.

The primary serious adverse effect of ACE inhibition is related to excessive efferent glomerular arteriolar vasodilation due to an acute decrease in plasma angiotensin II concentration, resulting in a functional azotemia due to a reduced

glomerular filtration rate (GFR). This is relatively rare but can happen in any animal given an ACE inhibitor. There are no known predictors in cats or dogs. Anorexia, vomiting, and lethargy (uremia) may occur, so owners should be warned to watch for these clinical signs. Renal function tests (BUN, creatinine) should be measured before starting an ACE inhibitor and again 3–7 days later. Many clinicians wait until a dog is hemodynamically stable before starting an ACE inhibitor. Although cough is a common adverse effect of ACE inhibitor therapy in people, this is not seen in dogs and cats.

Enalapril is the only approved ACE inhibitor in the USA for dogs with CHF. It is generally dosed at 0.5 mg/kg, PO, bid. ACE inhibitors are “all-or-nothing” drugs, so giving a lower or less frequent dose probably produces no effect. Long-term dosing in cats is recommended at 0.5 mg/kg/day (most commonly 2.5 mg/cat), PO. ACE inhibitors are not emergency drugs. Clinical benefits, if any, are not commonly seen before 2–3 wk. Renal values should be monitored periodically (at least every 6 mo) while on long-term ACE inhibitor therapy.

Other ACE inhibitors used for treatment of heart failure include benazepril (0.25–0.5 mg/kg/day, PO), captopril (0.5–2 mg/kg, PO, tid), and lisinopril (0.5 mg/kg, PO, 1–2 times/day). Unlike enalapril and other ACE inhibitors that are renally excreted, benazepril undergoes significant hepatobiliary elimination (as much as 50% in dogs and 85% in cats). This does not appear to reduce the incidence of functional azotemia. Whether benazepril is safer in animals with renal insufficiency is unknown.

Vasodilators: Vasodilators exert a positive effect in CHF through dilating systemic arterioles (reduce resistance to blood flow) or systemic venodilation. The **nitrates** (sodium nitroprusside, nitroglycerin ointment, isosorbide dinitrate) act via the common end pathway of increased nitric oxide production, with subsequent activation of cyclic guanosine monophosphate (cGMP) and endothelial smooth muscle relaxation. Sodium nitroprusside (administered IV) is a potent mixed vasodilator, acting on both the arterial and venous systems. The combination of sodium nitroprusside with dobutamine may be especially useful in cases with cardiogenic shock and severe pulmonary edema. Although sodium nitroprusside dramatically and acutely reduces preload and afterload, its use is limited by the need for close monitoring and administration as a

constant-rate infusion. The major adverse effect is systemic hypotension (with or without weakness, tachycardia, or vomiting); thus, concurrent blood pressure monitoring is recommended. However, its duration of effect is very short (1–2 min) so if problems arise, they dissipate rapidly once the infusion is stopped. Sodium nitroprusside is diluted in 5% dextrose and can be started at 1–3 mcg/kg/min, with careful up-titration every 5–10 min to desired effect, or started at 5 mcg/kg/min and the animal and/or blood pressure more carefully monitored. A dosage of 5–10 mcg/kg/min is usually sufficient to control clinical signs, and rarely is >10 mcg/kg/min required. Prolonged administration (>16 hr) increases the risk of cyanide toxicity (see the package insert).

If nitroprusside therapy is unavailable or undesired, nitroglycerin ointment and isosorbide dinitrate (venodilation only) might be tried, but neither is usually clinically beneficial. However, they are extremely unlikely to produce harm. Nitroglycerin is absorbed transcutaneously by the person administering the drug, so gloves must be worn during administration. It is applied at ~¼ in. per 5 kg (dogs and cats) every 6–8 hr on a hairless region such as the inner pinna or inguinal region. The latter may be preferable in animals with poor peripheral perfusion, in which the pinnae and extremities may be cool to the touch. The drug should be wiped or cleaned off after 8–12 hr or before the next dose is given. Isosorbide dinitrate is almost never used. In the one study designed to look for benefits in dogs in heart failure, none was identified when isosorbide was administered at 0.2–1 mg/kg, PO, tid. Another study showed acute benefit in dogs with mitral regurgitation when isosorbide was administered at 5 mg/kg (effect lasted 4 hr) and 10 mg/kg (effect lasted 11 hr). The largest pill size is 40 mg. Tolerance to nitrates has been demonstrated in many experimental canine models.

Hydralazine is a potent systemic arteriolar vasodilator typically reserved for dogs with mitral regurgitation due to myxomatous mitral valve degeneration that are refractory to conventional therapy, or in acute CHF when nitroprusside is unavailable. Its presumed mechanism of action is via production of vasodilatory prostaglandins. Hydralazine may reduce systemic vascular resistance up to 50%. This reduction in resistance results in the left ventricle pumping more blood flow forward through the systemic vasculature and less blood flow backward through the mitral

valve into the left atrium. This decreases left atrial and pulmonary capillary pressures, reducing development of pulmonary edema. Approximately 30% of dogs vomit when receiving hydralazine; the drug generally needs to be discontinued when this happens. The recommended starting dosage in a dog in chronic heart failure is 0.5 mg/kg, PO, bid, if the animal is already on an ACE inhibitor, and 1 mg/kg, PO, bid, if not, with gradual (every 1–3 days) up-titration to effect, as high as 3 mg/kg, PO, bid. The drug is effective within 30 min, peaks in 1–3 hr, and maintains that peak for 11–13 hr. In a dog in acute, severe heart failure, a dosage of 2 mg/kg, PO, can be administered. Hydralazine is an “all-or-nothing” drug, so the primary danger is in giving too low of a dose and producing no beneficial effect. Approximately 90% of dogs respond to a dosage of 2 mg/kg. A small percentage of those dogs become weak for ~12 hr and then recover. In a dog with chronic heart failure due to mitral regurgitation, a good target would be a decrease in systolic blood pressure of 10–15 mmHg, but given the inaccuracy of blood pressure measurement in dogs this type of documentation may not be feasible. Other evidence that the dose being given is adequate is the presence of bright red mucous membranes and a decrease in murmur intensity. In cats, hydralazine can be given at a starting dose of 2.5 mg/cat, PO, bid.

Amlodipine is a calcium channel blocker with only peripheral vascular effects (no cardiac effects) and moderate to marked vasodilatory effects on systemic arterioles. Its actions are very similar to those of hydralazine (decreased mitral regurgitation and pulmonary edema) but without the adverse effects of vomiting and tachycardia. Amlodipine has a relatively slow onset of action, so its effects take 1–2 days to be noticeable. It is typically reserved for animals refractory to conventional heart failure drug therapy or for those with moderate to severe systemic hypertension. Adverse effects are generally related to hypotension and are uncommon when up-titration is done gradually. In dogs, therapy is initiated at 0.3 mg/kg/day, PO, and up-titrated every 2–3 days to a maximal dosage of 1 mg/kg/day (if needed). In cats, therapy is generally started at 0.625 mg/day ($\frac{1}{4}$ of a 2.5-mg tablet) and gradually up-titrated to effect, up to as much as 1.25 mg, bid, in some cases. Because amlodipine reduces the amount of regurgitation, it may also effectively slow the progression of mitral regurgitation to heart failure in dogs.

Gingival hyperplasia can occur in dogs administered amlodipine, which often necessitates discontinuation of the drug.

Phosphodiesterase type 5 (PDE 5) inhibitors (eg, sildenafil, tadalafil) are used to relax the smooth muscle in pulmonary arterioles. Their mechanism of action is somewhat similar to that seen with nitrates, with a common increase in the second messenger cGMP. PDE 5 inhibitors are used in the treatment of moderate to severe pulmonary arterial hypertension. Studies in dogs have demonstrated modest clinical improvement (reduction or cessation of syncope, improved right heart failure) with usually minimal improvement in pulmonary artery pressures, at least at lower dosages (eg, 1 mg/kg, PO, bid-tid). Anecdotally, PDE 5 inhibitors seem to provide the most notable clinical benefit to animals with syncope secondary to pulmonary hypertension. Anecdotal success has also been reported in dogs with right-to-left shunting cardiac defects in which the shunt is due to the increase in pulmonary vascular resistance. Adverse effects are uncommon but may include GI upset and hypotensive-related effects (especially when combined with nitrates, which is contraindicated). A major drawback regarding clinical use of PDE 5 inhibitors is expense, particularly in larger animals. Fake (85% in one study) sildenafil is commonly sold online. Sildenafil is administered at 1–3 mg/kg, PO, bid-tid in dogs, and at 1 mg/kg, PO, tid in cats. Tadalafil is administered at 1 mg/kg, PO, once to twice daily in dogs.

β -Adrenergic Blockers: In people with myocardial failure (eg, DCM), β -blocker administration, with a very low starting dose titrated upward over months, results (seemingly paradoxically) in an improvement in myocardial function. To date, all attempts to replicate this phenomenon in client-owned dogs have failed. Dogs with experimentally induced heart failure have shown measurable improvements in cardiac performance after administration of metoprolol, but these were models of ischemic cardiomyopathy, which is a rare cause of DCM in dogs. Large dogs (>20 kg) with experimentally induced mitral regurgitation also have had lesser decreases in contractility over time when administered atenolol when compared with placebo.

β -Blockers are commonly administered to cats with hypertrophic cardiomyopathy, primarily to reduce systolic anterior motion of the mitral valve. However, evidence that this results in clinical improvement,

biochemical improvement, or prolonged survival is lacking. Atenolol (6.25–12.5 mg/cat, PO, bid) is the β -blocker most commonly used in cats. There are limited and preliminary data associating the use of atenolol in cats with hypertrophic cardiomyopathy and CHF with a shorter survival, and consideration might be given to dosage reduction or withdrawal if CHF develops.

Nutritional Considerations: Important metabolic changes may occur in animals with heart failure. Upregulation of the RAAS leads to increased plasma volume, largely mediated by increased sodium retention. Increased production of inflammatory cytokines such as tumor necrosis factor and interleukin 1 may promote increased metabolic demand and contribute to anorexia, thus worsening "cardiac cachexia." Studies in people and a study in dogs have shown that patients with CHF who lost weight during the course of these studies had a poorer prognosis. In some patients, nutrient deficiencies (taurine, carnitine) have been shown to cause DCM. Decreased levels of circulating fatty acids have been documented in people and dogs with heart failure. The overall nutritional goals in the management of animals with heart failure should therefore include supplying adequate calories, modulating the production of proinflammatory cytokines, managing sodium balance, and supplementing nutrients that may be deficient.

The idea that **sodium restriction** reduces circulating plasma volume and preload is well established. However, sodium restriction is known to activate the RAAS, and there is continued debate as to the role of sodium restriction in animals, especially those with asymptomatic cardiac disease or mild to moderate CHF. In contrast, moderate to severe sodium restriction may be indicated in animals with severe CHF, especially in those refractory to drug therapy. It is also important to counsel owners to avoid foods and treats with high sodium content, because an acutely high sodium load (as can be seen in animals fed human snacks or table foods) may precipitate CHF in animals with compensated heart disease. For animals in mild to moderate heart failure (ISACHC Class II), moderate sodium restriction (50–80 mg/100 kcal) may be tried if the dog or cat will readily eat such a diet. In animals with severe refractory CHF, more aggressive sodium restriction (<50 mg/100 kcal) may be tried. This becomes even more of a therapeutic challenge with some animals

in which cardiac cachexia is present, because lower sodium foods are often less palatable. In general, maintaining adequate caloric intake is more important than sodium restriction.

Supplementation with **n-3 fatty acids** has shown multiple benefits in people with CHF, and a study in dogs suggests antiarrhythmic benefits as well. These fatty acids may reduce circulating inflammatory cytokine levels and seem to improve appetite in some dogs with cardiac cachexia. Daily doses of eicosapentaenoic acid at 40 mg/kg and docosahexaenoic acid at 25 mg/kg can be tried.

Taurine supplementation is indicated in animals with documented taurine deficiency and DCM. The incidence of DCM has declined dramatically in cats since taurine deficiency was identified as a primary cause in the late 1980s. Taurine deficiency is still documented in some cats with DCM fed noncommercial diets (especially chicken, dog food, and vegetarian diets) and rarely a commercial cat food diet. Supplementation at 250 mg, PO, bid, can be started in cats while awaiting results of plasma and whole blood taurine concentrations. Dogs are able to synthesize more endogenous taurine than cats and do not have an obligatory loss in bile, so deficiency is less common in this species. However, American Cocker Spaniels with DCM uniformly have a low plasma taurine concentration and respond to taurine or taurine and carnitine supplementation. Newfoundlands are relatively predisposed to taurine deficiency, especially when fed lamb and rice or high-fiber, low-protein/taurine diets. Rarely, other breeds (mostly breeds not usually thought of as being predisposed to developing DCM) with DCM will be taurine deficient/responsive. Whole blood and plasma taurine concentrations should be obtained in any dog suspected of having a taurine-deficient cardiomyopathy, and supplementation can be started at 500–1,000 mg, PO, bid-tid, while awaiting results. Clinical improvement occurs within weeks of starting taurine supplementation in cats or dogs with DCM due to taurine deficiency. Echocardiographic improvement takes longer (2–3 mo).

L-Carnitine plays an important role in fatty acid metabolism and energy production. Carnitine deficiency has been documented in one family of Boxers and myocardial carnitine deficiency is common in dogs with DCM, but it is most likely that this deficiency is a result of cardiomyopathy, not the cause, in these dogs. Carnitine

has been supplemented in other breeds with DCM but with little success. Diagnosis of carnitine deficiency is difficult and requires an endomyocardial biopsy. Supplementation is also expensive, and given our limited knowledge of the role carnitine plays in canine cardiomyopathy, supplementation is not routinely recommended. Nevertheless, supplementation can be offered at 50–100 mg/kg, PO, bid–tid, to dogs with DCM.

Coenzyme Q₁₀ is involved with mitochondrial energy production and possesses general antioxidant properties. Anecdotal benefits of supplementation in people and dogs with DCM have been reported, but well-controlled studies are lacking, and reports are conflicting. Consequently, there is no known benefit. The dosage in dogs is 30–90 mg, PO, bid.

Oxygen Therapy: The presence of pulmonary edema in animals with CHF increases the alveolar-arterial diffusion distance for oxygen to pulmonary capillaries and disturbs ventilation/perfusion matching. Supplemental oxygen administration increases the alveolar-arterial diffusion gradient and thus increases arterial oxygen content. Oxygen may be administered via oxygen cage, flow-by method (least preferred), nasal cannula, or oxygen collar (constructed by covering the ventral 50%–75% of an Elizabethan collar with plastic wrap and taping oxygen tubing along the ventral aspect of the collar). The oxygen cage is least stressful for the animal but is expensive, because high flows of oxygen are required to achieve therapeutic concentrations (>40% inspired oxygen). The oxygen collar has the potential to achieve a very high concentration of inspired oxygen (as much as 80%) but may require light sedation to increase patient tolerance.

Thoracocentesis: Pleural effusion decreases the available area for alveolar ventilation and arterial oxygenation. Pleural effusion should always be excluded as the cause of dyspnea in animals in heart failure, especially cats. This is best accomplished using ultrasound. If ultrasound is unavailable, radiographs can be taken, but extreme care must be taken to avoid stressing the animal (especially cats), because stress in a dyspneic animal often results in death. If radiographs cannot be taken, a diagnostic thoracocentesis should be done. This can often be done in cats in the examination room using a butterfly catheter with the cat in sternal recumbency. If fluid is present, as much as possible should be removed. Thoracocentesis is the most effective

treatment in animals with respiratory distress due to a significant volume of effusion. However, caution again should be taken in particularly stressed animals, which may require pretreatment with oxygen and light sedation. Diuretic therapy is ineffective at acutely resolving a large volume of pleural effusion.

Abdominocentesis: Ascites may produce abdominal discomfort and worsen dyspnea by reducing available lung capacity in animals in right heart failure. Abdominocentesis should be performed at the time of initial diagnosis of right heart failure if the ascites is severe. In animals with recurrent ascites refractory to diuretic therapy, abdominocentesis may be performed every 1–4 wk to improve patient comfort and quality of life. Every attempt should be made to remove all or as much fluid as possible on each visit to prolong the time between repeat abdominocenteses. This does not result in hypoalbuminemia. Fluid can be removed manually using either a fenestrated catheter and large syringe or a suction device.

Ancillary Therapy: Bronchodilators (theophylline, terbutaline) are generally reserved for animals with chronic airway disease, which is common in older small-breed dogs. Caution should be taken in animals with CHF, especially with tachyarrhythmias, because of the sympathomimetic effects of these agents. In dogs with cardiovascular disease and syncope, theophylline has been used with some success for its positive chronotropic effects. Dosages of theophylline and terbutaline are as previously described under treatment of bradyarrhythmias (*see above*).

Cough suppressants generally should not be used if a cough is truly due to cardiogenic pulmonary edema. Instead, they are reserved for dogs with chronic bronchitis and airway collapse (malacia) and, even then, generally reserved for dogs not responsive to a corticosteroid and/or doxycycline with or without theophylline. It is common for dogs with CHF to have concomitant chronic bronchitis. Common antitussive agents used for dogs with cardiac disease include butorphanol at 0.05–0.3 mg/kg, PO, tid–qid, or hydrocodone at 0.22 mg/kg, PO, bid–tid.

Anxiolytic therapy may be used for some animals with severe respiratory distress secondary to CHF. Morphine has traditionally been recommended to alleviate anxiety in dogs with acute CHF because of its concurrent sedative and venodilating

(and thus preload reducing) properties, but it also can produce respiratory depression, which can be catastrophic. The dosage of morphine in dogs is 0.1–0.25 mg/kg, SC. It may also cause nausea or vomiting. Morphine is generally avoided in cats, because it may induce agitation and dysphoria. Butorphanol is a partial opiate agonist/antagonist with minimal cardiovascular effects. A sedative dosage of 0.2–0.5 mg/kg administered IM or IV can be used in cats and dogs. Butorphanol may also be combined with a benzodiazepine (midazolam or diazepam), with the latter also dosed at 0.2–0.5 mg/kg, IM or IV. Phenothiazine tranquilizers (eg, acepromazine) may be used to alleviate severe anxiety and have the potential added benefit of producing mild systemic arteriolar dilation; however, they should be used cautiously in animals with severe hemodynamic compromise or systemic hypotension. A low dosage of 0.01–0.1 mg/kg, IM or IV, can be used.

SPECIFIC CARDIAC DISEASES

Myxomatous AV Valve Degeneration

(Degenerative AV valvular disease, Endocardiosis)

Myxomatous degeneration is a process of the fibrous layer of an AV valve breaking down to cause mitral valve prolapse (hooding) and the spongiform layer proliferating to cause nodular thickening of the cardiac valve leaflets, most severely at their tips. Myxomatous degeneration commonly affects the mitral and tricuspid valves in dogs. Chordae tendineae are also affected by the degenerative process, making them prone to rupture. The exact cause is unknown, but in Cavalier King Charles Spaniels and Dachshunds it is an inherited trait. Myxomatous degenerative valve disease is the most common cardiac disease in dogs and accounts for ~75% of cardiovascular disease in this species; ~60% of affected dogs have only the mitral valve affected, 30% have lesions in both the tricuspid and mitral valves, and 10% have only tricuspid valve disease. In dogs, the disease is age- and breed-related, with older, small-breed dogs demonstrating a much higher incidence. Horses and cats are also affected by this disease (most commonly affecting the mitral valve leaflets); however, it is uncommon in these species. In horses, a degenerative valve disease can also affect the aortic valve cusps and consists of valvular nodules or fibrous bands at the free

borders of the valve. This condition is most common in older horses. It causes aortic regurgitation, which is heard as a diastolic murmur on the left side. The murmur is often “musical,” meaning it has one frequency caused by the valve structures vibrating at the frequency heard. The murmur may be high-pitched and sound truly musical, or it may be low-pitched and sound like a grunt or a dive bomber. The murmur is often loud, but the aortic regurgitation is usually mild. Clinical signs (eg, heart failure) are usually not seen, because severe aortic regurgitation is uncommon.

Insufficiency of an AV valve results in turbulent, systolic (ie, during ventricular contraction) flow through the affected valve from a ventricle into an atrium. This regurgitation results in an increase in volume within the atrium and thus to an increase in atrial chamber size. When regurgitation is severe, atrial pressure may also increase. If the mitral valve is affected, the increased left atrial pressure results in increased pulmonary capillary pressures and, if the increase is high enough (ie, >20 mmHg), in cardiogenic pulmonary edema (ie, left heart failure). If the tricuspid valve is affected, severe regurgitation can result in an increased systemic venous pressure and signs of right heart failure (most commonly ascites in dogs). The constant, high-velocity, regurgitant jet of blood through the affected mitral valve physically damages the endocardium of the left atrium, resulting grossly in jet lesions. In cases with severe regurgitation, the chronic increase in left atrial size and pressure can also result in left atrial rupture and acute cardiac tamponade, often resulting in death.

Pathophysiologically, the body compensates for valvular regurgitation primarily by renal sodium and water retention, causing an increase in blood volume and in venous return to the heart. This results in an enlargement in ventricular chamber size and a left ventricle capable of ejecting a larger total stroke volume with each beat. That way, even though some percentage of blood flow is going backward into the left atrium, a normal or near normal amount can be ejected forward into the aorta. Multiple mechanisms exist for sodium and water retention, but the renin-angiotensin-aldosterone system (RAAS, *see p 100*) is one of the most active and best studied. Renin release by the juxtaglomerular apparatus in the kidneys cleaves angiotensinogen into angiotensin I, and angiotensin-converting enzyme then cleaves angiotensin I into angiotensin II. One of the

main effects of angiotensin II is to stimulate aldosterone release by the adrenal glands. Aldosterone stimulates the cells in the distal renal tubules to bring sodium back into the vascular space, and water follows the sodium. The increase in blood volume and venous return to the heart places chronic stretch on cardiac myocytes, resulting in sarcomere replication within the myocytes and growth of longer myocytes. This allows the affected ventricle to develop a larger chamber (ie, eccentric or volume overload hypertrophy). This is the primary compensatory mechanism for valvular regurgitation. It is highly efficient and allows the heart to compensate not only for a valvular leak for years but also for an extreme amount of regurgitation. For example, a small dog can completely compensate for regurgitation in which as much as 75% of the blood flow from the left ventricle goes into the left atrium, while only 25% goes forward into the aorta.

Activation of the RAAS and other compensatory mechanisms are commonly seen as dysfunctional and increases of various neurohormones as detrimental, because overt increases are often seen in dogs that are in heart failure when compensatory mechanisms are overwhelmed. However, these mechanisms are detrimental for only a few months at the end stage of the disease.

Only ~30% of dogs with mitral regurgitation ever develop left heart failure. In dogs, there are no clinical signs in the early and middle stages of the disease, although a systolic murmur (grade I–VI) is heard with maximal intensity at the left apex. The heart murmur intensity often does not correlate with disease severity, although most soft murmurs are heard in dogs with mild mitral regurgitation. Some dogs may also develop a systolic click before developing a heart murmur. A systolic click is heard as a three-heart-sound rhythm and may be mistaken for a gallop sound (rhythm). A three-heart-sound rhythm in a middle-aged to older small-breed dog is almost always a systolic click rather than a gallop sound. A gallop sound may be heard in a dog with severe mitral regurgitation but is usually difficult to auscult because of the loud heart murmur also present. When the mitral regurgitation becomes severe and overwhelming, left heart failure (pulmonary edema) becomes evident, producing increases in respiratory rate (tachypnea) and effort (dyspnea), and cough. Syncope may also occur. Although syncope is not a sign of heart failure, it may be present when heart failure is evident and may improve

when heart failure is controlled. Sudden death is rare but may occur secondary to left atrial rupture or rupture of a primary mitral valve chord. Physical examination findings in animals that have developed left heart failure are primarily referable to the increased respiratory rate and effort. Some dogs may have respiratory crackles and wheezes; however, these are much more common and more obvious in dogs with chronic bronchitis, and many dogs with pulmonary edema have no demonstrable abnormal pulmonary sounds. If tricuspid valve degeneration is significant, signs of right heart failure may be noted (eg, ascites, jugular distention/pulses).

A CBC, serum chemistry profile, and urinalysis are usually within normal limits. Left atrial enlargement is the characteristic finding on thoracic radiographs of an animal with myxomatous degeneration of the mitral valve, and the size of the left atrium correlates directly with the severity of the regurgitation in small dogs. Other changes include enlargement of the left ventricle and pulmonary veins. As left heart failure develops, increased interstitial density to the pulmonary parenchyma occurs, and as severity increases, an alveolar pattern with air bronchograms (ie, severe pulmonary edema) appears. In dogs, these changes are classically seen in the caudodorsal lung fields and may be more prominent on the right side. In older dogs, it is common to have an increased interstitial density in the lungs and to have radiographs taken at or near end-expiration. This commonly creates the illusion of pulmonary edema and therefore the misdiagnosis of left heart failure. This can be avoided by remembering that for a dog to be in chronic left heart failure, the regurgitation must be severe and overwhelming so the left atrium is usually severely enlarged. The exception to this rule is in dogs with acute heart failure due to a ruptured chord and a left atrium that is not severely enlarged. If the respiratory rate in the examination room is normal (<30 breaths/min), the dog cannot be in left heart failure. If there is doubt regarding the diagnosis of pulmonary edema in a dog that is not in critical condition, it is usually best to send the dog home and have the owner count the dog's respiratory rate when it is sound asleep in a cool environment. If pulmonary edema is present, the sleeping respiratory rate (SRR) will always be increased. If the rate is increased, the dog should be administered furosemide at a dosage of at least 2 mg/kg, PO, bid. If the SRR then decreases, the diagnosis of left heart failure can be made. In cats, the

radiographic pattern is more diverse and often is not caudodorsal. A heavy interstitial to alveolar pattern in the accessory lung lobe on a lateral view is one of the more common findings. Cats in left heart failure also commonly have pleural effusion.

Echocardiography demonstrates thickened and irregular valve leaflets of normal to increased echogenicity. Chordae tendineae may be ruptured, causing the AV leaflets to flail (ie, leaflet tips to protrude) into the atrium during ventricular contraction. Mitral valve prolapse (hooding), in which the body of a leaflet (not the tip) protrudes into the left atrium in systole, may also be present. The size of the left atrium increases in direct correlation with the severity of the mitral regurgitation in small dogs. Left ventricular chamber enlargement (ie, eccentric or volume overload hypertrophy) also occurs in correlation to disease severity. In small dogs, left ventricular myocardial contractility or function is often normal as evidenced by a normal end-systolic diameter or volume. The increase in end-diastolic diameter coupled with the normal end-systolic diameter results in the left ventricular fractional shortening (ie, the amount of contraction [not contractility]) being increased. Myocardial contractility is decreased in some small dogs and many large dogs at the onset of heart failure and may become decreased in small dogs when being treated for heart failure.

Electrocardiographically, animals with mild to moderate degenerative valve disease have a normal sinus arrhythmia or normal sinus rhythm. When CHF develops, the increase in sympathetic tone often results in loss of sinus arrhythmia and usually in an increase in heart rate (ie, sinus tachycardia). Left atrial enlargement promotes the development of atrial arrhythmias such as atrial premature complexes and atrial fibrillation. Ventricular tachyarrhythmias are uncommon. There may be evidence of left atrial enlargement (P mitrale or widened P waves) and left ventricular enlargement (tall and widened R waves) on an ECG, but these changes are unreliable indicators of chamber enlargement.

Measurement of the plasma or serum concentration of NT-proBNP may be useful in dogs with mitral regurgitation. It is usually not increased in dogs with mild mitral regurgitation, may be increased in some dogs with moderate to severe mitral regurgitation, and is increased in most dogs with left heart failure secondary to mitral regurgitation. It would be most useful in dogs presented with severe tachypnea/dyspnea if a rapid assay (bedside test) were

available. It might be useful for differentiating dogs with chronic lung disease from dogs in chronic left heart failure, but this can often be accomplished with less expense and greater accuracy by having the owner count the dog's SRR and doing a furosemide response test if the rate is increased. NT-proBNP often decreases after successful treatment of left heart failure but frequently does not decrease to a value within the normal range. Predicting which dogs with mitral regurgitation will go into heart failure is difficult. As populations, dogs with a larger left ventricular diastolic dimension, larger left atrial size, and a higher NT-proBNP are at greater risk of developing heart failure, but translating that to an individual dog is often fraught with error. The same is true for predicting cardiac death (ie, from heart failure or sudden death) from severe mitral regurgitation. Higher dosages of furosemide are required in dogs with more severe heart failure, so higher furosemide dosages predict decreased survival.

Studies in dogs with degenerative mitral valve disease that are not yet in heart failure have failed to convincingly demonstrate a reduction in time to onset of CHF with use of ACE inhibitors. Thus, treatment in small-breed dogs should be reserved for dogs with clinical signs of heart failure, ie, those demonstrating cardiogenic pulmonary edema on thoracic radiographs and resting/sleeping tachypnea in the absence of other severe pulmonary disease. Treatment of CHF includes administration of a diuretic (almost always furosemide) and an ACE inhibitor as adjunctive therapy. Cardiogenic pulmonary edema should not be treated with an ACE inhibitor alone. Pimobendan (0.25–0.3 mg/kg, bid) is also indicated in dogs in heart failure. Spironolactone might have chronic, long-term benefits in dogs with heart failure due to myxomatous mitral valve degeneration, but there is no convincing evidence of this in dogs with mitral regurgitation, and it should not be relied on to produce clinically relevant diuresis. Dogs refractory to administration of a maximal dosage of furosemide (4 mg/kg, tid) can be treated with several additional drugs or a change in strategy. The pimobendan dosage can be increased to tid, or the bid dosage can be doubled. Amlodipine and hydralazine decrease the amount of regurgitation and improve perfusion and can be very effective. A thiazide diuretic combined with furosemide is another effective means of treating dogs with refractory heart failure, but care must be taken to not produce clinically relevant

dehydration and hypokalemia. Torsemide may be used to replace furosemide. Torsemide is more bioavailable (better absorbed) and has a longer and more consistent half-life. The starting dose is determined by multiplying the total daily dose of furosemide by 0.1 and dividing that dose bid. Care must be taken to have the owner closely monitor the SRR when this is done. If the SRR increases, the dose of torsemide must be increased promptly.

Surgical treatment of mitral regurgitation is routine in human medicine and most commonly consists of mitral valve repair. Successful mitral valve repair has also been accomplished in dogs, but the only currently truly successful program is in Japan. Replacement of the mitral valve with a prosthetic valve is almost uniformly unsuccessful.

Abnormal arrhythmias such as atrial fibrillation or other severe and sustained supraventricular arrhythmias, if present, should either be resolved or the rate controlled with digitalis glycosides and diltiazem or a β -blocker (eg, atenolol) to prevent tachycardia-induced myocardial failure. Optimal therapy should be planned for each stage of disease. In acute and severe CHF, oxygen and aggressive parenteral furosemide administration are warranted. Nitroprusside can also be beneficial.

Some affected dogs can live for >1 yr with appropriate therapy. However, survival time is highly variable, and no firm estimates should be provided. If a dog has been treated for left heart failure for >2 yr, the diagnosis should be reassessed.

Valvular Blood Cysts or Hematomas

These benign valvular lesions are present in as many as 75% of calves <3 wk of age. They are most commonly located on the AV valves.

Cardiomyopathies

Cardiomyopathy is defined as any disease involving primarily and predominantly the heart muscle. Most of the cardiomyopathies of animals are idiopathic diseases that are not the result of any systemic or other primary cardiac disease. In several instances, a mutational cause has been identified. In others, a genetic cause has been identified. In animals (primarily dogs and cats), they are classified as dilated cardiomyopathy, hypertrophic cardiomyopathy, arrhythmogenic right ventricular cardiomyopathy, and restrictive or unclassified cardiomyopathy. If a disease process has been identified as the cause of myocardial

dysfunction, these are more correctly identified as secondary myocardial diseases or with a descriptive term preceding the term cardiomyopathy (eg, taurine-responsive dilated cardiomyopathy).

Dilated Cardiomyopathy (DCM): This disease is characterized by the progressive loss of myocyte number and/or function and a decrease in cardiac contractility. Several forms of secondary DCM exist (eg, taurine deficiency in cats, doxorubicin- or parvovirus-induced in dogs). In some Doberman Pinschers (primarily those in the USA), the disease is caused by a mutation in the gene that encodes for pyruvate dehydrogenase kinase 4 (PDK4), an enzyme in mitochondria required for ATP production. A small percentage of Boxers with arrhythmogenic right ventricular cardiomyopathy (*see below*) develop DCM. These dogs have a mutation in the gene that encodes for striatin, a desmosomal protein. DCM has a protracted subclinical phase in dogs, with clinical signs evident for a relatively short time. During the subclinical phase, compensatory mechanisms, primarily volume overload or eccentric hypertrophy, maintain normal hemodynamics. As cardiac contractile function is progressively lost, cardiac output, and so renal blood flow, decreases and then is normalized again as renal sodium and water retention increase blood volume and venous return and the affected ventricle is stimulated to grow larger. The increased activation of the sympathetic nervous system and the RAAS, after years of initial benefit, cause deleterious effects during the late phases of the disease (*see p 100*). Excessive stimulation of the myocardium by the sympathetic nervous system may stimulate ventricular arrhythmias and myocyte death, while excessive activation of the RAAS causes vasoconstriction and continued retention of sodium and water in the presence of edema/effusion.

DCM is most prevalent in dogs and is especially prevalent in certain breeds. It most commonly affects large-breed dogs and far less commonly small-breed dogs (with a few exceptions such as American Cocker Spaniels, Springer Spaniels, and English Cocker Spaniels). Doberman Pinschers, Boxers, Great Danes, German Shepherds, Irish Wolfhounds, Scottish Deerhounds, Newfoundlands, Saint Bernards, and Labrador Retrievers, among other large-breed dogs, are particularly at risk. In Portuguese Water Dogs, a juvenile form of the disease is seen. The disease is

typically seen in middle-aged to older dogs; males are either affected more frequently or more severely than females. The incidence in cats has decreased dramatically since the discovery in 1987 that taurine deficiency was responsible for most cases (taurine-responsive DCM). Since then, taurine has been added to all commercial cat foods. Most cases today are not taurine responsive and reflect primary (or idiopathic) disease, although the disease is seen occasionally in cats fed noncommercial diets (eg, vegetarian, baby food, home-cooked food).

Doberman Pinschers typically develop concurrent and progressive ventricular arrhythmias along with progressive systolic dysfunction. Syncope and sudden death occur in as many as 20% of Doberman Pinschers, and signs of left heart failure eventually develop. Most Doberman Pinschers demonstrate evidence of myocardial failure at the time syncopal episodes are noted. In other breeds, such as Great Danes and Newfoundlands, sudden death and collapse are far less likely. Signs of left heart failure, including tachypnea and dyspnea due to pulmonary edema, weakness, and exercise intolerance often predominate, but signs of right heart failure (ascites) may also be present. Pleural effusion may be present, most commonly in dogs with both left and right heart failure. Ascites was noted in 35% of Newfoundlands with DCM in one study. Cats with DCM typically present with severe respiratory signs due to pulmonary edema and/or pleural effusion, and clinical signs are often rapidly progressive and refractory to therapy.

A soft systolic heart murmur, best heard at the left cardiac apex, is often present. A gallop sound may also be present but is subtle and usually identified in dogs only by an experienced examiner. It is often more obvious in cats. The femoral pulse may be weak, and an arrhythmia with associated pulse deficits may be noted. The arrhythmia is most commonly ventricular ectopy (eg, premature ventricular contractions, ventricular tachycardia) in Doberman Pinschers and Boxers, and atrial fibrillation in giant-breed dogs. Ascites, tachypnea, dyspnea, or cough may also be noted, depending on the type of heart failure that develops.

Blood work may demonstrate prerenal azotemia (increased BUN, creatinine). Thoracic radiographs typically demonstrate moderate to marked cardiomegaly. However, this finding may be masked by chest conformation (eg, a deep chest in a Doberman Pinscher). If left heart failure

is present, pulmonary edema is more commonly evident in a large dog than it is in a small dog with mitral regurgitation, and the left atrium is moderately to markedly enlarged. Echocardiography is the best test to definitively diagnose DCM. In dogs with severe DCM that are in heart failure, there is a dramatic decrease in left ventricular fractional shortening caused by an increase in left ventricular end-systolic diameter. Cardiac chambers, especially the left atrium and left ventricle, are dilated. Mitral insufficiency typically develops as progressive left ventricular chamber dilation results in separation of the valve leaflets. Abnormal ECG findings may include ventricular premature complexes and ventricular tachycardia (especially in Doberman Pinschers and Boxers), and atrial fibrillation (especially giant breeds). There may be electrocardiographic evidence of left atrial enlargement (P mitrale or widened P waves) and left ventricular enlargement (tall and wide R waves). The occurrence of ventricular premature complexes on a routine ECG in a presumed healthy Doberman Pinscher is highly suggestive of DCM.

The objectives of therapy are to lessen edema/effusion formation (eg, with diuretics), improve contractility (eg, with pimobendan), and reduce adverse effects of angiotensin II and other neurohormonal changes (eg, with an ACE inhibitor). Taurine-responsive myocardial failure occurs in some breeds, particularly American Cocker Spaniels, and anecdotally in a few Golden Retrievers, Dalmatians, Welsh Corgis, Tibetan Terriers, and other breeds. In many of these breeds, taurine deficiency can be diagnosed by low plasma or whole blood concentrations. Response to taurine supplementation (which may take 2–4 mo) can be dramatic and may obviate the need for other cardiac medications. Carnitine-responsive cardiomyopathy, although reported, is almost a nonentity. Coenzyme Q₁₀ supplementation is an unproven and, many say, irrational approach to the disease. Administration of fish oil might reduce the severity of cardiac cachexia in animals with DCM.

CHF, which may be severe, should be treated as discussed elsewhere (*see p 99*). As severe pulmonary edema resolves, furosemide can be administered orally, with oxygen continued until clinical signs are controlled. Pimobendan and an ACE inhibitor (eg, enalapril, benazepril) should be started. Pimobendan may be indicated in Doberman Pinschers with DCM before the onset of heart failure. Antiarrhythmic

therapy is frequently indicated, especially for Doberman Pinschers with severe ventricular arrhythmias. Holter monitoring is the ideal method to evaluate both the severity of an arrhythmia and therapeutic efficacy. Mexiletine (5–10 mg/kg, tid) may be useful in animals with ventricular arrhythmias and concurrent heart failure, because negative inotropy is less than with sotalol (1–3 mg/kg, bid); however, sotalol can be used if therapy is initiated with a low dose carefully titrated upward and if pimobendan is used concurrently. Amiodarone may be a more effective drug than mexiletine to prevent sudden death in Doberman Pinschers, but its use is associated with a relatively high incidence of hepatotoxicity in this breed.

The prognosis is grave for cats with DCM (not taurine responsive), with a median survival time of 2 wk. Cats that are taurine responsive also have an initial high risk of death. However, cats that survive long enough for taurine to become effective (2–3 wk) have an excellent prognosis, because the disease is completely reversible. Dogs that are taurine responsive also have a fair to good prognosis once signs of CHF abate. The short-term prognosis for other dogs with DCM depends primarily on the severity of the heart failure on presentation. Longterm prognosis is poor, with survival time measured in months. The prognosis is poor in most Doberman Pinschers: in the past, ~25% died within 2 wk of presenting with heart failure, and 65% died within 8 wk. Pimobendan apparently prolongs survival, sometimes dramatically (months). The prognosis in other breeds is better but remains guarded; 75% die within 6 mo of diagnosis. As expected, dogs with severe heart failure, particularly left heart failure, have a worse prognosis than those with milder signs or signs of right heart failure at presentation.

Arrhythmogenic Right Ventricular Cardiomyopathy: Arrhythmogenic right ventricular cardiomyopathy (ARVC) is seen almost exclusively in Boxers and is also known as Boxer cardiomyopathy. It is rarely seen in cats. ARVC is characterized by a fatty or fibrofatty infiltrate of the right ventricular myocardium. In Boxers, the most common manifestation of the disease is syncope caused by a very fast (>400 bpm) nonsustained ventricular tachycardia. It takes 6–8 sec of no blood flow to the brain to result in unconsciousness, so the tachycardia must last for that long for syncope to occur and then must stop spontaneously for sudden death not to

occur. The diagnosis is based on the number of premature ventricular complexes (PVCs) on a Holter monitor (>100–300 PVCs in 24 hr is generally considered diagnostic of ARVC in this breed). The QRS complexes of the PVCs are most commonly upright in the leads where the QRS complex is usually upright, meaning they originate from the right ventricle. The heart looks normal on thoracic radiographs and an echocardiogram in most Boxers with ARVC, although some will develop a true DCM and go into heart failure. Boxers presented for syncope without DCM are treated with sotalol (1–3 mg/kg, PO, bid) or a combination of mexiletine (5–10 mg/kg, PO, tid) and atenolol (12.5–25 mg/dog, PO, bid). Dogs refractory to sotalol may have mexiletine added. In Boxers with ARVC that do not have DCM, the prognosis is often good, and many live for several years on antiarrhythmic therapy. The longterm prognosis for dogs with DCM that are in heart failure is poor. Most live only several months.

In cats, the disease usually manifests as right ventricular and atrial enlargement and right heart failure, usually along with some supraventricular and ventricular tachyarrhythmias. Dyspnea and tachypnea due to pleural effusion, ascites, and nonspecific clinical signs such as anorexia and lethargy are reported in affected cats. Treatment is similar to that of DCM. Longterm prognosis is generally poor.

Hypertrophic Cardiomyopathy:

Hypertrophic cardiomyopathy (HCM) is characterized by primary concentric left ventricular hypertrophy (ie, thick walls) resulting from an inherent myocardial disorder rather than pressure overload (such as caused by aortic stenosis), hormonal stimulation (such as hyperthyroidism or acromegaly), infiltration of the myocardium (eg, lymphoma), or other noncardiac disease. It is primarily seen in domestic cats and rarely in small dogs. It has also been reported in cattle. Papillary muscle enlargement is a consistent feature of the disease in cats. In people, HCM is caused by mutations in a number of sarcomeric genes. Mutations in one sarcomeric gene, the cardiac myosin binding C gene, have been identified in Maine Coon and Ragdoll cats. These mutations are thought to result in the production of dysfunctional sarcomeres within myocytes. The myocardium then produces new sarcomeres to help the dysfunctional ones, resulting in hypertrophy that may be mild to severe. Severe hypertrophy is often accompanied by

cellular necrosis and resultant replacement fibrosis (myocardial scarring).

Increased fibrosis coupled with severe wall thickening results in a stiffer than normal left ventricle in diastole, which increases diastolic pressure for any given diastolic volume. The increased pressure is transmitted backward into the left atrium in diastole, resulting in left atrial enlargement and, if severe enough, in left heart failure. Left heart failure manifests as pulmonary edema and pleural effusion in cats. Myocardial contractility is normal, but left ventricular end-systolic diameter is usually less than normal and may become zero (end-systolic cavity obliteration) due to the increased wall thickness resulting in a decrease in systolic wall stress (ie, afterload). Severe left atrial enlargement can develop, which causes blood flow to stagnate. This can lead to the formation of a left atrial thrombus and the potential for systemic thromboembolism.

A cranial displacement of the anterior mitral valve leaflet during ventricular systole, a phenomenon termed systolic anterior motion of the mitral valve, is a common finding in cats with HCM and is due to marked enlargement of the papillary muscles that drag the mitral valve leaflet into the left ventricular outflow tract in systole. This phenomenon produces two turbulent jets—one of dynamic subaortic stenosis and the other of mitral regurgitation. Systolic anterior motion is the most common cause of a heart murmur in a cat with HCM. Gross pathology includes increased cardiac weight (>20 g), increased left ventricular wall thickness, papillary muscle hypertrophy, and often left atrial enlargement. The myocardium often contracts after death (ie, undergoes rigor), so the postmortem diagnosis of HCM often cannot be made based on left ventricular wall thickness alone.

HCM is the most common primary heart disease diagnosed in cats, but it is rare in dogs. It is familial in many breeds of cats, including Persians, Sphynx, Norwegian Forest Cats, Bengals, Turkish Vans, and American and British Shorthairs. As in Maine Coons and Ragdolls, the mode of inheritance is thought to be autosomal dominant. The disease is seen in cats from 3 mo to 17 yr of age, although most cats are middle aged at presentation. It is not present at birth but develops over time. Penetrance is often $<100\%$. Male and female cats are equally predisposed, but males tend to develop more severe disease at an earlier age. In Maine Coon and Ragdoll cats, cats that are homozygous for the mutation often

develop HCM earlier (often before 1 yr of age) and often develop a more severe form of the disease.

Many affected cats have no clinical signs, especially those with mild to moderate disease. Cats that develop severe disease may also have no clinical signs but will usually go on to develop left heart failure, systemic thromboembolism, or sudden death. Cats in heart failure have signs of tachypnea and dyspnea secondary to pulmonary edema or pleural effusion. Owners frequently do not note tachypnea and so do not present the cat for examination until dyspnea, often marked, is present. Cats with systemic thromboembolism most commonly have an acute onset of hindlimb paresis/paralysis coupled with acute pain, pulselessness, and poikilothermia. Cough is uncommon in cats with heart failure.

Physical examination frequently demonstrates abnormal heart sounds, including a soft to prominent systolic cardiac murmur and/or a gallop sound. The murmur is often dynamic, increasing in intensity with excitement and decreasing as the cat relaxes. A murmur is not present in at least one-third of cats with HCM. Increased respiratory sounds may suggest pulmonary edema, and decreased respiratory sounds may indicate pleural effusion, but auscultation of the lungs is often normal. The femoral pulse may be normal or weak, or absent if distal aortic thromboembolism has developed. Radiographically, there may be pronounced left atrial enlargement, especially in a cat in left heart failure, and variable left ventricular enlargement. The cardiac silhouette can appear relatively normal even in the presence of moderate to severe left ventricular hypertrophy if the left atrium is not enlarged. Echocardiography allows confirmation of the diagnosis and assessment of additional therapy needed (eg, anticoagulants may be more beneficial in cats with severe left atrial enlargement). Left ventricular wall thickening (≥ 6 mm; generalized or regional), along with papillary muscle hypertrophy are noted. Systolic anterior motion of the mitral valve may be present. ECG abnormalities may include supraventricular premature complexes, ventricular premature complexes, and ventricular tachycardia. With severe atrial enlargement, atrial fibrillation may rarely develop. An electrical axis deviation may be present. However, many cats with HCM have a normal ECG. The plasma concentration of NT-proBNP is often increased in cats with severe disease and particularly in those in heart failure (see p 101).

Treatment is directed at controlling signs of CHF, improving diastolic function, and reducing the incidence of systemic thromboembolism. Furosemide (2–4 mg/kg, IV or IM, as needed) administration and oxygen are needed when acute CHF is present. For chronic heart failure, furosemide and an ACE inhibitor, eg, enalapril (0.5 mg/kg/day, PO), are indicated. For cats not in heart failure, no drug strategy has been shown to alter the natural history of the disease. Diltiazem (7.5 mg, PO, tid), a calcium channel blocker, may improve diastolic function, but its effects are generally negligible and its use has diminished. Use of β -blockers such as atenolol (6.25–12.5 mg, PO, 1–2 times/day) may also be considered, but proof of benefit is lacking. People with HCM have shown improvement in exercise-induced angina and dyspnea, and exercise intolerance when given β -blockers. Cats rarely exert themselves, so those indications do not apply. However, a β -blocker does reduce systolic anterior motion of the mitral valve and should be considered when this abnormality is severe (pressure gradient across the dynamic subaortic stenosis is >80 mmHg). ACE inhibitors have no apparent beneficial effect before the onset of heart failure.

Prevention of left atrial thrombus formation and systemic thromboembolism is often a goal. Clopidogrel (18.75 mg/day/cat) is the only drug shown to decrease the incidence of systemic thromboembolism in cats. Warfarin (0.2–0.5 mg/day, PO) is probably ineffective and produces bleeding in some cats. Aspirin (80 mg, PO, every third day) is also believed to be ineffective. Clopidogrel plus aspirin is a common therapeutic strategy in people. A low-molecularweight heparin such as enoxaparin (1 mg/kg, bid) might be efficacious but is expensive and must be administered parenterally.

The prognosis for cats with HCM is highly variable. Many mildly affected cats have a good longterm prognosis. Cats in CHF have a poor prognosis, with a median survival time of 3 mo. However, as many as 20% of cats with CHF might survive for a more prolonged period.

Restrictive/Unclassified Cardiomyopathy:

A less common form of cardiomyopathy in cats is characterized by a relatively normal-appearing left ventricle with left atrial enlargement. Although it is logical to believe that these cats have diastolic dysfunction, many do not. Those that do have diastolic dysfunction have some form of restrictive cardiomyopathy.

However, because that diagnosis cannot be made using standard two-dimensional echocardiography, it is better to term this type of disease unclassified cardiomyopathy unless diastolic dysfunction can be documented, usually by using tissue Doppler imaging echocardiography. Restrictive cardiomyopathy is characterized by a stiff, noncompliant left ventricle, usually due to increased collagen (ie, scar) formation in the left ventricle. The increased stiffness increases diastolic pressure for any given diastolic volume. As in hypertrophic cardiomyopathy, this results in an increase in left atrial size and left heart failure. In some cats that have obvious endomyocardial thickening or partial cavity obliteration, the diagnosis of restrictive cardiomyopathy can be readily made using two-dimensional echocardiography. A left atrial thrombus may be evident. Systolic function is usually preserved. Color flow Doppler echocardiography may demonstrate mitral regurgitation.

Clinical signs of and treatment for heart failure are similar to those for HCM (see p 117); however, prognosis seems to be worse, especially in cats with CHF. The cause of restrictive/unclassified cardiomyopathy is unknown.

Myocarditis

Myocarditis is a focal or diffuse inflammation of the myocardium with myocyte degeneration and/or necrosis. Myocarditis is rare in companion animals, although there are numerous causes, including several viruses and bacteria. Canine parvovirus (see p 373), encephalomyocarditis virus (see p 718), and equine infectious anemia virus (see p 699) can cause myocarditis. Myocardial degeneration is seen in lambs, calves, and foals with white muscle disease and in pigs with mulberry heart disease or hepatosis dietetica. *Streptococcus* spp are the most common cause of bacterial myocarditis in horses. *Salmonella*, *Clostridium*, equine influenza, *Borrelia burgdorferi*, and strongylosis are other recognized causes. Mineral deficiencies (eg, iron, selenium, copper) can also result in myocardial degeneration (not myocarditis). Deficiencies of vitamin E or selenium may cause myocardial necrosis. Cardiac toxins include ionophore antibiotics such as monensin and salinomycin, cantharidin (blister beetle toxicosis, see p 3157), *Cryptostegia grandiflora* (rubber vine), and *Eupatorium rugosum* (white snakeroot). These diseases cause typical signs of CHF. In

horses, signs of right heart failure are common and include ventral edema, ascites, venous congestion, and jugular pulsations. A heart murmur of mitral or tricuspid regurgitation is usually audible as well as an irregular rhythm. Atrial fibrillation is common, and ventricular or atrial premature complexes may also be seen. Echocardiography reveals chamber dilation and poor contraction with essentially normal valves. Neutrophilic leukocytosis and hyperfibrinogenemia are common. Cardiac isoenzymes (CK, troponin, and lactate dehydrogenase) are often increased.

Treatment should be aimed at improving cardiac contractility, relieving congestion, and reducing vasoconstriction. Pimobendan and digoxin are used most commonly to improve contractility. Furosemide is indicated to control signs of pulmonary edema. Corticosteroids are often used when cardiac isoenzymes are increased and a viral infection is deemed unlikely.

Chagas' Myocarditis: *Trypanosoma cruzi*, a flagellate protozoa, causes Chagas' disease (see p 38). Acutely, ECG abnormalities such as first-, second-, or third-degree AV block; right bundle-branch block; sinus tachycardia; and depressed R wave amplitude are noted. There are usually no echocardiographic abnormalities during the acute phase; however, sudden death is a concern. An asymptomatic latent phase then develops for 27–120 days in dogs, followed by a chronic stage demonstrating systolic dysfunction indistinguishable from DCM. Treatment for the chronic phase is as for DCM but is typically ineffective at controlling signs of progressive myocardial failure. The disease is most commonly identified in southern states (eg, Texas) but may be spreading.

Tickborne Myocarditis: Lyme disease (see p 659) is caused by the spirochete *Borrelia burgdorferi*; infection might result in myocardial disease. In people, it causes a usually reversible third-degree AV block. Animals developing myocardial disease secondary to Lyme infection may, at least in theory, have ECG abnormalities such as ventricular arrhythmias or conduction disturbances such as first-, second-, or transient third-degree AV block. However, a recent study failed to identify evidence of any tickborne organism in a group of dogs presented for third-degree AV block. Two dogs with severe ventricular tachyarrhythmias with a high antibody titer to *Anaplasma phagocytophilum* required prednisone and azathioprine to control the

arrhythmias. There are no reports of DCM due to these organisms in dogs or cats.

Other Causes of Myocardial Failure

In addition to the diseases listed below, histophilosis in cattle (see p 754) can result in myocardial infarcts and abscesses.

Persistent Atrial Standstill: A form of cardiomyopathy resulting in destruction of the atrial myocardium (that may also affect the ventricular myocardium) has been reported in dogs. Affected breeds include English Springer Spaniels, Old English Sheepdogs, Shih Tzus, German Shorthaired Pointers, and mixed-breed dogs. The disease has also been reported in some cats with concurrent cardiomyopathy. Initially, atrial myocardial destruction leading to atrial standstill and an AV nodal escape rhythm is noted. Mitral regurgitation that may be severe is often seen at this stage. Eventually, myocardial failure may ensue. Clinical signs are similar to those in animals with DCM, with right or left heart failure being noted. Pacemaker implantation may improve heart rate and cardiac output. Other treatment aims to relieve signs of CHF. This treatment typically is ultimately unrewarding, similar to treatment results in other animals with myocardial failure.

Doxorubicin-induced Myocardial Failure

Doxorubicin is a common chemotherapeutic agent that causes well-recognized cardiotoxicity. Cardiotoxicity tends to be dose dependent, but rare patients show toxicity at far lower dosages than others. Abnormalities include isolated ventricular premature complexes (which develop in 80% of dogs administered 80 mg/m²/day for 2 days or 25 mg/m²/wk for 4–11 wk) and periods of ventricular tachycardia. Myocardial failure may also develop and has been documented in 100% of dogs experimentally administered 25 mg/m²/wk for 20 wk. (Sudden death and heart failure were noted in 65% of dogs after administration of ~17 wk of therapy.) The cardiotoxic effects are irreversible. Severe cardiotoxicity is rare with current chemotherapeutic protocols but depends on how aggressive the chemotherapeutic protocol is.

Endocardial Fibroelastosis: Endocardial fibroelastosis, a disease of unknown cause, is characterized by diffuse thickening of the left atrial, left ventricular, and/or mitral valve endocardium. It is a rare cause of myocardial failure in young dogs and cats. Affected animals are usually <6 mo old

and present with clinical signs of left heart failure. Breeds reported include Labrador Retrievers, Great Danes, English Bulldogs, Springer Spaniels, Boxers, Pit Bulls, and Siamese and Burmese cats (in which the disease is believed to be inherited).

Echocardiography demonstrates dilation of the left ventricular and atrial chambers, decreased left ventricular fractional shortening due to an increased left ventricular end-systolic diameter, and possibly diffuse endocardial thickening. Clinical signs, treatment, and prognosis are similar to those of DCM.

Duchenne Cardiomyopathy:

Duchenne cardiomyopathy is an inherited, X-linked neuromuscular disorder reported in dogs, particularly Golden Retrievers. A similar disease called X-linked muscular dystrophy has been reported in Irish Terriers, Samoyeds, and Rottweilers. These diseases may result in myocardial as well as neuromuscular disease. ECG abnormalities include deep and narrow Q waves, a shortened PR interval, sinus arrest, and ventricular tachyarrhythmias. Echocardiography may demonstrate focal hyperechoic lesions affecting primarily the left ventricular and papillary muscle myocardium. This usually develops by 6–7 mo of age, with the lesions decreasing in size throughout the next 2 yr. The lesions result from calcification and fibrosis. In animals that survive, myocardial failure may develop.

Infective Endocarditis

Infection of the endocardium typically involves one of the cardiac valves, although mural endocarditis may occur. Endothelial damage is a predisposing factor for infective endocarditis to develop, although in dogs it is most common for endocarditis to form on a normal valve. When the endothelium is partially eroded and underlying collagen exposed, platelets adhere and produce a microthrombus. Immune deficiency may also be a predisposing factor. Bloodborne bacteria may become enmeshed in this thrombic lattice, resulting in a localized infection that causes a progressive destruction of the valve and results in valvular insufficiency. Vegetative lesions are the most common finding on cardiac valves and can create valvular stenosis (eg, aortic stenosis) but more commonly produce valvular insufficiency. In dogs, horses, and cats, the aortic and mitral valves are most commonly affected. The tricuspid valve is rarely affected, and pulmonic valve infective endocarditis is exceedingly rare.

In contrast, the tricuspid valve is the most commonly affected valve in cattle. Infective endocarditis is rare in cats, and there are no breed predilections. In dogs, middle-aged, large-breed dogs are predisposed; <10% of dogs diagnosed with infective endocarditis weigh <15 kg. Most affected dogs are >4 yr old, and males are more commonly affected than females. Dogs with subaortic stenosis are at greater risk of developing infective endocarditis.

Infected thrombi released from the infected aortic or mitral valves enter the systemic circulation and can embolize other organs and limbs; therefore, infective endocarditis can produce a wide spectrum of clinical signs, including primary cardiovascular effects or signs related to the nervous system, GI tract, urogenital system, or joints. A chronic, intermittent or continuous fever is usually present. Shifting leg lameness may be reported, and weight loss and lethargy are frequently present. Acute to subacute mitral or aortic valve regurgitation can result in left heart failure (ie, pulmonary edema) and clinical signs of tachypnea, dyspnea, and cough. If the tricuspid valve is affected, ascites and jugular pulsations may be present. Mastitis and decreased milk production can be noted in affected cattle. Hematuria and pyuria may also be noted. A cardiac murmur is present in most cases; the exact type depends on the valve involved. When the aortic valve is affected, a low-intensity diastolic heart murmur is present, with maximal intensity over the left cardiac base. A soft systolic heart murmur caused by increased stroke volume may also be noted. In this instance, the arterial pulse is bounding (ie, increased pulse pressure) due to diastolic run-off and increased stroke volume. Mitral valve endocarditis results in a heart murmur similar to that caused by degenerative valve disease—a low-to high-intensity systolic heart murmur heard best over the left cardiac apex.

Bacteria most often isolated from affected dogs and cats include *Streptococcus*, *Staphylococcus*, *Klebsiella* spp, and *Escherichia coli*, although a host of other bacterial species may be involved. *Bartonella* is also a recognized cause of aortic valve infective endocarditis in dogs. In people, 60%–80% of patients with infective endocarditis have a predisposing cardiac lesion that facilitates bacterial attachment. In dogs, however, infection appears to develop commonly in those with no evidence of valve abnormalities. *Streptococcus* and *Actinobacillus* spp are the most common isolates in horses, and

Trueperella pyogenes is most commonly cultured from cattle.

A CBC often shows a neutrophilic leukocytosis. Active infection may be associated with the presence of band neutrophils, and chronic infection with a monocytosis (90% of cases in one series). Anemia of chronic disease is frequently present. Serum analysis abnormalities reflect organ involvement secondary to infective emboli and may include increases in liver enzymes, BUN, and creatinine. In animals that develop immune complex glomerulonephritis, significant urinary protein loss and hypoalbuminemia may develop. Blood cultures with antibiotic sensitivity should be obtained in affected animals. It is preferable to draw two or three blood samples, each 1–2 hr apart, in a 24-hr period. Strict aseptic technique is required. However, blood culture results are frequently negative (and are positive in other types of septicemia) and cannot be used alone to make the diagnosis of endocarditis.

Radiography may demonstrate cardiac chamber enlargement, depending on the location and degree of insufficiency of the involved valve. If the aortic or mitral valve is severely affected, there will be left atrial and left ventricular chamber dilation. Evidence of left heart failure may be seen as an increase in interstitial density or, in severe CHF, an alveolar pattern in the pulmonary parenchyma. If the tricuspid or pulmonic valve is affected, right-side chamber enlargement is expected. Echocardiography is the diagnostic test of choice, because blood cultures are positive in only 50%–90% of dogs. The affected valve is usually easily detected—the involved area is hyperechoic (bright), thickened, and often vegetative (ie, looks like a cauliflower). The vegetative lesion may oscillate. Erosive lesions may predominate in some animals. Doppler echocardiography will confirm insufficiency of the valve, and chamber enlargement on the side of the affected valve is expected when significant insufficiency is present. Electrocardiography may demonstrate atrial and ventricular premature complexes. Infrequently, other arrhythmias such as atrial fibrillation or conduction disturbances are found.

Therapy is directed at controlling clinical signs of CHF, resolving any significant arrhythmias, sterilizing the lesion, and eliminating the spread of infection. The heart failure may be severe and intractable if the aortic valve is significantly involved; the prognosis is grave in these cases. The prognosis is much more favorable when

infection is mild and limited to one of the AV valves. Controlling heart failure requires the use of diuretics such as furosemide, an ACE inhibitor, and when myocardial failure is present, pimobendan. Initially in dogs, parenteral antibiotics are indicated for 1–2 wk (which may be cost prohibitive), followed by oral antibiotics for at least 6–8 wk. Initial broad-spectrum bactericidal antibiotics (a combination of ampicillin plus gentamicin or enrofloxacin, or cephalothin plus gentamicin) should be used and changed, if needed, based on antibiotic sensitivity studies. Renal function should be monitored when gentamicin is used, because it is nephrotoxic. The prognosis is poor in most dogs. Those that respond to therapy often require longterm medications for heart failure (eg, diuretics, vasodilators, pimobendan) and frequent reevaluations. In large animals, rifampin (5 mg/kg, PO, bid), together with another broad-spectrum antibiotic, has been demonstrated to improve short-term outlook. Aspirin (100 mg/kg/day in ruminants and 17 mg/kg every other day in horses) or heparin (30 U/kg, SC, bid in ruminants and horses) may prevent further thrombus and vegetative growth in large animals.

Antibiotic prophylaxis is indicated in dogs with subaortic stenosis when any type of procedure that can result in significant bacteremia is performed. Routine antibiotic prophylaxis for dental procedures is not warranted with other types of cardiac disease and especially not in dogs with myxomatous mitral valve degeneration, because there is no evidence these dogs are at increased risk of infective endocarditis.

Pericardial Disease

Pericardial disease most commonly causes an accumulation of fluid within the pericardial sac (ie, pericardial effusion). This accumulation can be acute or chronic, but chronic is much more common in veterinary medicine. When the fluid accumulation is severe enough to markedly increase the intrapericardial pressure, cardiac tamponade occurs. Acute cardiac tamponade (eg, due to left atrial rupture or thoracic trauma) primarily results in decreased cardiac filling and an abrupt decrease in cardiac output. Chronic cardiac tamponade primarily increases the diastolic intraventricular pressures. This causes signs of CHF. Right-side diastolic—and so systemic venous and capillary pressure—only have to increase from a normal of 5 mmHg to 10–15 mmHg to produce signs of right heart failure, whereas left-side

pressures must increase from a normal of <10 mmHg to >20 mmHg to produce left heart failure. Thus, signs of right heart failure predominate.

Pericardial effusion is a relatively common form of acquired cardiovascular diseases in dogs, is uncommon in cattle, and is rare in horses and cats. In dogs, cases involving middle-aged, predominantly male, large breeds are most frequent. Idiopathic pericarditis and cardiac neoplasia are the most common causes of pericardial effusion in dogs. Hemangiosarcoma and heart base tumors (chemodectoma, ectopic thyroid carcinoma) are the most frequently seen cardiac neoplasms. Mesothelioma is a less common form of pericardial neoplasia. Using echocardiography, hemangiosarcoma is most frequently identified on the right auricle, in the right AV groove, and in the right atrial chamber in dogs. Heart base tumors usually are identified between the aorta and main pulmonary artery. In cats, the most common cardiac neoplasia is lymphoma, but the most common cause of mild pericardial effusion is heart failure. Most cases of pericardial effusion in cats are not severe enough to cause cardiac tamponade. Less common causes of pericardial effusion in dogs are infections (eg, coccidioidomycosis), trauma, left atrial rupture, and CHF. Cattle most often develop pericardial effusion secondary to traumatic reticulopericarditis (see p 230) or cardiac neoplasia (lymphoma). Lymphoma in cattle can also result in valvular insufficiencies. In horses, septic pericarditis and idiopathic pericarditis are most commonly reported.

The severity of clinical signs depends on the rate of pericardial fluid accumulation. In dogs, ascites is by far the most common clinical manifestation. Collapse and vomiting may be seen. The femoral pulse may be weak or decrease on inspiration and increase on expiration (pulses paradoxus). In horses, there is often a history of respiratory tract infection, fever, anorexia, and depression. Physical examination findings, in addition to abdominal distention, include generalized weakness, jugular venous distention, muffled heart sounds, and occasionally a pericardial friction rub. With slow development of pericardial fluid, the pericardial sac is able to stretch or enlarge, and clinical signs of right heart failure may not develop until severe pericardial effusion is present.

CBC, serum chemistry profile, and urinalysis results are usually normal. Mild anemia, neutrophilic leukocytosis, hyperfibrinogenemia, and hyperprotein-

emia may be seen in horses with septic pericarditis and effusion. In horses with suspected septic pericarditis, culture and sensitivity of the fluid should be performed. In septic pericarditis, there will be a large number of neutrophils, with some being degenerate. Protein content of the fluid will be high, and bacteria may be seen. Cytologic features of idiopathic pericardial effusion in horses are variable, with neutrophils, eosinophils, and macrophages present in variable numbers. Cytologic evaluation of the pericardial fluid usually does not provide a definitive cause for the pericardial effusion in dogs unless an infection is present, which is uncommon. Rarely a tumor (most commonly a hemangiosarcoma) will acutely bleed, producing an effusion with a PCV similar to that of blood.

Radiographs often show an increase in the size of the cardiac silhouette, which often takes on a rounded (globoid) appearance. However, this classic appearance is not always present. If the cause is a cardiac tumor, especially a heart base tumor, the cardiac silhouette may have a bulge at the top of the heart cranial to the carina or at the region of the cranial waist if no or only slight effusion is present. The caudal vena cava may be dilated if cardiac tamponade is present. Pleural effusion may also be present, more commonly if mesothelioma is the cause of the pericardial effusion. The ECG in most cases shows normal sinus rhythm to sinus tachycardia.

Severe pericardial effusion in a dog, dorsoventral projection. Courtesy of Dr. Mark D. Kittleson.

Occasional atrial premature and ventricular complexes may occur. The height of the R wave is often decreased (<1 mV in dogs), and there may be a pattern of alternating variation in R wave amplitude, referred to as electrical alternans, when there is a large amount of effusion present. This results from the swinging motion of the heart within the fluid-filled pericardial sac. Echocardiography is the most sensitive and specific test for detection of pericardial effusion. A tumor can be visualized in most cases of neoplastic effusion. When cardiac tamponade is present, the walls of the right atrium and right ventricle may collapse in systole or diastole.

Animals with cardiac tamponade require mechanical drainage of the pericardial space (pericardiocentesis) using a catheter. Medical therapy is typically ineffective at reducing pericardial effusion. Diuretics are contraindicated in acute cardiac tamponade because they decrease blood volume and cause a further decrease in cardiac output. Pericardiocentesis in dogs and cats is done by placement of a catheter through the chest wall on the right side, just above the costochondral junction at the fourth to fifth intercostal space. Echocardiography can be used to guide catheter placement at the point where the pericardial sac is closest to the thoracic wall and most distended with fluid, but it is not necessary. Fenestrating the catheter helps prevent blockage. A syringe or extension set with stopcock and syringe (preferred) is attached to the catheter. The system must be closed to air at all times once the chest wall has been penetrated, to avoid creating a pneumothorax. The catheter is passed directly toward the heart while gently aspirating. When the pericardial sac is entered, fluid (usually quite bloody) flows freely into the syringe. The catheter should be carefully advanced over the needle into the pericardial sac. The fluid should be placed either in a glass tube or in a tube containing thrombin to cause clotting if blood from the heart is aspirated; if it does clot, the catheter should be removed from the cardiac chamber it is in. As much fluid as possible should be removed from the sac and a sample submitted for analysis. When performing pericardiocentesis in horses, the left fifth intercostal space should be used to avoid the atria, coronary arteries, and right ventricle. Pericardial lavage, with or without antibiotics, is often performed in horses after pericardiocentesis. Pericardiocentesis is relatively easy to perform in dogs, and serious complications are rare. However, confirming the presence of

pericardial effusion by echocardiography is advisable before performing pericardiocentesis.

Parenteral fluids may be given immediately before and after pericardiocentesis. Corticosteroids have not been shown to be beneficial in idiopathic pericarditis (benign pericardial effusion) in dogs, although they have been used with success in horses. Most tumors that cause neoplastic effusion do not respond well to chemotherapy. A heart base tumor can be surgically debulked, but only by a highly skilled surgeon. Rarely, a hemangiosarcoma can be surgically removed if it is confined to the right auricle and no metastatic disease is present. Chemotherapy (eg, **adriamycin**) might be beneficial in some dogs with hemangiosarcoma, although survival times are generally measured in months.

When idiopathic pericarditis is suspected (ie, no mass visible by echocardiography), the owner should be instructed to carefully monitor the animal for any signs of recurrence. Should this occur, a repeat pericardiocentesis is indicated. A subtotal pericardectomy is generally recommended after the third pericardiocentesis. Heart base tumors only rarely metastasize in dogs, although they can grow to be quite large and may compromise function of surrounding structures. If recurrent pericardial effusion secondary to a heart base tumor is diagnosed, subtotal pericardectomy should be considered. A dog can survive as long as 2 yr after successful subtotal pericardectomy. The prognosis for right atrial hemangiosarcoma is poor to grave. Many dogs have metastasis or micrometastasis (most commonly to the lungs and not visible on radiographs) at the time of diagnosis.

Constrictive and constrictive/effusive pericarditis is rare and primarily seen in dogs. It is thought to be an end result of chronic idiopathic pericarditis. A dog with constrictive pericarditis usually presents with ascites, no murmur, normal heart sounds, normal cardiac silhouette on thoracic radiographs, a positive hepatojugular reflux test, and distended hepatic veins on ultrasound. Diagnosis can be difficult and may require cardiac catheterization. Treatment is surgical. With constrictive/effusive pericarditis, there is still a fluid layer between the pericardial sac and the surface of the heart, so surgical removal of the pericardium is relatively easy. With constrictive pericarditis, the pericardium and epicardium are fused into one fibrous layer that must be painstakingly removed surgically.

Systemic and Pulmonary Hypertension

Systemic hypertension is an increase in systemic arterial blood pressure. There are two major types of systemic hypertension. Essential hypertension, which is idiopathic (primary) hypertension, is rare (essentially nonexistent) in dogs and cats but common in people. Secondary hypertension results from a specific underlying disease. In dogs, the most common cause of hypertension is renal disease/failure; in cats, the most common causes are renal disease/failure and hyperthyroidism. Hyperadrenocorticism, diabetes mellitus, and pheochromocytoma are other causes of systemic hypertension in dogs.

The diagnosis of systemic hypertension is made by measurement of systemic blood pressure. The most accurate assessment method is direct measurement via arterial puncture, which is impractical in most instances. The next most accurate method (although still often inaccurate) is indirect measurement using a Doppler probe to assess blood flow in an artery (typically the superficial palmar arterial branch of the radial artery) distal to pressure cuff placement (typically on the forelimb). Cuff width should be 30% of the circumference of the forelimb in cats and 40% of the forelimb circumference in dogs. Shaving the hair just proximal to the palmar metacarpal pad for application of the Doppler probe allows for more accurate results. The hindlimb can also be used, in which case the superficial plantar arterial branch of the caudal tibial artery is assessed. The disadvantage of Doppler blood pressure measurement is that only systolic blood pressure is reliably measured. Other methods to measure systemic blood pressure, such as the oscillometric method, are even less accurate than the Doppler method, especially in small dogs and cats. Although indirect blood pressure measurement is less accurate than direct assessment, it can detect acute trends in blood pressure during anesthesia. In conscious animals, normal values vary with patient stress; values higher than expected for a healthy animal often are caused by the stress of examination. With certain exceptions, systolic pressures >180 mmHg are likely to be truly increased in an animal that appears calm, and values >200 mmHg should be strongly considered evidence of systemic hypertension. Because of the inaccuracy of noninvasive blood pressure measurement and the influence that stress has on blood

pressure, blood pressure measurements should be done only in dogs and cats that have a disease that causes hypertension or that have a clinical problem referable to systemic hypertension (eg, detached retina). Blood pressure measurement is not a screening tool in veterinary medicine as it is in human medicine, except in patient populations that have a disease that causes systemic hypertension (eg, dogs with renal failure should be screened for systemic hypertension). Even in an animal with a disease that causes hypertension that has an increased blood pressure measurement, documenting end-organ damage (eg, presence of hypertensive retinopathy) is recommended before instituting therapy.

Dogs and cats with severe systemic hypertension often have no clinical signs. Acute blindness is the most common clinical sign. Retinal lesions (eg, retinal hemorrhage, retinal detachment, arterial tortuosity, focal or diffuse retinal edema) were found in 80% of hypertensive cats in one study. Blood tests may demonstrate abnormalities consistent with the cause of hypertension (eg, increased T_4 levels in hyperthyroid cats, increased BUN and creatinine in animals with renal failure). Treatment should be initiated in animals with consistently measurable hypertension that are documented to have an underlying cause such as renal disease/failure and evidence of end-organ damage. Systemic hypertension in cats and dogs appears to be due to constriction of systemic arterioles, because only potent systemic arteriolar dilators are reasonably effective to decrease systemic blood pressure to a clinically significant degree. The treatment for cats is amlodipine (0.625–1.25 mg/day, PO). Other drugs, such as enalapril, diltiazem, β -blockers (eg, atenolol), and diuretics (eg, furosemide) are generally ineffective. In dogs, amlodipine (0.2–1 mg/kg/day) and hydralazine (1–3 mg/kg, bid) are the only consistently effective drugs. Some clinicians have had success with prazosin (1–4 mg [total dose], PO, 1–2 times/day) in dogs. Phenoxybenzamine (0.25–2 mg/kg, PO, bid) is expensive but can also be effective in dogs. It is most often used in dogs with a pheochromocytoma but can also be effective in dogs with systemic hypertension due to other causes.

Pulmonary hypertension is increased blood pressure in the pulmonary arterial circulation. Possible causes include increased pulmonary blood flow (eg, ventricular septal defect, patent ductus arteriosus), increased pulmonary vascular

resistance due to decreased overall cross-sectional area of the pulmonary vascular bed (such as caused by pulmonary arterial wall hypertrophy, pulmonary thromboembolism, and pulmonary vasoconstriction), or both. Primary pulmonary hypertension is rare in any species other than people. In cattle, the most common cause is hypoxia-induced pulmonary vasoconstriction caused by high altitude (see p 137). Chronic ingestion of locoweed (*Oxytropis* and *Astragalus* spp) or chronic pulmonary disease caused by bronchopneumonia or lungworm infestation can also result in pulmonary hypertension severe enough to result in right heart failure. In horses, pulmonary hypertension may occur secondary to left heart failure. In dogs, pulmonary hypertension most commonly occurs secondary to heartworm disease, pulmonary thromboembolism, severe hypoxemia due to primary pulmonary disease, and left heart failure.

Clinical signs are typically those of right heart failure (ascites, exercise intolerance) and episodic collapse or syncope, usually after exercise or excitement. Physical examination findings may include evidence of ascites in dogs and ventral edema in cattle and horses along with jugular vein distention and pulsation. Definitive diagnosis requires direct measurement of pulmonary arterial pressure (rarely performed), or estimation of pulmonary pressures by Doppler echocardiography (via measuring the velocity of a tricuspid or pulmonary regurgitant jet). Echocardiography may demonstrate flattening of the interventricular septum in systole, right ventricular chamber dilatation and/or free wall thickening, and right atrial enlargement. Treatment is typically unrewarding, and the prognosis is often poor, depending on the cause. In heartworm disease, successful clearance of adult worms from the pulmonary arterial vasculature often results in a reduction in pulmonary artery pressure and resolution of right heart failure. Dogs with a right-to-left shunting PDA can live for several years despite severe pulmonary hypertension if their polycythemia is adequately controlled. Sildenafil (1–3 mg/kg, bid-tid), a phosphodiesterase V inhibitor, is probably the most effective drug to lower pulmonary artery pressure and improve clinical signs in dogs with pulmonary hypertension, but it is expensive. It is primarily warranted in dogs with clinical signs due to pulmonary hypertension, most commonly syncope and right heart failure. In these patient populations, sildenafil often will reduce or stop syncope and allow easier control

of ascites. Exercise tolerance may be improved. There is limited experience with tadalafil (1 mg/kg, PO, 1–2 times/day) but, in theory, it should have the same effects. Pimobendan reduces pulmonary artery pressure in dogs with pulmonary hypertension secondary to left heart failure. The best chance for a successful longterm outcome is when the underlying disease can be identified and treated, but this is rare.

Arterial Thromboembolism

Overt intravascular thrombus formation is rare with heart failure in most species other than domestic cats and people. Cats frequently form a thrombus in a severely enlarged left atrium, most commonly in the left auricle. This thrombus then commonly breaks loose and flows into the systemic circulation. Although this occurs most commonly in a cat with a large left atrium due to cardiomyopathy, it can also occur without left atrial enlargement, sometimes even happening in an otherwise healthy cat. In a cat with severe left atrial enlargement, it is assumed that the primary reason the thrombus develops is because of blood flow stasis. Red cells aggregate when blood flow decreases below a critical velocity. When the left atrium enlarges, blood flow velocity decreases (assuming no mitral regurgitation). The area of lowest velocity is the left auricle. In some cats, red cell aggregation can be visualized as so-called spontaneous contrast or “smoke” within the left atrium. In a few cats, both a thrombus and spontaneous contrast can be noted. However, in most cats, the thrombus has already become an embolus by the time an echocardiogram is done.

The site the thromboembolus lodges once it has broken loose from its site of attachment in the left atrium depends on the size of the thrombus and blood flow patterns. A very small thrombus can gain entrance to a coronary artery and cause myocardial infarction. A mid-sized thrombus can exit into a branch coming off the aorta, such as the brachiocephalic trunk (and then most commonly to the right subclavian) or an intestinal branch. Most of these thrombi, however, are large and so cannot exit off any branch of the aorta and end up at the terminal aorta. Here, they occlude aortic flow and release vasoactive amines that shut down collateral circulation. Consequently, they cause acute cessation of blood flow to the hindlimbs. This results in pulselessness (no femoral pulse), pallor (pale or purple foot pads), poikilothermia (decreased rectal temperature and cold hindlimbs), and initially

extreme pain. The gastrocnemius muscles are often very firm. The cat can often move the legs above the stifles, and the tail is commonly unaffected. In some cats, only one hindlimb is affected.

Diagnosis is most commonly based on clinical signs, physical examination findings, and Doppler blood flow readings of the hindlimbs. Ultrasound can also be used to identify the thromboembolus. Misdiagnosis of neurologic abnormalities as an arterial thromboembolus in cats is common. In some cats, the clot will lyse on its own over time (1–72 hours). However,

some of these cats have residual problems (eg, dry gangrene). Numerous treatments, including surgery, thrombolytic agents, and rheolytic thrombectomy, have been tried but are largely unsuccessful when compared with waiting for the thromboembolus to lyse on its own. Euthanasia is common. Clopidogrel (18.75 mg/day/cat) has been shown to be effective at preventing recurrence of these events in cats and so is assumed to be effective at preventing first occurrence also; however, it is, by no means, 100% effective. Aspirin is believed to be ineffective.

HEARTWORM DISEASE

(Dirofilariosis, Dirofilariosis)

Heartworm (HW) disease is caused by the filarial organism, *Dirofilaria immitis*. At least 70 species of mosquitoes can serve as intermediate hosts; *Aedes*, *Anopheles*, and *Culex* are the most common genera acting as vectors. Patent infections are possible in numerous wild and companion animal species. Wild animal reservoirs include wolves, coyotes, foxes, California gray seals, sea lions, and raccoons. In companion animals, HW infection is diagnosed primarily in dogs and less commonly in cats and ferrets. HW disease has been reported in most countries with temperate, semitropical, or tropical climates, including the USA, Canada, Australia, Latin America, and southern Europe. In companion animals, infection risk is greatest in dogs and cats housed outdoors. Although any dog or cat, indoor or outdoor, is capable of being infected, most infections are diagnosed in medium- to large-sized, 3- to 8-yr-old dogs living outside.

Infected mosquitoes are capable of transmitting HW infections to people, but there are no reports of such infections becoming patent. Maturation of the infective larvae may progress to the point where they reach the lungs, become encapsulated, and die. The dead larvae precipitate granulomatous reactions called “coin lesions,” which are visible with thoracic radiographs and significant because they mimic lung cancer.

HW infection rates in other companion animals such as ferrets and cats tend to parallel those in dogs in the same geographic region. No age predilection has been

reported in ferrets or cats, but male cats have been reported to be more susceptible than females. Indoor and outdoor ferrets and cats can be infected. Other infections in cats, such as those caused by the feline leukemia virus or feline immunodeficiency virus, are not predisposing factors.

Life Cycle: Mosquito vector species acquire microfilariae (a neonatal larval stage) while feeding on an infected host. Once ingested by the mosquito, microfilariae develop into the first larval stage (L_1). They then actively molt into the second larval stage (L_2) and again to the infective third stage (L_3) within the mosquito in ~1–4 wk, depending on environmental temperatures. This development phase requires the shortest time (10–14 days) when the average ambient temperature is $>81^\circ\text{F}$ (27°C) and the relative humidity is 80%. When mature, the infective larvae migrate to the labium of the mosquito. As the mosquito feeds, the infective larvae erupt through the tip of the labium with a small amount of hemolymph onto the host's skin. The larvae migrate into the bite wound, beginning the intramammalian phase of the life cycle. A typical *Aedes* mosquito is capable of surviving the complete development of only small numbers of HW larvae, usually <10 larvae per mosquito.

In canids and other susceptible hosts, infective larvae (L_3) molt into a fourth stage (L_4) in 3–12 days. After remaining in the subcutaneous tissue, abdomen, and thorax for ~2 mo, L_4 undergo their final molt at day

50–70 into young adults, arriving in the heart and pulmonary arteries ~70–120 days after initial infection. Only 2.5–4 cm in length on arrival, worms rapidly grow in the pulmonary vasculature to adult worms (males ~15 cm long, females ~25 cm). When juvenile heartworms first reach the lungs, blood flow forces them into the more distal small pulmonary arteries of the caudal lung lobes; as the parasites grow, they occupy larger and larger pulmonary arteries, moving into the right ventricle and atrium when the worm burden is high. Gravid females produce microfilariae as early as 6 mo after infection but more typically at 7–9 mo after infection.

Microfilariae are detectable in most infected canids (~80%) not receiving macrolide prophylaxis and occasionally in those dogs placed on macrolide preventives when a HW infection was already present. The number of circulating microfilariae does not correlate well to the adult female HW burden. Adult worms typically live 3–5 yr, whereas microfilariae may survive for up to 2 yr in the dog, while awaiting arrival of a mosquito intermediate host.

Most dogs are highly susceptible to HW infection, and most (an average of 56%) experimentally administered infective larvae (L_3) develop into adults. Ferrets and cats are susceptible hosts, but the rate of infective larvae developing into adults is low (an average of 6% in cats and 40% in ferrets). In cats, the adult burden is often only one to three worms. It appears that early death of juvenile worms on arrival at the pulmonary vasculature is largely responsible for the heartworm-associated respiratory disease (HARD) syndrome in cats. HARD does not require maturation of heartworms but is due to the body's response to the dying/dead heartworms. When maturation does occur, adult worm survival in cats is typically not longer than 2–3 yr. In all animals capable of being infected, aberrant larval migration may occur, resulting in parasitic lesions in the CNS, systemic arterial system, and in visceral and subcutaneous sites.

Pathogenesis: The severity of cardiopulmonary pathology in dogs is determined by worm numbers, host immune response, duration of infection, and host activity level. Live adult heartworms cause direct mechanical trauma, and other suspected factors (eg, antigens and excretions) are thought to directly irritate or to stimulate the hosts' immune system to damage vessel intima, leading to proliferative endarteritis and perivascular cuffing with inflammatory

cells, including infiltration of high numbers of eosinophils. Live worms seem to have an immunosuppressive effect; however, the presence of dead worms leads to more severe vascular reactions and subsequent lung pathology, even in areas of the lung not directly contacting the dead heartworms. Longterm infections, due to all of the factors noted (ie, direct irritation, worm death, and immune response) result in chronic lesions and subsequent scarring. Active dogs tend to more often develop pulmonary hypertension than inactive dogs for any given worm burden. Frequent exertion increases pulmonary arterial pathology and pulmonary artery resistance (with resultant pulmonary hypertension) and thereby may precipitate overt clinical signs, including congestive heart failure (CHF). High worm burdens are most often the result of infections acquired from numerous mosquito exposures. High exposures in young, naive dogs in temperate climates can result in severe infections, possibly precipitating vena cava syndrome the year after. In general, because of the worm size and smaller dimensions of the pulmonary vasculature, small dogs do not tolerate infections and treatment as well as large dogs.

The role of the endosymbiotic bacteria *Wolbachia pipiens*, which live intracellularly within the filarid parasite, is still being determined. However, these bacteria have been implicated as playing a role in the pathogenesis of filarial diseases, possibly through endotoxin production. Furthermore, studies have demonstrated that a primary surface protein of *Wolbachia* (WSP) induces a specific IgG response in hosts infected by *D immitis*. For veterinarians, the most important aspect of *Wolbachia* is its symbiotic relation with *D immitis*. This bacterium is necessary for normal maturation, reproduction, and infectivity of the heartworm. If *Wolbachia* are eradicated, the heartworm gradually dies, after first becoming sterile. This can be accomplished with doxycycline therapy.

HW-associated inflammatory mediators that induce immune responses in the lungs and kidneys (eg, immune complex glomerulonephritis) cause vasoconstriction and possibly bronchoconstriction. Leakage of plasma and inflammatory mediators from small vessels and capillaries causes parenchymal lung inflammation and mild, noncardiogenic edema formation. Pulmonary artery disease compromises vascular compliance, and this, with reduced ability to adequately vasodilate, results in increased flow velocity, especially with

exertion, and resultant shear stresses further damage the endothelium. The process of endothelial damage, vascular dysfunction, increased flow velocity, and local ischemia is a vicious cycle. Inflammation with ischemia can result in irreversible interstitial fibrosis.

Pulmonary arterial pathology in cats and ferrets is similar to that in dogs, although the small arteries develop more severe muscular hypertrophy. Despite this, pulmonary hypertension with CHF is less common in cats than in dogs or ferrets. Arterial thrombi, thromboemboli, and living or dead worms become lodged within pulmonary arteries or arterioles, resulting in complete or partial obstruction. In cats, parenchymal changes associated with dead heartworms differ from those observed in dogs and ferrets. Rather than type I alveolar cell damage, as found in dogs, cats develop type II alveolar cell hyperplasia, which can act as a significant barrier to oxygenation. Most significantly, because of restricted pulmonary vascular capacity and subsequent pathology, ferrets and cats are more likely than dogs to die as a result of HW infection.

Clinical Findings: In dogs, infection is ideally identified by serologic testing before onset of clinical signs; however, at the earliest, HW antigenemia and microfilaremia do not appear until ~5 and 6.5 mo after infection, respectively. When dogs do not receive preventive medication and are not appropriately tested, infection and disease progress undetected. Clinical signs of HW infection, such as coughing, exercise intolerance, unthriftiness, dyspnea, cyanosis, hemoptysis, syncope, epistaxis, and ascites (right-side CHF) may develop. The frequency and severity of clinical signs correlate to lung pathology and level of animal activity. Signs are often not observed in sedentary dogs, even though the worm burden may be relatively high. Infected dogs experiencing a dramatic increase in activity, such as during hunting seasons, may develop overt clinical signs. Likewise, worm death and thromboemboli precipitate clinical signs.

A dog may be classified as low- or high-risk for developing clinical signs, based on assessment of potential worm burden, the health and age of the dog, and its lifestyle. There is also a more complex classification system in which dogs are classified from I to IV, based on severity of signs. Class I dogs are minimally affected clinically. Class II dogs exhibit cough. Class III dogs are severely affected and variably

present with cough, hemoptysis, weight loss, lethargy, exercise intolerance, dyspnea, heart failure (ascites), and radiographic findings suggestive of HW disease (large main pulmonary artery and lobar pulmonary arteries, truncated and tortuous pulmonary arteries, pulmonary infiltrate, and hilar lymphadenopathy). Class IV includes dogs with caval syndrome. Dogs 5–7 yr old are at higher risk of having a heavy worm burden, presumably because of increased time of exposure and for disease development. Other concurrent health factors (eg, concurrent cardiopulmonary or other organ system disease) affect risk assessment. The degree to which exercise can be restricted during the recovery period is another important consideration.

Infected cats may be asymptomatic or exhibit intermittent coughing, dyspnea, heart failure, vomiting, lethargy, anorexia, or weight loss. When evident, signs usually develop during two phases of the HW life cycle: 1) the arrival of juvenile worms in the pulmonary vasculature ~3–4 mo after infection, and 2) death of adult heartworms. The early signs are associated with an acute vascular and parenchymal inflammatory response to the newly arriving young worms and the subsequent death of many or all of these juveniles. This initial phase is often misdiagnosed as asthma or allergic bronchitis. However, this is now considered to be part of HARD. Antigen tests in such cats are negative (measured antigens are associated with mature female worms) during the early eosinophilic pneumonitis syndrome, although antibody tests typically are positive. Although not yet well characterized, it is believed that clinical signs often resolve and may not reappear for months. HARD has been postulated to contribute to long-term lung damage. Cats harboring mature worms may exhibit intermittent vomiting, lethargy, coughing, or episodic dyspnea. Death of even one adult heartworm can lead to acute respiratory distress and shock, which may be fatal and appears to be the consequence of pulmonary thrombosis and/or anaphylactic-like shock.

Ferrets, more so than cats, mimic canine HW infection in terms of clinical signs. The large parasite:host body weight ratio dictates that ferrets (and cats) develop clinical signs with relatively small worm burdens. Ferrets with HW disease may demonstrate one or more of the following: weight loss, fatigue, rapid and/or labored breathing, heart murmur, distended and pulsatile jugular veins, cough, grey and cold mucous membranes, ascites, pleural effusion, fainting, and sudden death. See TABLE 8.

TABLE 8

DIAGNOSTIC TESTS, CLINICAL SIGNS, AND TREATMENT FOR HEARTWORMS IN DOGS, CATS, AND FERRETS

Diagnosis (Test Utility)				
Host	Microfilaria	Ag or Ab Test	Thoracic Radiographs	Echocardiography
Dog	****	***** (Ag)	*** MPA, PA, RHE, PTE, PIE	**
Cat	*	** (Ag) ***** (Ab)	** PA, PIE	*****
Ferret	*	*** (Ag)	* RH	***

^aImidacloprid-moxidectin is the only approved microfilaricide.

* = rarely useful; ** = somewhat useful; *** = moderately useful; **** = often useful;

***** = excellent test; Ag = antigen; Ab = antibody; MPA = main pulmonary artery enlargement;

PA = pulmonary artery enlargement; PTE = pulmonary thrombus/thromboembolus; PIE = pulmonary infiltrate with eosinophils; RH = right heart enlargement; NA = not applicable

Adapted from McCall, JW. *Clin Tech Small Anim Pract.* 1998;13(2):112.

Diagnosis: The antigen detection test is the preferred diagnostic method for routine screening of asymptomatic dogs or when seeking verification of a suspected HW infection. Antigen testing is the most sensitive and specific diagnostic method available to veterinary practitioners. Even in areas where the prevalence of HW infection is high, ~20% of infected dogs are not microfilaremic, which diminishes the utility of screening by testing for microfilariae. This figure is even higher for dogs infected with adult heartworms and that are consistently administered monthly macrolide prophylaxis, because this kills microfilariae and induces embryo stasis in mature female dirofilariae.

Timing of antigen testing is critical. A pre-detection period must be considered, because these tests detect only adult, female worms. This takes into account the time from exposure to seroconversion to a positive antigen test. A reasonable interval is 7 mo after last possible exposure. There is no value in testing a dog for antigen or microfilariae before ~7 mo of age. To ensure that a previously acquired infection does not exist in these young dogs, they should be tested 6–7 mo after beginning HW prophylaxis. For dogs >7 mo old, testing should be performed when preventive therapy is started and 7–12 mo later. Subsequently, annual antigen detection tests are recommended.

The terminology for HW antigen tests has changed, with the word negative being replaced by “below detectable limits” to underscore the possibility of HW-infected pets being antigen negative and that a negative test may become positive as worms mature.

The level of antigenemia is directly related to the number of mature female worms present. Most dogs harboring more than two adult female worms will test positive with most available tests. For low-burden suspects, commercial laboratory-based microwell titer tests are the most sensitive. There is, however, no test that can determine worm burden. Testing for microfilariae may be useful as an adjunctive test in suspect cases that have negative antigen test results.

In dogs, echocardiography is relatively unimportant as a diagnostic tool. Visualization of worms in the right heart and vena cava is associated with high-burden infection with or without caval syndrome. Severe, chronic pulmonary hypertension causes right ventricular hypertrophy, septal flattening, underloading of the left heart, and high-velocity tricuspid and pulmonic regurgitation. The ECG of infected dogs is usually normal. However, right ventricular hypertrophy patterns are seen when there is severe, chronic pulmonary hypertension, often associated with overt or impending

TABLE 8 **DIAGNOSTIC TESTS, CLINICAL SIGNS, AND TREATMENT FOR HEARTWORMS IN DOGS, CATS, AND FERRETS** (*continued*)

Clinical Signs	Prevention	Treatment	
		Adults	Microfilariae
Respiratory, weight loss, exercise intolerance	Ivermectin, milbemycin, selamectin, moxidectin	Melarsomine, doxycycline, symptomatic treatment	Moxidectin ^a , ivermectin + doxycycline, milbemycin
Respiratory, vomiting, sudden death	Ivermectin, milbemycin, selamectin, moxidectin	Symptomatic treatment, worm extraction	NA
Heart failure, respiratory, sudden death	Topical imidacloprid-moxidectin	Symptomatic treatment, moxidectin?	NA

right-side CHF (ascites). Cardiac rhythm disturbances are usually absent or mild, but atrial fibrillation is an occasional complication in dogs.

The diagnosis of HW disease in cats is based on historical and physical findings, index of suspicion, thoracic radiographs, echocardiography, and serologic test results. Cats may develop a positive antigen test 7–8 mo after L_3 inoculation. However, antigen tests alone are considered too unreliable (insensitive, missing 25%–50% of mature infections) as the initial screening test for cats. This occurs with unisex (all male) infections, infections with insufficient numbers of mature females to be detectable, and in cats with HARD. Cats with HARD may remain antigen negative if no adults develop, in all-male infections, or when only one adult female matures. These cats can also be only temporarily negative if tested before detectable antigenemia develops. The antigen test is strongly recommended in cats in which HW infection is suspected.

Antibodies to heartworms, produced by 90% of infected cats, often appear by 2–3 mo after L_3 infection and are generally present by 5 mo. However, antibodies can persist for several months after worm death. Also, antibodies induced by larvae can persist in aborted infections and after macrolide prophylaxis has been instituted, killing the early larval stages. Thus, a positive antibody test indicates infection by HW larval stages, and possibly HARD, but not necessarily of a mature infection. In conjunction with other provocative findings, antibody seropositiv-

ity is useful in making a clinical diagnosis of HW disease in cats, and it certainly identifies cats at risk. False-positive results from cross-reactivity with other parasites have not been seen. A negative antibody test indicates $\geq 90\%$ probability of the absence of mature infection. Microfilariae are rarely detected by modified Knott's tests ($< 10\%$) in cats. Annual screening of cats is not necessary but may yield information for concerned cat owners. For this purpose, the antibody test is preferred in that it detects cats with heartworms and those at risk. The antigen test is not appropriate for screening in cats because of its low sensitivity.

In cats, worms can often be imaged using echocardiography. This is because of the relative sizes of the heartworm(s) and the right heart and pulmonary arterial system of cats. Heartworms, particularly the females, are long enough to occupy the pulmonary arteries as well as the right heart, where they can be easily imaged. Parallel hyperechoic lines, produced by the HW cuticle, may be seen in the right heart and pulmonary arteries. Echocardiography is more important in cats than in dogs because of the increased difficulty of diagnosis in cats (low antigen test sensitivity and low antibody test specificity for mature infection) and the relatively high sensitivity of the test in experienced hands.

In addition to special diagnostic tests in cats and dogs, a CBC, chemistry profile, urinalysis, and particularly thoracic radiographs are indicated. Laboratory data are often normal. Eosinophilia and

basophilia alone or together may occur in dirofilariasis. Eosinophilia is most often seen at the time that stage 5 (young adult) larvae arrive in the pulmonary arteries. Subsequently, eosinophil counts vary but are usually high in dogs with immune-mediated occult infections, especially if eosinophilic pneumonitis develops (<10% of total infections).

Hyperglobulinemia due to antigenic stimulation may be present in dogs and cats. Hypoalbuminemia in dogs can be associated with proteinuria in severe immune-complex glomerulonephritis or with severe emaciation/cardiac cachexia. Serum ALT and alkaline phosphatase are occasionally increased but do not correlate well with abnormal liver function, efficacy of adulticide treatment, or risk of drug toxicity. Urinalysis may reveal proteinuria that can be quantitated by a urine protein:creatinine ratio. Occasionally, severe glomerulonephritis can lead to hypoalbuminemia and nephrotic syndrome. Dogs with hypoalbuminemia, secondary to glomerular disease, also lose antithrombin III and are at risk of thromboembolic disease. Hemoglobinuria is associated with caval syndrome and occurs when RBCs are lysed in the circulation.

In dogs, thoracic radiography provides the most information on disease severity and is a necessary screening tool to assess the clinical status of dogs with dirofilariasis, particularly when symptomatic. High-risk infections are characterized by a large main pulmonary artery segment and dilated, tortuous caudal lobar pulmonary arteries. Right ventricular enlargement may also be seen and, along with enlarged pulmonary arteries, is indicative of pulmonary hypertension. With pulmonary thromboembolism and pulmonary infiltrate with eosinophils (pneumonitis), ill-defined parenchymal infiltrates surround the caudal lobar arteries, typically most severe in the right caudal lobe.

In cats, cardiac changes and pulmonary hypertension are less common. In ~50% of infected cats, caudal lobar arteries are larger than the corresponding vein and >1.6 times the diameter of the ninth rib at the ninth intercostal space. Patchy parenchymal infiltrates may also be present in cats with respiratory signs. The main pulmonary artery segment usually is not visible because of its relatively midline location.

In ferrets, the diagnosis is less readily made with thoracic radiographs, because only the right ventricle tends to be enlarged. However, the commercial antigen tests have detected HW antigen experimentally, as early as 5 mo after infection, and have been shown to be effective in clinical situations. False-negative

results may occur, especially in species that harbor lower worm burdens (cats and ferrets). Furthermore, although microfilaria testing is only rarely helpful, adult worms can often be seen with echocardiography and nonselective angiography.

Treatment in Dogs: The extent of the preadulticide evaluation varies, depending on the clinical status of the dog, the likelihood of coexisting diseases that may affect the outcome of treatment, the owner's ability to restrict the dog's exercise, and cost considerations. Clinical laboratory data should be collected selectively to complement information obtained from a thorough history, physical examination, antigen test, and thoracic radiography.

Two important variables known to directly influence the probability of thromboembolic complications after adulticide treatment and the outcome of treatment are the extent of concurrent pulmonary vascular disease and the current worm burden. Assessment of cardiopulmonary status is indispensable for evaluating a dog's prognosis. Pulmonary thromboembolic complications after adulticide treatment are most likely to occur in heavily infected dogs already exhibiting clinical and radiographic signs of severe pulmonary vascular disease, especially when severe pulmonary hypertension and CHF are present.

Before adulticide therapy, HW-infected dogs are assessed and rated for risk of postadulticide thromboembolism. Dogs can be categorized as follows: 1) low risk of thromboembolic complications, light worm burden, and no evidence of parenchymal and/or pulmonary vascular lesions; or 2) high risk of thromboembolic complications. Dogs in the low-risk category would ideally fulfill the following conditions: no clinical signs, normal thoracic radiographs, a low level of circulating antigen or a negative antigen test with circulating microfilariae, no worms visualized by echocardiography, no concurrent disease, and with owners capable of completely restricting exercise. The low-risk group would also include dogs having previously undergone adulticidal therapy but that remain antigen positive. Dogs with near-normal thoracic radiographs may develop severe thromboembolic disease, occurring most often when exercise is not restricted. Dogs at high risk of thromboembolic complications include those with signs related to HW infection (eg, coughing, dyspnea, ascites), abnormal thoracic radiographs, high level of circulating antigen, worms visualized by

echocardiography, concurrent disease, and little or no possibility that the owners will restrict exercise.

The only approved heartworm adulticide is melarsomine dihydrochloride, which is variably effective against mature (adult) and immature heartworms of both sexes, with male worms being more susceptible. Melarsomine is given at 2.5 mg/kg, deep IM in the belly of the epaxial (lumbar) musculature in the area of the third to fifth lumbar vertebrae, using a 22-gauge needle (1 in. long for dogs <10 kg or 1.5 in. for dogs >10 kg). Pressure at the injection site is applied and maintained for 5 min to prevent drug migration. Approximately one-third of dogs will exhibit local pain, swelling, soreness with movement, or sterile abscessation at the injection site. Local fibrosis is not uncommon (and is the reason for targeting the belly of the epaxial musculature). In standard use, the procedure is repeated on the opposite side 24 hr later for dogs at low risk of treatment complications. However, to reduce the danger of thromboembolism, a two-phase (also termed "split-dose" or "three-dose" method) treatment is highly recommended for at-risk dogs and, indeed, for all patients, unless cost considerations prohibit this approach. Using this protocol, a single injection of melarsomine is given, followed by two injections 24 hr apart, after an interval of at least 30 days. The American Heartworm Society recommends this three-dose alternative regimen, regardless of the stage of disease or risk category. Exercise restriction is essential once treatment is started to minimize the risk of pulmonary thromboembolism due to dead and dying adult worms.

An approach to adulticidal therapy in which preventive is started at time of diagnosis is doxycycline (10 mg/kg, bid for 30 days) and monthly HW preventive, at the standard preventive dosage. After 2 mo, adulticidal injections (melarsomine at 2.5 mg/kg, IM) are initiated, as the dog's condition allows. Daily corticosteroids, using a tapering dosage, may also be administered during this period to reduce pulmonary inflammatory lesions from dying worms and from melarsomine. Although exercise is minimized from the day of diagnosis, cage rest must be enforced from the day of each initial injection for 4–6 wk. If the dog's condition allows, melarsomine injections are repeated in 1 mo (2 injections 24 hr apart), with the same regimen of prescribed exercise restriction. If, after the first injection, the dog has suffered significant pulmonary damage from the

resultant worm death, the second and third injections can be withheld indefinitely.

Dogs with high worm burdens are at risk of severe respiratory complications. Because only ~50% of heartworms are destroyed after the first injection, the cumulative impact of worm emboli on severely diseased pulmonary arteries and lungs is reduced. Furthermore, if serious thromboembolism develops, the second two-dose part of the regimen can be delayed, allowing the lungs to heal from the first insult. Lastly, this approach destroys a higher percentage of adult heartworms than the standard two-dose protocol. For the utility and advisability of various therapeutic protocols, see TABLE 9.

Doxycycline has become an important part of treatment of HW infection in dogs. Through its negative action on *Wolbachia*, it provides benefits to the canid host and works to the detriment of *D. immitis*. Doxycycline is indicated in preadulticide therapy (at 10 mg/kg, bid, for 30 days) in HW-infected dogs. It is given in conjunction with ivermectin at the preventive dosage (6–12 mcg/kg/mo). This combination reduces the severity of lung injury after adulticidal therapy, probably through reducing the amount of *Wolbachia* antigen and the proteins released from the HW uterus as the bacteria die and the uterus degenerates. Doxycycline at this dosage hastens worm death when the "slow-kill" approach is used, thereby presumably reducing the negative impact of worms on the host. Doxycycline with ivermectin also clears the host of microfilariae. Therefore, in dogs undergoing slow-kill treatment, this combination decreases risk of macrolide resistance, which is a concern in the slow-kill method using ivermectin alone. Doxycycline is advocated in treating dogs with HW infection regardless of severity classification or protocol.

The American Heartworm Society recommends administration of prophylactic doses of macrolides for 2 mo before administration of melarsomine, with the first dose given concurrently with the first dose of doxycycline (day 1) and a second dose given after the end of the doxycycline treatment (day 30). A third dose is then given concurrently with the first dose of melarsomine (day 60). Macrolide administration is continued monthly thereafter at the preventive dosage. The rationale for this approach is to eliminate susceptible migrating *D. immitis* larvae and to allow nonsusceptible 2–4 mo old larvae to age to a point at which they are more susceptible to melarsomine. This approach of a 2-mo

TABLE 9 GUIDE TO CHOOSING HEARTWORM THERAPEUTIC PROTOCOL

	Protocol	Advantages	Disadvantages	Utility ^a
1	Split dose (3 injections), melarsomine and doxycycline; thoracic radiographs, CBC, UA, chemistry panel, coagulation profile	↑ efficacy, ↓ risk of PTE, safety of phased worm kill, no resistance concern	Cost \$\$\$\$; exercise restriction for 2 mo	Appropriate for all; best approach for severe HW disease
2	Standard dose (2 injections), melarsomine and doxycycline; thoracic radiographs, CBC, UA, chemistry panel, coagulation profile	↓ cost, ↓ risk of PTE (vs standard dose), exercise restriction only 1 mo, no resistance concern	Cost \$\$\$; ↑ risk of PTE (vs split dose); ↓ kill efficacy (vs split dose)	Appropriate when financial constraints and mild to moderate HW disease
3	Standard dose (2 injections), melarsomine	↓ cost; exercise restriction only 1 mo, no resistance concern, easier for shelters	Cost \$\$; ↑ risk of PTE (vs standard dose); ↓ kill efficacy (vs split dose); cage rest imperative	Appropriate when financial constraints and mild HW disease
4	Slow kill with ivermectin, doxycycline	↓ cost, no injections, no hospitalization, shorter treatment duration than slow kill	Cost \$; ↑ risk of resistance, not approved by AHS, ~12-mo course, lung disease progression, time of HW death unknown	Appropriate only when severe financial or other constraints
5	Slow kill with ivermectin	Inexpensive; no injections	↑ risk of resistance, 30-mo course, lung disease progression, time of HW death unknown	Should be avoided

^aNone of these is appropriate for initial management of caval syndrome but may be used to complete therapy after worm removal.

UA = urinalysis; PTE = pulmonary thromboembolism; AHS = American Heartworm Society;

\$ = relative cost

pretreatment with macrolides has become less compelling with the recent knowledge that doxycycline kills developing larvae ($I_{a_1} > L_1 > \text{young adults}$) when administered at 10 mg/kg, bid, for 30 days, thereby closing the gap during which developing larvae are not susceptible to melarsomine treatment.

High-risk dogs should be stabilized before melarsomine administration. Stabilizing treatment includes cage confinement, oxygen, corticosteroids, and possibly heparin (75–100 U/kg, SC, tid) for 1 wk before the alternative (split-dosage) melarsomine treatment protocol.

Dogs with right-side CHF should be treated with furosemide (1–2 mg/kg, bid), an angiotensin-converting enzyme (ACE) inhibitor such as enalapril (0.5 mg/kg/day, increased to 0.5 mg/kg, bid, after 1 wk pending renal function test results), moderate dietary sodium restriction, and abdominal paracentesis, as needed.

The inodilator, pimobendan, is also indicated at 0.25 mg/kg, bid, to support myocardial function and reduce cardiac work. Sildenafil can be used initially at 1 mg/kg, tid, as a pulmonary vasodilator. Caution is warranted with this and other vasodilators to avoid the adverse effect of systemic hypotension.

After melarsomine injection(s), exercise must be severely restricted for 4–6 wk to minimize pulmonary thromboembolic complications. Adverse effects of melarsomine are otherwise limited to local inflammation, cough, brief low-grade fever, and salivation. Hepatic and renal toxicity are seldom, if ever, seen.

Laboratory findings associated with adjuvant therapy may include an inflammatory leukogram, thrombocytopenia, and prolonged activated clotting time or prothrombin time. A postinjection increase in serum CK may be noted. Local or disseminated intravascular coagulopathy may occur when platelet counts are $<100,000/\mu\text{L}$. Treatment for severe thromboembolism should include oxygen, cage confinement, a corticosteroid at an anti-inflammatory dosage (eg, prednisone at 1 mg/kg/day, PO), and low-dose heparin (75–100 U/kg, SC, tid) for several days to 1 wk. Severe lung injury is likely present if, after 24 hr of oxygen therapy, no improvement is noted and partial pressures of oxygen remain <70 mmHg.

The standard melarsomine protocol (two-dose, 24-hr treatment regimen) kills most adult worms, clearing 50%–85% of dogs. Antigen testing should be performed 8–12 mo after the third dose of the split-dose (alternative) protocol. If a positive test result is obtained at this time, consideration can be given to abbreviated retreatment (two injections, 24 hr apart). A “slow-kill” approach with ivermectin (0.6 mcg/kg, every 2 wk for 6 mo) can be substituted for repeated melarsomine injection but should definitely be preceded by 30 days of doxycycline therapy (10 mg/kg, bid) because this minimizes the reaction to dead and dying worms, enhances the kill rate to ~1 yr (vs 2.5 yr with ivermectin alone) versus the standard slow-kill approach, and is thought to decrease the risk of resistance (see above). The standard “slow-kill” approach with ivermectin alone is against the current recommendations of the American Heartworm Society. Longterm use of macrolides, rather than melarsomine, to kill adult worms allows pulmonary pathology to progress during the lengthy period in which worms are dying and being processed.

Caval syndrome results from worms migrating retrograde to the right atrium and great veins and is usually the result of a precipitous fall in cardiac output, as might occur with pulmonary thrombosis. Severe pulmonary hypertension is then complicated by worm-induced tricuspid valve leakage, hemolysis, and damage to liver and kidneys. In caval syndrome, removal of worms from

the right atrium and orifice of the tricuspid valve is typically necessary to save the life of the dog. This may be accomplished by using light sedation, local anesthesia, and either a rigid or flexible alligator forceps, or an intravascular retrieval snare, introduced preferentially via the right external jugular vein. With fluoroscopic guidance, if available, the instrument should continue to be passed until worms can no longer be retrieved. Immediately after a successful operation, the clinical signs should lessen or disappear. Fluid therapy may be necessary in critically ill, hypovolemic dogs to restore hemodynamic and renal function. After full recovery from surgery, adjuvant therapy is undertaken to eliminate remaining worms. Particular care should be taken if many worms are still visible echocardiographically.

Microfilaricide Treatment: At specific preventive dosages, the macrolide preventive drugs are effective microfilaricides, although not approved by the FDA for this purpose. Adverse reactions may occur in dogs with high microfilarial counts ($>40,000/\mu\text{L}$), depending on the type of macrolide given. However, the microfilarial count is usually lower, and mild adverse reactions occur in ~10% of dogs. Most adverse reactions are limited to brief salivation and defecation, occurring within hours and lasting up to several hours. Dogs, especially small dogs (<10 kg), with high microfilariae counts ($>40,000/\mu\text{L}$) may develop tachycardia, tachypnea, pale mucous membranes, lethargy, retching, diarrhea, and even shock. Treatment includes an IV balanced electrolyte solution and a soluble corticosteroid. Recovery is usually rapid when treatment is administered quickly. Microfilarial counts are not routinely performed, and thus severe reactions are seldom expected. Treatment specifically targeting circulating microfilariae has historically been undertaken 3–4 wk after adulticide administration. More commonly, microfilariae are eventually eliminated, even from dogs not treated with adulticide, after several months of treatment with prophylactic doses of the macrocyclic lactones. The current practice is to start a macrocyclic lactone for prevention and microfilarial eradication at the time of diagnosis. Although all macrocyclic lactones have microfilaricidal activity and are the safest and most effective drugs available, this characteristic varies within this drug group. Only the combination topical product containing imidacloprid and moxidectin is FDA approved as a microfilaricide. Livestock preparations of

these drugs should not be used to achieve higher doses for the purpose of obtaining more rapid results. Performance of a microfilaria test is recommended at the time of diagnosis and 1–3 mo after microfilaricidal therapy has begun.

Treatment in Cats: There is currently no satisfactory treatment approach for heartworm infection in cats. Infection often is lethal. Thus, all cats in regions endemic for canine HW disease should receive drug prophylaxis. The lifespan of adult heartworms in cats has traditionally been thought to be 2 yr, so spontaneous recovery is possible. Cats may remain asymptomatic, experience episodic vomiting and/or episodic dyspnea (resembling asthma), may die suddenly from pulmonary thromboembolism or an anaphylactoid reaction, or rarely, develop CHF.

Because there is no safe or approved adulticide for cats, many are managed conservatively with restricted activity and corticosteroid therapy, such as prednisolone (1–2 mg/kg, PO, every 24–48 hr). Steroids reduce the severity of vomiting and respiratory signs. The hope is that episodes of pulmonary complications will not prove fatal as the worms die. Barring consecutive, additional infection, 25%–50% of cats may survive with this approach. Serial antigen and antibody testing (at intervals of 6–12 mo) can be used to monitor status. Although there are no supportive data, administration of doxycycline (10 mg/kg, bid for 30 days) and ivermectin (24 mcg/kg/mo) to an infected cat could be theorized to cause worm degradation and contracture, thereby lessening the potential for catastrophic consequences when the worms die. Of course, the macrocyclic lactone would also protect the cat from a new infection, if more exposure is encountered.

Surgical retrieval of worms from the right atrium, right ventricle, and vena cavae via jugular venotomy can be attempted in cats with high worm burdens detected by echocardiography. An endoscopic basket, snare, or horsehair brush can also be advanced via the right jugular vein under fluoroscopy. Cats in CHF have been cured by worm removal.

Treatment in Ferrets: Treatment in ferrets is, likewise, difficult, because there is no approved agent for this purpose. Adulticidal therapies (thiacetarsenide and melarsomine) have resulted in ~50% mortality in ferrets. Moxidectin (injectable and topical formulations) has been widely thought to be adulticidal for heartworms in ferrets and

is given at the same dosage and frequency as in dogs. Moxidectin and imidacloprid (combination) is approved by the FDA for use in ferrets to prevent HW infection and to prevent and treat flea infestations.

Prevention: Heartworm infection is generally completely preventable with macrolide prophylaxis. Year-round prevention is advised. Preventive therapy in dogs is recommended beginning at 6–8 wk of age. No testing is necessary at this age, because the presence of mature female heartworms is required to produce a positive heartworm test (antigen or microfilaria). When prophylaxis is started after 7 mo of age, an antigen test and a test for presence of microfilariae is recommended, followed by another antigen test 6–7 mo later. This series of tests will help to avoid unnecessary delay in detecting subclinical infections, as well as potential confusion concerning effectiveness of the preventive program, because it cannot be determined until the second test whether infection existed before beginning chemoprophylaxis.

Formulations of the macrolide preventives ivermectin, milbemycin oxime, moxidectin, and selamectin are safe and effective, as prescribed, for all breeds of dogs. Currently marketed products have additional chemicals and parasite spectra, including GI and ectoparasites: ivermectin (hookworms), ivermectin/pyrantel pamoate (hookworms and roundworms), ivermectin/pyrantel pamoate/praziquantel (hookworms, roundworms, and tapeworms), milbemycin/lufenuron (hookworms, roundworms, whipworms, and sterilizes fleas), milbemycin/lufenuron/praziquantel (hookworms, roundworms, whipworms, tapeworms, and sterilizes fleas), selamectin (fleas, ticks, ear mites, sarcoptic mites), moxidectin injectable (hookworms), moxidectin/imidacloprid (roundworms, hookworms, whipworms, adult fleas, microfilariae), milbemycin/spinosad (hookworms, roundworms, whipworms, fleas).

At the approved dosage, milbemycin kills microfilariae quickly, and in the face of high microfilarial concentrations a shock reaction may occur. Thus, milbemycin should not be administered without close monitoring and/or prophylactic pretreatment (steroids and/or antihistamine) as a preventive in dogs with high numbers of microfilariae.

HW prevention is also recommended for all cats in endemic regions, regardless of housing status, because of the potential for severe consequences with infection. Performing microfilaria testing in cats before starting preventive therapy is not required,

because cats have small microfilarial numbers and the presence of microfilaria is typically transient. Ivermectin for cats is safe and effective at 24 mcg/kg, PO, once monthly. At this dosage, the formulation is also effective against *Ancylostoma tubaeforme* and *A. braziliense*. Preventive treatment should be started in kittens at 6 wk of age and continued lifelong. There is currently no milbemycin product marketed for use in cats in the USA.

Formulations of selamectin and a combination of imidacloprid/moxidectin are labeled for both dogs and cats. Selamectin is administered topically at a monthly dosage of ~6 mg/kg and also kills adult fleas and prevents flea eggs from hatching for 1 mo. It also is indicated for treatment and control of *Otodectes cynotis* in dogs and cats, sarcoptic mange, *Dermacentor variabilis* infestations in dogs, *Ancylostoma tubaeforme*, and *Toxocara cati* in cats. A topical combined formulation of imidacloprid and moxidectin administered at dosages of 10 mg/kg for imidacloprid and 1 mg/kg for moxidectin is also effective against HW infection and flea infestations. Although all currently marketed preventives are likely effective in ferrets, only imidacloprid with moxidectin is approved by the FDA. Importantly, the

preventive dosage for ferrets is the same as that for dogs (not cats).

Sporadic resistance of heartworms to the macrocyclic preventive class has been recognized since 2013. All the current molecules used to prevent heartworm disease have been implicated. However, some formulations appear to be more effective against resistant isolates than others. There have been isolates from six dogs with varying degrees of resistance. There is little evidence of spread out of the Mississippi Delta region, where resistance was first recognized. It is important to realize that the current preventives are effective in the vast majority of cases and should not be abandoned. Emphasis should be placed on owner compliance and year-round preventive therapy, as well as on alternative methods of HW prevention, including topical and oral mosquito repellants, indoor/screened housing, especially at night, and mosquito abatement programs. The role of slow-kill macrolide adulticidal therapy has been questioned in the development of resistance and should be avoided. If such therapy is unavoidable, it should absolutely be accompanied by 30 days of doxycycline treatment at the outset, with assurance that microfilariae are eradicated.

BOVINE HIGH-MOUNTAIN DISEASE

("Brisket" disease, Big brisket, Dropsy, High-altitude disease, Pulmonary hypertension, Congestive right heart failure)

Bovine high-mountain disease (BHMD) is characterized by a noncontagious swelling of edematous fluid in the ventral parasternal muscles (brisket region), the ventral aspect of the body including the abdomen, and the submandibular region in cattle raised in high-altitude regions (>5,000 ft [1,524 m]) in the western USA most commonly and substantially affecting Colorado, Wyoming, New Mexico, and Utah. It also affects cattle in mountainous ranges of the world, most commonly at elevations >6,500 ft (1,981 m) in western Canada and South America. BHMD affects cattle of all ages and breeds, but not necessarily equally.

BHMD is a result of pulmonary arterial hypertension induced by pulmonary hypoxia occurring at high altitude. Hypoxia-induced pulmonary arterial vasoconstriction and arterial hyperplasia reduce the diameter of the pulmonary

arterioles, resulting in pulmonary hypertension and subsequent right ventricular (RV) hypertrophy. Without intervention to reduce the hypoxia-induced pulmonary hypertension, the disease will eventually progress to RV congestive/dilatatory cardiac failure. Rarely, similar lesions have been described in severely stressed and parasitized sheep and deer. Etiologically similar hypoxia-related heart failure has also been described in chickens in the Andes Mountains and in people living at extreme elevations. The incidence in cattle on high mountain pastures averages 3%–5% with variations from 0.5%–10% but has been as much as 65% in a genetically susceptible calf crop. A 25% calf loss is not uncommon in the high elevations of Colorado and Wyoming.

Although most commonly associated with altitude, other genetic, physiologic, environmental, and toxic factors play

important roles in disease development and progression. Any pulmonary disease, acute or chronic, that hinders pulmonary function can result in a hypoxic condition similar to altitude-induced BHMD.

Etiology: Although many factors may contribute to the incidence of BMHD, the pathogenesis is directly related to the hypoxic condition that results from high altitude. Pulmonary vascular shunting is a normal physiologic response to hypoxic conditions and is seen in all animals. Strong responses are seen in cattle, horses, and pigs, whereas people, dogs, guinea pigs, and llamas are less responsive. These findings and the high incidence of disease in cattle indicate they are uniquely susceptible. The vasoconstriction mechanism of shunting is a way to divert unoxygenated blood to oxygen-rich regions of the lungs (dorsal aspect) and away from poorly oxygenated regions (ventral aspect). Exaggerated shunting in response to hypoxia, the anatomic pattern of the bovine lobulated lung, and the small lung-size/body-weight ratio all contribute to a severe loss of functional pulmonary capacity.

Pulmonary vascular shunting is initially mediated through pulmonary arteriole constriction in the acute stages of hypoxia. Vascular hypertrophy and thickening of the medial layers of the pulmonary arterioles (medial hypertrophy) and adventitial tissues occurs with chronic hypoxic exposure (>3 wk). Vascular remodeling leading to loss of peripheral pulmonary arteries also contributes to increased pulmonary resistance. This combination of events causes significant pulmonary hypertension, which leads to a progression of cardiac pathology: RV hypertrophy, followed by RV dilation, and finally right congestive heart failure (CHF). *

This pathogenesis of exaggerated vasoconstrictive shunting, arterial medial and adventitial hypertrophy, and vascular obliteration resulting in pulmonary hypertension appears to be characteristic of some cattle and is highly heritable. Some cattle appear to be more naturally resistant to this process, both on an individual and breed basis. There is marked individual and interspecies variability in hypoxia-induced increases in pulmonary vascular resistance. The role of genetics in BHMD is supported by high familial incidence with marked variation in susceptibility between individual animals, breeds, and other species of animals. There is strong evidence that the susceptibility of cattle to hypoxia-induced pulmonary hypertension is

inherited. In addition to underlying genetic predisposition, altered chemoreceptor activity or myocardial metabolism may also play a role. Acute viral or bacterial respiratory disease can exacerbate pulmonary hypoxia of high altitude, resulting in a rapid onset of RV failure.

Various range plants, both browse and non-browse types, have been associated with increased incidence of BHMD, but only locoweed has been experimentally shown to induce the disease. When consumed by cattle at high elevation, locoweed (certain *Oxytropis* and *Astragalus* spp that contain the alkaloid swainsonine) markedly increase the prevalence and severity of CHF, which develops relatively quickly (within 1–2 wk) with an incidence as high as 100%. Swainsonine, the toxin in locoweed, is excreted in milk, thereby predisposing nursing calves to developing CHF. Locoweed-poisoned cows often abort, and many develop severe hydrops amnii in addition to showing signs of BHMD. Locoweed poisoning directly contributes to increased pulmonary vascular resistance and hypertension; immunohistochemistry and electron microscopy studies have shown that poisoning causes severe swelling and cytoplasmic vacuolation of pulmonary intravascular macrophages and endothelial cells. The myocardium also is compromised by locoweed, seen as extensive vacuolation of the myocardial interstitial cells. Finally, swainsonine has systemic endocrine and paracrine effects due to altered glycoprotein metabolism, which may also contribute to the pathogenesis of BHMD.

Clinical Findings: The clinical changes of RV CHF of high-mountain disease usually develop slowly over several weeks, commonly within the first 3–4 wk after cattle are moved from lower to higher elevations. This 3–4 wk period may be an average time, but clinical signs and death from pulmonary hypertension and right CHF have been seen within 24 hr after altitude exposure and have also been seen in animals that have lived in higher elevations for years. In those areas in North America where cattle spend summer and fall grazing at high altitudes and return to lower elevations later in the fall, the disease is usually manifest in late summer and early fall and seems to be associated with weather and environmental conditions as seen in high elevations with cold nights and hot days. Pulmonary hypertension and right CHF seem to follow respiratory disease seen with these same climatic influences. In areas where cattle live year round at high altitudes, the disease incidence is greatest in

late fall, winter, or early spring. Periods of severe cold or other environmental stress (eg, pregnancy, change in nutrition) appear to precipitate the onset of signs. Affected animals initially appear depressed and reluctant to move. As the syndrome progresses, subacute edema develops in the brisket region and extends cranially to the intermandibular space and caudally to the ventral abdominal wall. Pleural effusion and ascites are usually abundant. Marked distention and pulsation of the jugular veins are usually prominent. Appetite may be decreased. Profuse diarrhea may develop as a result of intestinal venous hypertension. Respiration is labored, and animals may appear cyanotic. As the disease progresses, affected cattle become more reluctant to move and may become recumbent. With forced exertion, severely affected animals may collapse and die. In the terminal stages, the animal is often anorexic, recumbent, and unable to rise. To the rancher and cattlemen, an animal experiencing "brisket disease" is most often characterized by severe brisket and abdominal edema and swelling, jugular enlargement and pulsation, bulging eyes, exophthalmos (secondary to venous congestion), ventral abdominal distention (ascites), bloating, recumbency or inability to travel with the herd, and profuse diarrhea.

Lesions: Generalized edema is especially severe in the ventral subcutaneous tissues, skeletal musculature, perirenal tissues, mesentery, and wall of the GI tract. Ascites, hydrothorax, and hydropericardium are consistent findings. Fluid characteristics include low cellularity and low to normal protein, consistent with a transudate secondary to cardiac failure. The liver lesions, due to chronic passive congestion, vary from an early "nutmeg" appearance to severe lobular and vascular fibrosis. The lungs may have varying degrees of atelectasis, interstitial emphysema, edema, and pneumonia. The heart has marked RV hypertrophy and dilatation; the cardiac apex is displaced to the left, making the enlarged heart appear round. The right atrium is often 2–3 times larger than the left and is flaccid. Pulmonary arterial thrombosis is a frequent finding. Microscopically, there is hypertrophy of the media of small arteries and arterioles in the lungs. Acute rupture of the pulmonary artery (aneurysm) secondary to the severe pulmonary hypertension is often seen as a reason for acute death without clinical signs of RV CHF.

Diagnosis: There is no definitive diagnostic test for BHMD. A diagnosis may be

based on clinical findings related to CHF in cattle kept at high altitudes. Body temperature and CBC are generally normal unless there is other underlying inflammatory pathology. Recent studies in elevations $\geq 9,000$ ft (2,743 m) found body temperatures in calves experiencing pulmonary hypertension to be increased ($>104^{\circ}\text{F}$ [40°C]). This is hypothesized to be secondary to an increased metabolic demand and tachypneic response to the hypoxic condition. Thoracic auscultation may reveal a decreased intensity of breath sounds in the ventral thorax and muffled heart sounds if pleural effusion is present. The heart and respiratory rates are generally increased, and a systolic cardiac murmur may be auscultated if RV enlargement has resulted in right atrioventricular or pulmonic valve insufficiency. In end-stage CHF, a gallop rhythm is often detected. Although jugular distention is a characteristic clinical sign, an abnormal jugular pulse may or may not be seen. The common clinical pathologic changes are increases in hepatic enzymes, particularly AST and L-lactate dehydrogenase. Clinically affected animals may be azotemic because of decreased renal perfusion secondary to heart failure and dehydration/hypovolemia.

BHMD should be differentiated from other causes of CHF, including pericarditis, traumatic reticulopericarditis, cardiac lymphosarcoma, valvular endocarditis, viral or bacterial myocarditis, cardiomyopathy (nutritional, hereditary, or idiopathic), pulmonary arterial obstruction from embolic pneumonia, or chronic hypoxia and cor pulmonale due to other primary pulmonary disease. Brisket edema may not always be present in animals with peracute RV CHF; this can result in BHMD in calves being mistaken for acute viral or bacterial pneumonia.

Treatment and Control: Affected animals should be moved to a lower altitude with minimal restraint, stress, and excitement. General supportive therapy, including diuretics, thoracocentesis, antibiotics, and appetite stimulants such as vitamin B complex, may be beneficial. Thoracocentesis is the single treatment that most dramatically improves an affected animal's chance of survival. At high elevations, use of oxygen or a hyperbaric chamber may be considered for valuable animals. Because the disease may recur, affected animals should not be returned to high altitudes.

Affected cattle should not be retained for breeding because of heritability. Treatment of concurrent diseases, including respiratory/cardiac disease, GI disease, parasitism,

and plant toxicosis, should be addressed. Because locoweed poisoning has been directly linked to the development of CHF in cattle, the exposure of susceptible animals to locoweed should be minimized by ensuring that animals have a good selection of forages. Animals should be moved to pastures free of locoweed as soon as poisoning is recognized to prevent severe and irreversible damage.

Treatment of BHMD can be expensive and unrewarding, so prevention is preferred. Genetic selection through the use of pulmonary arterial pressure (PAP) measurements to select cattle resistant to the effects of hypoxia is a more effective way to control BHMD. Identifying animals highly susceptible to the effects of altitude hypoxia (those with high PAP measurements) and eliminating them from the breeding pool are practical methods to reduce the prevalence of BHMD in a herd. The PAP measurement procedure involves passing flexible polyethylene catheter tubing (1.19 mm internal diameter $\times$ 1.7 mm external diameter) through a large-bore needle (12 or 13 gauge, 3.5 in.) inserted into the jugular vein. The catheter is advanced through the jugular vein to the right atrium, into the right ventricle, and then into the pulmonary artery.

At altitudes of 5,000–7,000 ft (1,524–2,133 m), a normal mean PAP measurement should be 34–41 mmHg. In cattle displaying signs of pulmonary artery hypertension, the PAP can range from 48–213 mmHg. The PAP and the RV pressure may be normal to subnormal in cattle with end-stage right CHF because of the failing myocardium. Cattle with ventricular septal or atrial septal defects often have mean systolic and diastolic measurements in the hundreds. Any animal with a PAP measurement >48 mmHg is considered at risk of developing BHMD and may be a potential genetic carrier and should not be maintained or used in breeding programs at high altitude. These animals should also be auscultated for cardiac murmurs and evaluated for possible congenital cardiac defects. In general, cattle >1 yr old that have a PAP <41 mmHg at an elevation $>5,000$ feet (1,524 m) are likely to maintain an acceptable PAP at high altitude and serve as good breeding stock for herds at high elevation. PAP measurements between 41 and 49 mmHg are difficult to interpret consistently; these animals should be used with caution at high elevation.

Multiple factors contribute to the variation of PAP in cattle, including breed, gender, age, body condition, concurrent illness, environmental conditions, elevation, and genetics. Based on tests of $>300,000$ head of

cattle, it appears that no one breed is resistant to the effects of high-altitude hypoxia, although some breeds, and pedigrees within breeds, appear to be more naturally resistant. It is not unusual to see a difference in PAP measurements between heifers and bulls because of husbandry practices. Bulls are often pushed nutritionally for faster growth and muscling, which may affect pulmonary function and give rise to pulmonary hypertension. Pregnant cattle have been noted to have a higher PAP measurement than nonpregnant cattle. The age of the animal at the time of PAP testing should always be considered, because there is greater variation and less predictability in cattle ≤ 1 yr old. Testing animals at ≥ 16 mo of age appears to be the most consistent and accurate at predicting susceptibility to pulmonary hypertension induced by high altitude. Any concurrent illness, especially respiratory disease, or any cause of temporary or permanent pulmonary hypoxia can influence the PAP measurement.

Some cattle appear to be prone to developing right CHF, whereas others live at high altitude with a documented increased PAP and never have a clinical problem. Even though these animals may not develop clinical BHMD, they can pass the genetic predisposition to their offspring. This variable expression of clinical disease and the variable penetrance of the gene makes PAP testing challenging at all elevations and becomes an even greater concern at elevations $<5,000$ ft (1,524 m) where the hypoxic conditions needed to stimulate a pulmonary response are not sufficient. PAP measurements taken at low elevations ($<5,000$ ft [1,524 m]) should not be used as a positive selection tool but only to identify animals highly susceptible to hypoxic conditions and hypertensive even at elevations $<5,000$ ft (1,524 m). Cattle moved from low elevations to high elevations should remain at the altitude for ≥ 3 wk before PAP testing.

Future advancements in the research of pulmonary hypertension in cattle are concentrating on identifying DNA markers for recognition of genetic carriers of pulmonary hyperresponders to hypoxic conditions. Other areas of interest and research are being directed at and addressing the alarming increase in incidence of RV CHF at lower elevations as seen in heavy feedlot cattle at elevations $\leq 4,000$ ft (1,219 m). These fat cattle at this elevation seem to have the same postmortem lesions as those seen at higher elevations.

THROMBOSIS, EMBOLISM, AND ANEURYSM

A **thrombus** is an aggregation of platelets and fibrin that may form when certain conditions exist. Historically, these have included some combination of Virchow's triad such as blood stasis (reduced flow), endothelial injury, and/or an existing hypercoagulable state. A thrombus can develop in a cardiac chamber and be attached (mural) or less likely free floating (ball), or can originate *in situ* within a blood vessel where it can cause a partial or complete obstruction. The thrombus can be classified based on its location and the clinical signs it produces (eg, jugular venous thrombosis in large animals associated with prolonged venous catheterization, pulmonary arterial thromboembolism associated with heartworm disease in dogs).

All or part of a thrombus may break off and be carried through the bloodstream as an **embolus** that lodges distally at a point where the size of the embolus exceeds the vascular diameter. Poor injection or catheterization techniques along with inferior catheter material can result in vascular thrombosis. However, clinically significant vascular thrombosis is more commonly seen in animals with underlying diseases that result in a hypercoagulable state, such as systemic inflammation, endotoxemia, neoplasia, or antithrombin deficiency. If left untreated or uncontrolled, systemic thrombosis can result in hemorrhagic diathesis or disseminated intravascular coagulation (DIC), a life-threatening disorder of hemostasis with deposition of microthrombi and consumption of coagulation factors that results in concurrent hemorrhage.

Thrombus formation can occur in both large and small arteries and veins. Horses and cattle are more likely to develop venous thrombi, whereas in dogs and cats, arterial thrombi appear to be more clinically important. Arterial thrombosis or embolization results in ischemia of the tissues supplied by the infarcted vessel (eg, cats with cardiac disease and subsequent arterial thromboembolism). Emboli from infective conditions such as endocarditis are classified as septic (bacteria contained in the embolus). Septic emboli can result in bacterial dissemination and infection of distal capillary beds. Neoplastic emboli can

also occur and may contribute to metastasis. Systemic arterial thromboembolism is more important in cats, whereas dogs and large animals appear to develop *in situ* arterial thrombosis more commonly. Thrombosis of limb arteries causing lameness and gangrene has been reported in adult horses and foals. This occurs secondary to hypercoagulation and systemic inflammation (eg, septicemia in foals).

An **aneurysm** is a vascular dilation caused by weakening of the tunica media of blood vessels. The weakness might be primary or caused by degenerative or inflammatory changes progressing from an intimal lesion. False aneurysms (pseudoaneurysms) are caused by damage to all three layers of the arterial wall and result in extravascular accumulation of blood. Disruption of the endothelium associated with a true aneurysm can cause formation of a thrombus with subsequent embolization; thus, aneurysms, thrombi, and emboli may be recognized simultaneously. Aneurysms are rare in domestic animal species, although they have been reported in dogs, cats, horses, primates, and turkeys.

Clinical Findings and Diagnosis: Acute onset of dyspnea is often associated with pulmonary thromboembolism, although some animals may develop hemoptysis; the latter is most associated with pulmonary arterial disease such as that resulting from heartworm infection (*see* p 127). Septic cardiac thrombi are associated with endocarditis; nonseptic cardiac thrombi are associated with myocardial disease (most commonly in cats), or rarely with cardiac or pulmonary neoplasia. Infarction within the genitourinary system can present with hematuria, abdominal pain, and splinting. Splanchnic infarction usually results in abdominal pain, with vomiting seen in small animals.

Aneurysms cause no clinical signs unless hemorrhage occurs or an associated thrombus develops. Except for dissecting aneurysm in turkeys (*see* p 2787), aortic or sinus of Valsalva rupture in horses with sudden death, hemorrhage associated with guttural pouch mycosis in horses (*see* p 1463), or pulmonary arterial aneurysm in cattle, spontaneous aneurysmal hemorrhage is rare, and clinical signs usually

relate to thrombosis. An aneurysm of the abdominal aorta and its branches in large animals may be palpated rectally as a fixed firm swelling with a rough, irregular surface that pulsates with the heart beat. Fremitus may be present. In excess thrombus formation, the pulse may be delayed distally and have a slow rate of rise in pressure, or it may be absent. Other helpful diagnostic modalities include ultrasonography and angiography.

Cattle: Thrombosis of the caudal vena cava occurs in association with hepatic abscessation and vascular erosion of the abscess. Embolic pneumonia with secondary pulmonary abscessation, thromboembolism, and pulmonary arterial aneurysms are common sequelae. Affected animals may present with coughing, tachypnea, dyspnea, and abnormal lung sounds. Aneurysms in pulmonary arteries that contain septic emboli may rupture and cause intrapulmonary hemorrhage, or pulmonary abscesses may erode into bronchi and result in hemorrhage into the airways. The sequelae to these disorders may include epistaxis, hemoptysis, and death. Clinical pathologic data usually support a diagnosis of vena caval syndrome but are not specific. Increased fibrinogen, anemia, and in cases with an active abscess process, increased liver enzymes may be seen. Pulmonary arterial embolism and embolic pneumonia are also frequent complications of tricuspid or pulmonic valvular endocarditis in cattle, but aneurysms rarely develop. Intermittent fever and anorexia due to bacteremia at times of embolic showering are often present, and the animal typically has a history of a chronic active infection (eg, foot abscess, reticular abscess) as well as chronic weight loss with poor body condition score. Most cases of right heart endocarditis in cattle are bacterial and are commonly associated with a cardiac murmur, with a point of maximal intensity over the tricuspid valve. Echocardiography and blood cultures help identify right heart vegetative lesions and the causative bacterial agent, respectively. Thrombosis of the cranial vena cava in cattle produces bilateral jugular engorgement; edema of the head, submandibular area, and brisket; and pronounced oral mucosal hyperemia. However, similar clinical signs are seen with right-side congestive heart failure, which could be a sequela of tricuspid valve endocarditis. Significant lingual, pharyngeal, or laryngeal edema may develop and result in dysphagia and dyspnea.

Horses: Cranial vena cava thrombosis may result from extension of a jugular thrombus. Jugular vein thrombosis in horses is often associated with phlebitis following catheterization or extravasation of injected material and will cause swelling, heat, and pain of the affected area. Bilateral jugular vein thrombosis can cause edema and swelling of the head and neck, mimicking cranial caval thrombosis. Ultrasonographic examination of the affected vein can determine the extent of the thrombus and degree of occlusion. Doppler ultrasound is a more sophisticated method to determine blood flow and vessel patency. If a catheter-associated thrombophlebitis is suspected, blood culture and catheter-tip culture can be performed. Horses with colitis and other GI disorders are at increased risk of developing jugular thrombosis; ruminants are much less prone to jugular thrombosis than horses. Caudal vena cava-like syndrome has been described in a Quarter horse with respiratory signs. Hepatic abscesses, caudal vena cava thrombosis, pulmonary thromboembolism, and embolic pneumonia were identified at necropsy.

Migrating *Strongylus vulgaris* larvae (see p 316) can cause arteritis with development of thrombi and verminous aneurysms in the aorta, cranial mesenteric, or iliac artery. In some horses, emboli develop and partially or completely occlude terminal branches of the mesenteric arteries. Affected intestinal segments show changes ranging from ischemia to hemorrhagic infarction. Clinical signs are those of colic, constipation, or diarrhea. The colic usually is recurrent, and attacks may be severe and prolonged. Newer anthelmintics and improved therapeutic regimens have resulted in verminous arteritis becoming an uncommon disorder.

Thrombosis with or without aneurysm of the terminal aorta and proximal iliac arteries produces a characteristic syndrome in horses. Although associated with parasitism, other causes are possible. Affected horses appear normal at rest; however, graded exercise results in an increasing severity of weakness of the hindlimbs with unilateral or bilateral lameness, muscle tremor, and sweating. Severely affected animals may show signs of exercise intolerance, weakness, and atypical lameness that resolves after a short rest. Subnormal temperature of the affected limbs may be detectable, along with decreased or absent arterial pulsations and delayed and diminished capillary filling. Rectal palpation may show variation in

pulse amplitude of the internal or external iliac arteries (or both) and asymmetric vasculature. In severe cases, the hindquarter muscles atrophy, and lameness may become evident with only mild exercise. Complete embolic or thrombotic occlusion of the distal aorta may produce acute bilateral hindlimb paralysis and recumbency in horses. Affected animals are anxious, appear painful, and rapidly go into shock. The hindlimbs are cold, and rectal palpation reveals an absence of pulsation in either iliac artery. Transrectal ultrasound can help determine bloodflow in the aorta and iliac arteries.

Aneurysm of the aortic root has been reported in horses, commonly noted at the right aortic sinus with or without concurrent endocarditis. Similar to those in people, aneurysms of the sinuses of Valsalva in horses can be congenital or acquired. Rupture of an aortic aneurysm typically leads to sudden death, a scenario most commonly seen in breeding stallions during live cover.

Dogs and Cats: In dogs, and less commonly in cats, heartworm disease may lead to pulmonary arterial thromboembolism that commonly results in dyspnea and tachypnea. Affected animals are often reportedly healthy until sudden onset of coughing, hemoptysis, respiratory distress, or sudden death. Clinical signs most commonly develop in the weeks after treatment with adulticide; however, pulmonary thromboembolism may also develop from spontaneous worm death, or pulmonary thrombosis can form *in situ* secondary to pulmonary endothelial damage. Chest radiographs in affected animals may be normal or show underperfusion of the affected lung lobe, interstitial to alveolar infiltrates, or pleural effusion. Arterial blood-gas analysis typically demonstrates hypoxemia with a normal or low level of CO_2 in the blood. Ventilation/perfusion scanning with radionuclide-labeled macroaggregated albumin and gases or pulmonary CT angiography can confirm the diagnosis. Other diseases associated with pulmonary thromboembolism in dogs and cats include protein-losing nephropathy or enteropathy, hyperadrenocorticism, immune-mediated hemolytic anemia, and neoplasia.

In cats, cardiogenic embolism (arterial thromboembolism) is a devastating complication of cardiac disease. Although hypertrophic cardiomyopathy is the most common type of cardiac disease in cats (*see* p 117), any condition that results in left

atrial enlargement, including other cardiomyopathies, hyperthyroidism, or congenital heart disease, can predispose to arterial thromboembolism. Intracavitary thrombi typically form in the dilated left atrium where stagnant flow exists or, less commonly, within abnormal areas in the left ventricle. Although the condition is poorly understood, these cats most likely possess some degree of concurrent hypercoagulability, because all cats with cardiomyopathy do not develop cardiogenic embolism. Portions of these intracavitary thrombi can break off and form emboli that infarct arterial branches, most commonly the aortic trifurcation (saddle emboli). Clinical signs include pain and paresis or lower motor neuron paralysis of the hindlimbs. The arterial pulse (either femoral or pedal) is reduced to absent in the affected limbs, which are cooler than normal and have firm, swollen gastrocnemius muscle bellies. These clinical signs can be unilateral, bilateral, or bilateral but asymmetric. Emboli may also infarct other arterial beds, including the right forelimb, renal, splanchnic, cerebral, or myocardial circulation. Decompensation of the underlying myocardial disease is not uncommon and may result in congestive heart failure (pulmonary edema or pleural effusion). Ischemia and necrosis of infarcted pelvic limb musculature results in increases in serum CK and AST, and subsequent reperfusion of affected muscles can result in life-threatening hyperkalemia and acidosis. Echocardiography is the imaging modality of choice to assess cardiac structure, function, and presence of an intracardiac thrombus, whereas chest radiographs are used to diagnose left-side congestive heart failure. Nuclear perfusion studies, using the unbound radioisotope $^{99\text{m}}\text{Tc}$ can give sensitive information regarding the degree of perfusion of the hindlimbs and areas that may require amputation in select cases, although this is rarely done.

Systemic hypertension in cats and patent ductus arteriosus, aortic coarctation, degenerative processes, and infections in dogs have been associated with aortic aneurysms.

Cranial vena caval thrombosis and subsequent chylothorax has been reported in dogs and cats with transvenous pacemakers and other indwelling jugular devices/catheters. Successful treatment of caval thrombosis in affected animals has been described using a combination of anticoagulants, thrombolytics, and balloon venoplasty.

Treatment: Treatment of endocarditis includes longterm antibiotics (several weeks to months) and in some cases intermittent administration of antipyretic, anti-inflammatory, or antithrombotic drugs. Antibiotic choice should be based on culture and sensitivity results obtained from blood cultures. The prognosis for recovery is poor to guarded at best, and persistent debilitating cardiac disease is common even if the active infection can be controlled.

Treatment of venous thrombosis in horses and cattle is usually limited to supportive care, including hydrotherapy of accessible veins, anti-inflammatory agents, and systemic antimicrobials to control secondary sepsis. Surgical removal of thrombosed jugular veins has been performed successfully in horses, but unless both veins are severely affected, inflammation will resolve with medical treatment, and formation of collaterals will usually result in sufficient venous circulation. Thrombosis of the cranial or caudal vena cava results in more severe clinical signs and requires more aggressive therapy, which could include thrombolytic drugs and/or intravascular/surgical removal followed by aggressive anticoagulation. Response to anticoagulation therapy alone is generally inadequate.

Measures to minimize trauma to, and bacterial contamination of, veins remain the best means to prevent venous thrombosis. Extreme care should be taken when placing catheters or giving IV injections. The effectiveness of antiplatelet therapy (aspirin 0.5–5 mg/kg/day or clopidogrel 1–3 mg/kg/day), anticoagulant therapy (unfractionated heparin, 40–80 IU/kg, SC, bid-tid, or low-molecular-weight heparin [enoxaparin at 1 mg/kg, SC, bid, or dalteparin at 150–200 IU, SC, bid]) to facilitate intrinsic thrombus resolution is unknown but should at least prevent further thrombus formation.

In horses, aneurysms due to *Strongylus vulgaris* rarely rupture; the chief concern is thromboembolism of intestinal vasculature with subsequent colic. Generally, the arterial wall is sufficiently involved that thrombus removal is impractical. Antibacterial treatment and anthelmintics to kill the migrating larvae are of considerable value. The most rational approach to cranial mesenteric and aortic-iliac thrombosis in horses is prevention and control of strongylosis (see p 316).

Acute management of aortic emboli in cats can be approached in several ways. More than 50% of cats that survive a cardioembolic event will regain some function of the hindlimbs over 4–6 wk

with conservative medical therapy. More aggressive therapy aimed at dissolution of the thrombus through thrombolytic drugs or rheolytic intervention may result in improved short-term functional outcome, but survival is no better than that from conservative therapy and, in some cases, may actually be worse. Conservative therapy usually consists of initial pain management (hydromorphone, 0.1 mg/kg, SC, IM, or IV every 4–6 hr; or buprenorphine HCl, 0.01–0.03 mg/kg, SC, IM, or IV, every 6–8 hr) and anticoagulant therapy (heparin, 250–300 U/kg with first dose IV if animal is in shock, followed by administration SC, tid-qid; or dalteparin 150–170 IU/kg, SC, bid-tid). The activated partial thromboplastin time can be used to monitor heparin therapy, with a goal of 1.5–1.7 × the pretreatment value. The use of antiplatelet therapy (clopidogrel, 75 mg, PO, once on admission, then 18.75 mg/day, PO) should be considered to further reduce the thrombotic potential; in addition, it may have a beneficial effect on collateral circulation. Thrombolytic therapy, although not routinely recommended, could include streptokinase (90,000 IU/cat, IV over 20 min, followed by 45,000 IU as a continuous infusion for 2–24 hr), recombinant tissue-type plasminogen activator (tPA, 0.25–1 mg/kg/hr, IV, up to a total dose of 1–10 mg/kg), or urokinase (4,400 IU/kg, IV over 10 min, then 4,400 IU/kg/hr for 12 hr). These drugs promote thrombolysis by converting plasminogen to plasmin, which subsequently breaks down fibrin strands. Streptokinase is considered a nonspecific activator of plasminogen, because it activates circulating fibrin as well as fibrin contained within thrombi/emboli, which can lead to a systemic proteolytic state and bleeding. Although urokinase and tPA are more fibrin-specific than streptokinase, bleeding can also be seen with these agents. Moreover, all of these agents are prohibitively expensive and difficult to obtain. The use of antiplatelet agents such as clopidogrel has been shown to hasten thrombus dissolution and reduce acute arterial rethrombosis in experimental studies and human clinical trials, respectively. However, an in vitro feline study did not identify a significant difference in thrombolysis rates. It is not known whether these results can be applied to the natural clinical disease. Thrombolytic therapy appears to have the best response in cats with acute onset of clinical signs and incomplete or unilateral infarction. However, these cats may respond similarly well to conservative therapy, without the risk of reperfusion injury or expense of these agents. Although a severe complete infarction is more likely to develop reperfusion injury

with thrombolytic therapy, these cats are also less likely to recover with conservative therapy alone. The reported survival rates for initial aortic infarction events are similar whether conservative (35%–39%) or thrombolytic (33%) therapy is used. Cats with single limb infarction do much better (68%–93%) than cats with bilateral hindlimb infarction (15%–36%) regardless of therapy used. Aspirin (25 mg/kg, PO, every 48–72 hr; or 5 mg/cat, PO, every 48–72 hr) has historically been the most widely used preventive therapy for cardioembolic disease in cats. Although aspirin appears relatively safe in cats (up to 20% GI adverse effects) and is inexpensive unless compounding is done, the antiplatelet efficacy of aspirin in cats has been called into question, and currently there is no evidence that aspirin prevents first-time or recurrent cardioembolism. Clopidogrel may be a more effective antiplatelet drug in this species.

Clopidogrel (18.75 mg/cat/day, PO) inhibits both primary and secondary platelet aggregation. These effects are more potent than those induced by aspirin. Clopidogrel also impairs the platelet-release reaction, decreasing the release of pro-aggregating and vasoconstrictive agents. Adverse effects are rare but can include vomiting in up to 10% of cats; this appears to be ameliorated by giving the drug with food. A combination protocol of aspirin and clopidogrel has been used previously. Although this protocol has not been studied objectively, it seems to be well tolerated despite a theoretical increased risk of bleeding. A multicenter, randomized, prospective study revealed that clopidogrel was associated with a significantly prolonged survival time compared with aspirin in cats that presented with cardiogenic arterial thromboembolism. The time to recurrence of arterial thromboembolism or death in the clopidogrel group was >365 days versus 192 days in the aspirin group.

Warfarin (0.25–0.5 mg/day/cat, PO) has also been used for prevention of primary or secondary cardioemboli. Dosing is adjusted to prolong the prothrombin time to 1.5–1.7 × the pretreatment value. Because warfarin decreases the anticoagulant proteins C and S before reduction in factors II, VII, IX, and X, joint treatment with heparin is recommended for the first 5–7 days of warfarin therapy. Problems with warfarin therapy include large inter- and intra-individual variability, difficult dosing because of tablet size, and bleeding, including fatal hemorrhage. Because of these limitations and lack of objective clinical data demonstrating efficacy, warfarin is not a first-line

antithrombotic for cardioembolic prevention in cats.

The low-molecular-weight heparins (LMWHs) are smaller in size than unfractionated heparin but maintain the ability to inhibit factor Xa, with a greatly reduced inhibition of IIa. The reduced anti-IIa activity translates into a negligible effect on the activated partial thromboplastin time, but measurement of anti-Xa activity can be used to monitor dosing efficacy. Enoxaparin (1–1.5 mg/kg, SC, once or twice daily) and dalteparin (150–170 IU/kg, SC, bid-tid) have both been used in cats. These drugs have been well tolerated with only rare bleeding reported, but objective clinical studies evaluating their efficacy have not been performed. These agents have been frequently combined with clopidogrel in an attempt to provide a more complete antithrombotic effect. This protocol appears to be well tolerated, although some minor bleeding has been seen. Reported recurrence rates for cats receiving some form of antithrombotic prevention are 17%–75%, with a 1-yr recurrence rate of 25%–50%. Long-term median survival times after an initial cardioembolic event have ranged from 51–376 days. Although these numbers may seem daunting, many of these cats can do well. If owners are willing to treat, they should be encouraged to give cats 24–72 hr of supportive care before deciding on euthanasia, unless severe infarction, severe CHF, or reperfusion injury are present.

Arterial thrombosis in dogs is most commonly associated with protein-losing nephropathy and neoplasia, though idiopathic thrombosis is also seen. There is very little clinical experience with arterial thromboembolism in dogs, but thrombolytic therapy using streptokinase, urokinase, and tPA have been reported in isolated cases with variable success. There are no clinical trials evaluating the efficacy of antithrombotic therapy for prevention of arterial thromboembolism in dogs, but dosing protocols for aspirin (0.5–5 mg/kg, PO, once or twice daily), clopidogrel (1–3 mg/kg/day, PO), warfarin (0.1–0.22 mg/kg/day, PO), dalteparin (150 IU/kg, SC, bid-tid), enoxaparin (1–1.5 mg/kg, SC, once or twice daily), and rivaroxaban (0.5–1 mg/kg/day, PO) have been reported.

Treatment recommendations for pulmonary embolism in dogs are similar to those for cardioembolic disease in cats. Aspirin (0.5 mg/kg/day, PO) has improved survival in dogs with immune-mediated hemolytic anemia when added to standard immunosuppressive therapy.

DIGESTIVE SYSTEM INTRODUCTION

The digestive tract includes the oral cavity and associated organs (lips, teeth, tongue, and salivary glands), the esophagus, the forestomachs (reticulum, rumen, omasum) of ruminants and the true stomach in all species, the small intestine, the liver, the exocrine pancreas, the large intestine, and the rectum and anus. Gut-associated lymphoid tissue (tonsils, Peyer's patches, diffuse lymphoid tissue) is distributed along the GI tract. The peritoneum covers the abdominal viscera and is involved in many GI diseases. Fundamental efforts to manage GI disorders should always be directed toward localizing disease to a particular segment and determining a cause. A rational therapeutic plan can then be formulated.

Function

The primary functions of the GI tract include prehension of feed and water; mastication, ensalivation, and swallowing of feed; digestion of feed and absorption of nutrients; maintenance of fluid and electrolyte balance; and evacuation of waste products. There are four primary functions—digestion, absorption, motility, and evacuation—and, correspondingly, four primary modes of dysfunction.

Normal GI tract motility involves peristalsis, muscle activity that moves ingesta from the esophagus to the rectum; segmentation movements, which churn and mix the ingesta; and segmental resistance and sphincter tone, which retard aboral

progression of gut contents. In ruminants, these movements are of major importance in normal forestomach function.

Pathophysiology

Abnormal motor function usually manifests as decreased motility. Segmental resistance is usually reduced, and transit rate increases. Motility depends on stimulation via the sympathetic and parasympathetic nervous systems (and thus on the activity of the central and peripheral parts of these systems) and on the GI musculature and its intrinsic nerve plexuses. Debility, accompanied by weakness of the musculature, acute peritonitis, and hypokalemia, produces atony of the gut wall (paralytic ileus). The intestines distend with fluid and gas, and fecal output is reduced. In addition, chronic stasis of the small intestine may predispose to abnormal proliferation of microflora. Such bacterial overgrowth may cause malabsorption by injuring mucosal cells, by competing for nutrients, and by deconjugating bile salts and hydroxylating fatty acids.

Vomiting is a neural reflex act that results in ejection of food and fluid from the stomach through the oral cavity. It is always associated with antecedent events such as premonition, nausea, salivation, or shivering and is accompanied by repeated contractions of the abdominal muscles.

Regurgitation is characterized by passive, retrograde reflux of previously swallowed material from the esophagus, stomach, or rumen. In diseases of the esophagus, swallowed material may not reach the stomach.

One of the major consequences of subnormal motility is distention with fluid and gas. Much of the accumulated fluid is saliva and gastric and intestinal juices secreted during normal digestion. Distention causes pain and reflex spasm of adjoining gut segments. It also stimulates further secretion of fluid into the lumen of the gut, which exacerbates the condition. When the distention exceeds a critical point, the ability of the musculature of the wall to respond diminishes, the initial pain disappears, and paralytic ileus develops in which all GI muscle tone is lost.

Dehydration, acid-base and electrolyte imbalance, and circulatory failure are major consequences of GI distention. Accumulation of gut fluids stimulates additional secretion of fluids and electrolytes in the anterior segments of the intestine, which can worsen the abnormalities and lead to shock.

Abdominal pain associated with GI disease usually is caused by stretching of

the intestinal wall. Contraction of the gut causes pain by direct and reflex distention of neighboring segments. Spasm, an exaggerated segmenting contraction of one section of intestine, results in distention of the immediately anterior segment when a peristaltic wave arrives. Other factors that may cause abdominal pain include edema and failure of local blood supply, eg, in local embolism or twisting of the mesentery.

Specific diseases cause diarrhea by varied and characteristic mechanisms, the recognition of which is useful in understanding, diagnosing, and managing GI diseases. The major mechanisms of diarrhea are increased permeability, hypersecretion, and osmosis. Disorders of motility are often secondary. In healthy animals, water and electrolytes continuously transfer across the intestinal mucosa. Secretions (from blood to gut) and absorptions (from gut to blood) occur simultaneously. In clinically healthy animals, absorption exceeds secretion, ie, there is net absorption. Inflammation in the intestines can be accompanied by an increase in "pore size" in the mucosa, permitting increased flow through the membrane ("leak") down the pressure gradient from blood to the intestinal lumen. If the amount exuded exceeds the absorptive capacity of the intestines, diarrhea results. The size of the material that leaks through the mucosa varies, depending on the magnitude of the increase in pore size. Large increases in pore size permit exudation of plasma protein, resulting in protein-losing enteropathies (eg, lymphangiectasia in dogs, paratuberculosis in cattle, nematode infections). Greater increases in pore size result in the loss of RBCs, producing hemorrhagic diarrhea (eg, hemorrhagic gastroenteritis, parvovirus infection, severe hookworm infection).

Hypersecretion is a net intestinal loss of fluid and electrolytes that is independent of changes in permeability, absorptive capacity, or exogenously generated osmotic gradients. Enterotoxic colibacillosis is an example of diarrheal disease due to intestinal hypersecretion; enterotoxigenic *Escherichia coli* produce enterotoxin that stimulates the crypt epithelium to secrete fluid beyond the absorptive capacity of the intestines. The villi, along with their digestive and absorptive capabilities, remain intact. The fluid secreted is isotonic, alkaline, and free of exudates. The intact villi are beneficial because a fluid (administered PO) that contains glucose, amino acids, and sodium is absorbed, even with hypersecretion.

Osmotic diarrhea is seen when inadequate absorption results in a collection of solutes in the gut lumen, which cause water to be retained by their osmotic activity. It develops in any condition that results in nutrient malabsorption or maldigestion or when an animal ingests a large amount of osmotically active substances that are not absorbed, eg, an overeating puppy.

Malabsorption (*see* p 353 and *see* p 373) is failure of digestion and absorption due to some defect in the villous digestive and absorptive cells, which are mature cells that cover the villi. Several epitheliotropic viruses directly infect and destroy the villous absorptive epithelial cells or their precursors, eg, coronavirus, transmissible gastroenteritis virus of piglets, and rotavirus of calves. Feline panleukopenia virus and canine parvovirus destroy the crypt epithelium, which results in failure of renewal of villous absorptive cells and collapse of the villi; regeneration is a longer process after parvoviral infection than after viral infections of villous tip epithelium (eg, coronavirus, rotavirus). Intestinal malabsorption also may be caused by any defect that impairs absorptive capacity, such as diffuse inflammatory disorders (eg, lymphocytic-plasmacytic enteritis, eosinophilic enteritis) or neoplasia (eg, lymphosarcoma).

Other examples of malabsorption include defects of pancreatic secretion that result in maldigestion. Rarely, because of failure to digest lactose (which, in large amounts, has a hyperosmotic effect), neonatal farm animals or pups may have diarrhea while they are being fed milk. Reduced secretion of digestive enzymes at the surface of villous tip cells is characteristic of epitheliotropic viral infections recognized in farm animals.

The ability of the GI tract to digest food depends on its motor and secretory functions and, in herbivores, on the activity of the microflora of the forestomachs of ruminants, or of the cecum and colon of horses and pigs. The flora of ruminants can digest cellulose; ferment carbohydrates to volatile fatty acids; and convert nitrogenous substances to ammonia, amino acids, and protein. In certain circumstances, the activity of the flora can be suppressed to the point that digestion becomes abnormal or ceases. Incorrect diet, prolonged starvation or inappetence, and hyperacidity (as occurs in engorgement on grain) all impair microbial digestion. The bacteria, yeasts, and protozoa also may be adversely affected by the oral administration of drugs that

are antimicrobial or that drastically alter the pH of rumen contents.

Clinical Findings of GI Disease

Signs of GI disease include excessive salivation, diarrhea, constipation or scant feces, vomiting, regurgitation, GI tract hemorrhage, abdominal pain and distention, tenesmus, shock and dehydration, and suboptimal performance. The location and nature of the lesions that cause malfunction often can be determined by recognition and analysis of the clinical findings. In addition, abnormalities of prehension, mastication, and swallowing usually are associated with diseases of the oral mucosa, teeth, mandible or other bony structures of the head, pharynx, or esophagus. Vomiting is most common in single-stomached animals and usually is due to gastroenteritis or nonalimentary disease (eg, uremia, pyometra, endocrine disease). The vomitus in a dog or cat with a bleeding lesion (gastric ulcer or neoplasm) may contain frank blood or have the appearance of coffee grounds. Horses and rabbits do not vomit. Regurgitation may signify disease of the oropharynx or esophagus and is not accompanied by the premonitory signs seen with vomiting.

Large-volume, fluid diarrhea usually is associated with hypersecretion (eg, in enterotoxigenic colibacillosis in newborn calves) or with malabsorptive (osmotic) effects. Blood and fibrinous casts in the feces indicate a hemorrhagic, fibrinonecrotic enteritis of the small or large intestine, eg, bovine viral diarrhea, coccidiosis, salmonellosis, or swine dysentery. Black, tarry feces (melena) indicate hemorrhage in the stomach or upper part of the small intestine. Tenesmus of GI origin usually is associated with inflammatory disease of the rectum and anus.

Small amounts of soft feces may indicate a partial obstruction of the intestines. Abdominal distention can result from accumulation of gas, fluid, or ingesta, usually due to hypomotility (functional obstruction, adynamic paralytic ileus) or to a physical obstruction (eg, foreign body or intussusception). Distention may, of course, result from something as direct as overeating. A "ping" heard during auscultation and percussion of the abdomen indicates a gas-filled viscus. A sudden onset of severe abdominal distention in an adult ruminant usually is due to ruminal tympany. Ballottement and succussion may reveal fluid-splashing sounds when the rumen or bowel is filled with fluid. Varying degrees of dehydration and acid-base and

electrolyte imbalance, which may lead to shock, are seen when large quantities of fluid are lost (eg, in diarrhea or sequestered in intestinal obstruction) or in gastric or abomasal volvulus.

Abdominal pain is due to stretching or inflammation of the serosal surfaces of abdominal viscera or the peritoneum; it may be acute or subacute, and its manifestation varies among species. In horses, acute abdominal pain is common (see p 248). Subacute pain is more common in cattle and is characterized by reluctance to move and by grunting with each respiration or deep palpation of the abdomen. Abdominal pain in dogs and cats may be acute or subacute and is characterized by whining, meowing, and abnormal postures (eg, outstretched forelimbs, the sternum on the floor, and the hindlimbs raised). Abdominal pain may be difficult to localize to a particular viscus or organ within the abdomen.

Examination of the GI Tract

A complete, accurate history and routine clinical examination can often determine the diagnosis. In outbreaks of GI tract disease in farm animals, the history and epidemiologic findings are of prime importance. In small animals, travel history or other details such as recent adoption from a shelter or recent kenneling or exposure to other animals in dog parks might give clinical suspicion to certain infectious diseases. If the history and epidemiologic and clinical findings are consistent with GI disease, the lesion should be localized within the system, and the type of lesion and its cause determined.

The abnormality may sometimes be localized to the large or small intestine by history, physical examination, and fecal characteristics (see TABLE 1). The distinction is important because it narrows the

differential diagnoses and determines the direction of further investigation. However, the clinician should appreciate that in some instances the disorder can involve the entire bowel, with one set of localizing signs overshadowing the other.

The clinical and laboratory techniques and their applications include the following: 1) visual inspection of the oral cavity and of the contour of the abdomen for distention or contraction; 2) palpation through the abdominal wall or per rectum to evaluate shape, size, and position of abdominal viscera; 3) abdominal percussion to detect "pings," which suggest gas-filled viscera; 4) auscultation to determine the intensity, frequency, and duration of GI movements, as well as fluid-splashing sounds associated with fluid-filled stomachs and intestines and fluid-rushing sounds associated with diarrheal disease; 5) succussion to reveal fluid-splashing sounds; 6) ballottement to evaluate density and size of abdominal organs by their movement away from and back to the abdominal wall; and 7) gross examination of feces to assess bulk, consistency, color, and presence of mucus, blood, or undigested food particles.

Microscopic studies include examination for parasites. Cytology of a rectal or colonic mucosal smear stained with new methylene blue or Wright stain for fecal leukocytes is useful to detect inflammatory bowel disease or the presence of intracellular fungal organisms in the case of infection with *Histoplasma capsulatum*. The following may be useful (or necessary): 1) bacterial culture and virus isolation; 2) endoscopy to visualize the mucosal surface of the esophagus, stomach, duodenum, colon, and rectum; 3) abdominocentesis to collect fluid from distended viscera or from the peritoneal cavity for examination; 4) radiography (contrast) to diagnose obstructive disease; 5) abdominal ultra-

TABLE 1

DIFFERENTIATION OF SMALL-INTESTINAL FROM LARGE-INTESTINAL DIARRHEA

Clinical Sign	Small Intestine	Large Intestine
Frequency of defecation	Normal or slightly increased	Very frequent
Fecal volume	Normal to increased	Decreased
Urgency	Absent	Usually present
Tenesmus	Absent	Usually present
Mucus in feces	Usually absent	Frequent
Blood in feces	Dark black (melena)	Red (fresh)
Weight loss	May be present	Rare

sonography to evaluate the wall thickness of the stomach and intestines and to detect abdominal masses, intussusceptions, and mesenteric lymphadenopathy in small animals, and to investigate abdominal disorders in horses and cows; 6) biopsy (endoscopic, laparoscopic, ultrasound-guided, surgical) to obtain samples for microscopic examination (samples of intestines and liver are useful to diagnose chronic enteritis and liver disease); and 7) tests for digestion and absorption to estimate and differentiate malabsorption and maldigestion. Common absorption tests include the measurement of the serum concentrations of cobalamin (vitamin B₁₂) and folate. In addition, in small animals, an increased serum folate concentration in conjunction with a decreased cobalamin is consistent with antibiotic-responsive diarrhea. Exocrine pancreatic function can be evaluated by the determination of serum trypsin-like immunoreactivity and by measurement of serum canine and feline

pancreas-specific lipase, which are sensitive and specific markers for the diagnosis of pancreatitis; laparotomy and biopsy may be indicated in cases in which the diagnosis is not clear or in which surgical correction may be required.

INFECTIOUS DISEASES

The GI tract is subject to infection by many pathogens, which are a major cause of economic loss due to illness, suboptimal performance, and death (see TABLE 2). These infections spread by direct contact or the fecal-oral route. Many of the pathogens are part of the normal intestinal flora, and disease develops only after a stressful event, eg, salmonellosis in horses after transportation, extended anesthesia, or surgery. The intestinal flora becomes established within a few hours after birth, which emphasizes the importance of the early ingestion of colostrum to provide protection against septicemia and intestinal infection.

TABLE 2 COMMON PATHOGENS OF THE GASTROINTESTINAL TRACT

Pathogen	Cattle, Sheep, and Goats	Pigs
Viruses	Bovine viral diarrhea, rotavirus, coronavirus, rinderpest, malignant catarrhal fever, bluetongue, foot-and-mouth disease	Transmissible gastroenteritis, porcine circovirus type II, porcine epidemic diarrhea virus, rotavirus, foot-and-mouth disease, vesicular stomatitis, vesicular exanthema
Rickettsiae		
Bacteria	Enterotoxigenic <i>Escherichia coli</i> , <i>Salmonella</i> spp, <i>Mycobacterium paratuberculosis</i> , <i>Fusobacterium necrophorum</i> , <i>Clostridium perfringens</i> (types B, C, and D), <i>Actinobacillus lignieresii</i> , <i>Yersinia enterocolitica</i> , <i>Campylobacter jejuni</i>	Enterotoxigenic <i>E coli</i> , <i>Salmonella</i> spp, <i>Brachyspira hyodysenteriae</i> , <i>Clostridium perfringens</i> types B and C, <i>Lawsonia intracellularis</i> , <i>Clostridium difficile</i>
Protozoa	<i>Eimeria</i> spp, <i>Cryptosporidium</i> spp	<i>Eimeria</i> spp, <i>Isospora suis</i>
Fungi	<i>Candida</i> spp (cattle)	<i>Candida</i> spp
Algae	<i>Prototheca</i> spp	<i>Prototheca</i> spp
Parasites (helminths)	See GASTROINTESTINAL PARASITES OF RUMINANTS, p 303.	See GASTROINTESTINAL PARASITES OF PIGS, p 320.

Definitive etiologic diagnosis of infectious disease of the GI tract depends on demonstrating the pathogen in the tract or in the feces of the affected animal. In herd epidemics, such as an outbreak of acute undifferentiated diarrhea in newborn calves or piglets, the best opportunity to establish a diagnosis is in the earliest stage of the disease by selecting untreated animals and submitting them for necropsy and detailed microbiologic examination of the intestinal flora. When selective necropsy is not an option, a series of carefully collected daily fecal samples should be submitted to a diagnostic laboratory with a request for special culture techniques, depending on the infectious disease suspected. Molecular technologies, including ELISA and PCR, have been developed to demonstrate the presence of viral, bacterial, or protozoal proteins or nucleic acids within the feces, which can provide a definitive diagnosis

(eg, canine parvovirus, salmonellosis, cryptosporidiosis).

Overview of Gastrointestinal Parasitism

The GI tract may be inhabited by many species of parasites. Their cycles may be direct, in which eggs and larvae are passed in the feces and stadial development occurs to the infective stage, which is then ingested by the final host. Alternatively, the immature stages may be ingested by an intermediate host (usually an invertebrate) in which further development occurs, and infection is acquired when the intermediate host or free-living stage shed by that host is ingested by the final host. Sometimes, there is no development in the intermediate host, in which case it is known as a transport or paratenic host, depending on whether the larvae are encapsulated or in the tissues. Clinical parasitism depends on the number and pathogenicity of the parasites, which

TABLE 2

COMMON PATHOGENS OF THE GASTROINTESTINAL TRACT (continued)

Horses	Dogs and Cats
Rotavirus, vesicular stomatitis, coronavirus	Canine parvovirus, canine coronavirus, feline panleukopenia virus, feline enteric coronavirus, canine and feline rotaviruses, canine and feline astroviruses
<i>Neorickettsia risticii</i> (Potomac horse fever [equine monocytic ehrlichiosis])	<i>Neorickettsia helminthoeca</i> (salmon poisoning in dogs)
Enterotoxigenic <i>E coli</i> , <i>Salmonella</i> spp, <i>Rhodococcus equi</i> , <i>Actinobacillus equuli</i> , <i>Clostridium perfringens</i> types B and C, <i>Clostridium difficile</i> , <i>Lawsonia intracellularis</i>	<i>Salmonella</i> spp, <i>Yersinia enterocolitica</i> , <i>Campylobacter jejuni</i> , <i>Clostridium</i> spp, <i>Clostridium piliforme</i> , <i>Mycobacterium</i> spp, <i>Shigella</i> spp, adherent invasive <i>E coli</i> , <i>Brachyspira</i> spp
<i>Eimeria</i> spp, <i>Cryptosporidium</i> spp	<i>Isospora</i> spp, <i>Sarcocystis</i> spp, <i>Besnoitia</i> spp, <i>Hammondia</i> sp, <i>Toxoplasma</i> sp, <i>Giardia</i> sp, <i>Trichostrongylus</i> spp, <i>Entamoeba histolytica</i> , <i>Balantidium coli</i> , <i>Cryptosporidium</i> spp, <i>Neospora</i> sp
<i>Aspergillus fumigatus</i>	<i>Histoplasma capsulatum</i> , <i>Aspergillus</i> spp, <i>Candida albicans</i> , phicomycetes
<i>Prototheca</i> spp	<i>Prototheca</i> spp
See GASTROINTESTINAL PARASITES OF HORSES, p 315.	See GASTROINTESTINAL PARASITES OF SMALL ANIMALS, p 412.

depend on the biotic potential of the parasites or, when appropriate, their intermediate host and the climate and management practices. In the host, resistance, age, nutrition, and concomitant disease also influence the course of parasitic infection. The economic importance of subclinical parasitism in farm animals is also determined by the above factors, and it is well established that lightly parasitized animals that show no clinical evidence of disease perform less efficiently in the feedlot, dairy, or finishing house.

Feed conversion in light to moderate parasitism is adversely affected and is primarily due to reduced appetite and poor use of absorbed protein and energy. Carcass quality and size also are reduced, which further reduce financial returns. Endoparasites of companion animals can cause severe disease or unthriftiness and are aesthetically undesirable. Furthermore, some of these parasites also infect people.

Because parasitism is easily confused with other debilitating conditions, diagnosis depends heavily on the seasonal character of parasitic infection; previous farm history; and examination of feces for evidence of oocysts, worm eggs, or larvae. Increased serum pepsinogen levels can support the diagnosis of some abomasal infections, as can increased serum liver enzymes for liver fluke infection. ELISA are being used, and other serologic (including monoclonal antibody) techniques are under development; serodiagnosis will likely be used more frequently as the specificity of the tests improves. These tests should be particularly useful in companion animals harboring parasites incriminated in zoonoses.

Advances in epidemiology (particularly regarding factors affecting seasonal development of the free-living stages and their survival), coupled with the discovery of highly efficient broad-spectrum anthelmintics, have made successful treatment and control of GI parasites both possible and practical. Response to therapy is usually rapid, and single treatments usually suffice unless reinfection occurs or the lesions are particularly severe. Preventive control in large animals is generally achieved by integrating grassland management with the use of anthelmintics. Improved methods of administering anthelmintics (eg, the pour-on method or sustained or pulsed-release devices) have also helped. Strategies to prevent parasitism and related production losses are part of any modern herd-health, flock, or stud program. Similar preventive programs are equally important in controlling parasitism

in pet animals. Control by vaccination is limited to lungworms; vaccine for cattle is available in several European countries, and vaccine for sheep is available in parts of eastern Europe and in the Middle East.

To estimate parasite load, see p 1620.

Treatment of Infectious Diseases

Antimicrobial agents are used for the treatment of bacterial diseases, and anthelmintics for parasitic diseases. There is no specific therapy for treatment of viral diseases. Antimicrobials are commonly given PO daily for several days until recovery is apparent, but there is little objective evidence of efficacy. There is evidence that overdosage or prolonged oral treatment may be detrimental (eg, bacterial overgrowth, villous atrophy). Parenteral administration of antimicrobials is indicated when septicemia is apparent or may occur. The choice of antimicrobial agent depends on the suspected disease, previous results, and cost. In herd epidemics, antimicrobials may be added to the feed or water supplies at therapeutic levels for several days, followed by preventive levels for an extended period, depending on the infection pressure in the population. The feed and water supplies of in-contact animals also may be medicated in an attempt to prevent new cases from developing. (See also SYSTEMIC PHARMACOTHERAPEUTICS OF THE DIGESTIVE SYSTEM, p 2544.)

Control of Infectious Diseases

Effective control of the common infectious diseases of the GI tract depends on practicing good sanitation and hygiene, developing and maintaining nonspecific resistance in the animal, and in certain cases, providing specific immunity by vaccinating the pregnant dam or susceptible animal.

Effective sanitation and hygiene is achieved primarily by providing adequate space for animals and by regular cleaning of pens and efficient removal of manure from the immediate environment. Development and maintenance of nonspecific resistance depends on the genetic selection of animals that have a reasonable degree of inherent resistance and on the provision of adequate nutrition and housing, which minimizes stress and allows the animals to grow and behave normally. The development of infected but clinically healthy animals, which can shed pathogens for weeks or months, is a major problem with some infectious diseases of the GI tract, eg, salmonellosis. Ideally, these carrier animals should be identified by microbiologic means and

isolated from the rest of the herd until free of the infection or culled.

Certain diseases (eg, enterotoxigenic colibacillosis in calves and piglets) can be controlled by vaccination of the pregnant dam several weeks before parturition. This method depends on achieving a protective level of antibodies in the colostrum. There are exceptions but, in most cases, systemic immunity provides little protection against the infectious enteritides; effective immunity against GI disease depends on stimulation of local intestinal immunity after the neonatal period. During the neonatal period, protection can be provided through the local action of maternally derived antibodies. For example, secretory IgA progressively increases in sow's milk from the time of farrowing until weaning, which provides the piglet with daily protection during the nursing period.

NONINFECTIOUS DISEASES

The major causes of noninfectious disease of the GI tract include dietary overload or indigestible feeds, chemical or physical agents, obstruction of the stomach and intestines caused by the ingestion of foreign bodies or by any physical displacement or injury to the GI tract that interferes with the flow of ingesta, enzyme deficiencies, abnormalities of the mucosa that interfere with normal function (eg, gastric ulcers, inflammatory bowel disease, villous atrophy, neoplasms), and congenital defects. GI manifestations such as vomiting and diarrhea may develop secondary to systemic or metabolic diseases such as uremia, liver disease, and hypoadrenocorticism. The causes are uncertain in several diseases, including abomasal ulcers in cattle, gastric ulcers in pigs and foals, gastric torsion in dogs, and acute intestinal obstruction and displacement of the abomasum in cattle. In noninfectious diseases of the GI tract, usually only a single animal is affected at one time; exceptions are diseases associated with excessive feed intake or poisons, in which herd outbreaks are common.

PRINCIPLES OF THERAPY

See also SYSTEMIC PHARMACOTHERAPEUTICS OF THE DIGESTIVE SYSTEM, p 2544, and THE RUMINANT DIGESTIVE SYSTEM, p 2561. Although eliminating the cause of the disease is the primary objective, the major part of treatment is supportive and symptomatic, aimed at relieving pain, correcting abnormalities, and allowing healing to occur.

Elimination of the primary cause may involve antimicrobials, coccidiostats, antifungal agents, anthelmintics, antidotes for poisons, or surgical correction of displacements.

Correction of excessive or depressed motility appears rational, but often the nature and degree of abnormal motility are uncertain; in addition, available drugs may not give consistent results. There is little clinical evidence to recommend the routine use of anticholinergic or opioid drugs to slow intestinal transit. Slowing intestinal transit may be counterproductive to the defense mechanism of diarrhea, which acts to evacuate harmful organisms and their toxins. In general, anticholinergic drugs probably are justified only for short-term symptomatic relief of pain and tenesmus associated with inflammatory diseases of the colon and rectum. In some disorders of gastric or colonic motility, prokinetic drugs (eg, metoclopramide, erythromycin) may be useful.

Replacement of fluid and electrolytes is necessary when dehydration and electrolyte and acid-base imbalance occur as in diarrhea, persistent vomiting, intestinal obstruction, or torsion of the stomach(s), in which large amounts of fluid and electrolytes are sequestered.

Relief of distention medically by stomach tube (as in bloat in ruminants) or surgically (as in acute intestinal obstruction, or in torsion of the abomasum in ruminants or of the stomach in monogastric animals) may be required. The GI tract may become distended with gas, fluid, or ingesta at any level due to physical or functional obstruction.

Relief of abdominal pain by administration of analgesics should be done when the pain is reflexly affecting other body systems (eg, cardiovascular collapse) or when it is causing the animal to injure itself because of rolling, kicking, or throwing itself. Animals treated with analgesics must be monitored regularly to ensure that the relief of pain does not provide a false sense of security; the lesion may be progressively worsening while the animal is under the influence of the analgesic.

Reconstitution of ruminal flora should be done in situations in which the ruminal flora may be seriously depleted (eg, in prolonged anorexia or acute indigestion). Transfauna-tion (ruminal fluid transfer; *see* p 2562) involves oral administration of ruminal contents from a healthy animal that contains rumen bacteria and protozoa and volatile fatty acids.

CONGENITAL AND INHERITED ANOMALIES OF THE DIGESTIVE SYSTEM

MOUTH

Congenital Oronasal Fistulas (Cleft Palate and Cleft Lip): Congenital oronasal fistulas are the result of failure of fusion of the palatine shelves during gestation (which occurs at 25–28 days of gestation in dogs). Clefts can be either of the primary palate (involving the lip and incisive bone) causing cleft lip (harelip), or of the secondary palate (involving the hard and soft palate) causing cleft palate. The conditions can occur singly or together. In dogs, CT studies have shown association of cleft palate with other craniofacial abnormalities, including hypoplastic tympanic bullae, hypoplastic nasal turbinates, and maxillary malocclusions, mostly of the incisors. Neurologic examination should be performed in affected animals, because concurrent hydrocephalus has also been described. Animals are typically diagnosed at, or shortly after, birth by oral examination, by observation of dysphagia or milk from the nares after nursing, and/or by respiratory compromise and aspiration pneumonia. Many affected neonates are euthanized or die early in life.

Cleft palate and cleft lip have been described in most domesticated animal species, including dogs, cats, ruminants, horses, and camelids. In dogs, brachycephalic breeds are overrepresented, with up to 30% risk factor. Other breeds with higher incidence include Beagles, Cocker Spaniels, Dachshunds, German Shepherds, Labrador Retrievers, Schnauzers, Old Spanish Pointers, and Shetland Sheepdogs. The most commonly affected cat breed is the Siamese. Etiologies include genetic, teratogenic, and nutritional causes. Modes of inheritance are monogenic autosomal recessive or incomplete dominant in several breeds. In Brittaney Spaniels, Pyrenean Shepherds, Beagles, Old Spanish Pointers, and Boxers, it is believed to be an autosomal recessive trait, whereas in Bulldogs (French and English) and Shih Tzus, an autosomal dominant with incomplete penetrance mode of inheritance is suspected. Autosomal recessive inheritance patterns are seen in Angus cattle with arthrogryposis multiplex, in Charolais cattle with cleft palate and arthrogryposis, and in

Texel sheep with cleft lip. Teratogens and nutritional causes during pregnancy include high levels of vitamin A in the diet, administration of griseofulvin, folic acid deficiency, and ingestion of toxic plants. In cattle, ingestion of lupine during days 40–100 of gestation results in arthrogryposis and cleft palate, due to the effects of anagrine found in *Lupinus sericeus* and *L. caudatus*. Ingestion of poison hemlock (*Conium maculatum*), which contains the toxic principle coniine, results in similar signs in both cattle and goats, whereas ingestion of *Veratrum californicum* in sheep, goats, and cattle all result in cleft lip and/or palate in the fetus.

For puppies and kittens in which euthanasia is not elected, medical management is required until surgical options are explored. Animals are fed via orogastric intubation until dry food can be tolerated. Water can be offered by overhead dispenser. A custom-molded palate guard has been described in experimental settings to allow adult dogs to eat and drink normally. Aspiration pneumonia should be quickly identified and treated. Surgical correction is recommended after at least 12 wk of age, although some studies have shown higher success when performed at >20 wk, or as adults. Surgical correction has a high failure rate because of continued growth of puppies or kittens postoperatively, the size of the patient, and irritation of the surgery site by the tongue and feed material. Surgical techniques depend on the location and size of the cleft defect. For secondary palate defects, sliding mucoperiosteal flaps or overlapping flaps are most commonly used.

Extensive involvement of the soft palate carries a poor prognosis, even with surgical intervention. Surgical repair should be attempted only after ethical questions have been addressed, and the affected animal should be surgically sterilized or removed from breeding stock to prevent reproducing the anomaly in future offspring.

Occlusal Anomalies: Occlusal abnormalities due to abnormal lengths of the maxilla and mandible are common in animals. **Brachygnathia**, also called overbite, overshot, overjet, short lower jaw, or parrot mouth in horses, is manifest when

the mandible is shorter than the maxilla. It can be found, with varying severity and incidence, in all species of animals and is diagnosed by oral examination. In Red Angus cattle, it is inherited in a recessive manner through a deletion mutation on chromosome 4, which results in stillborn calves with osteopetrosis (see p 1044), brachygnathism, and impacted molars. In Simmental cattle, brachygnathism can be seen in calves as an autosomal recessive trait, or in combination with trisomy 17, a lethal condition. A lethal, autosomal recessive disorder of Merino sheep results in brachygnathism, cardiomegaly, and renal hypoplasia. Brachygnathism is common in horses, due to either a lengthened maxilla or shortened mandible. Modes of inheritance are unknown. It may occur in utero due to treatment of the mare with griseofulvin. Most horses do not experience dysphagia; however, cheek teeth malocclusions are common, and regular dental care is required. Correction can be attempted in foals via surgical placement of tension band wires around the maxillary incisors to inhibit maxillary growth.

In small animals, mild forms may be of no clinical significance; however, more severe forms may result in trauma to the hard palate or the restriction of normal mandibular growth secondary to erupting adult mandibular canine teeth. Treatment varies from none to various orthodontic or endodontic procedures, depending on severity. The mandibular canine teeth are often removed or a crown reduction procedure performed, with concurrent pulpotomy or root canal. Intervention early in life is recommended and improves both short- and long-term outcomes.

Prognathia, also called undershot, underjet, or monkey or sow mouth in horses, is identified when the mandible is longer than the maxilla. It is diagnosed by oral examination. In brachycephalic dogs and Persian cats, it is considered a normal breed characteristic. In horses, it is more commonly seen in miniature and Arabian breeds. The degree of severity is variable and may not require treatment. In severe cases in foals, surgical placement of tension band wires can allow for continued maxillary growth. The most severe consequences are the result of malocclusions. Affected foals may have difficulty nursing, and older animals may experience difficulty grazing. Cheek teeth malocclusions should be addressed with regular dental care.

Chondrodysplasia, a simple dominant trait of Dexter cattle, is a lethal defect that

can result in "bulldog calves," with severe skeletal malformation and craniofacial dysplasia that has the appearance of prognathism.

Tongue Anomalies: Ankyloglossia, also called "tongue-tie," is a disorder of Anatolian Shepherd dogs characterized by a short, thickened lingual frenulum that inhibits normal movements of the tongue. By unknown mechanism, the normal fetal apoptosis of the cranial $\frac{2}{3}$ of the frenulum does not occur. Clinically, the tongue appears notched or with a "W" shape. Animals may experience dysphagia; difficulty suckling, drinking, or licking; trouble vocalizing; and impendence of panting and therefore thermoregulation. Frenuloplasty is corrective. Breeding of affected animals is not recommended.

Microglossia is a congenital defect characterized by missing or underdeveloped lateral and rostral thin portions of the tongue that result in prehensile and motility disturbances. It is often referred to as "bird tongue" in dogs and may be a component of the fading puppy syndrome, because affected puppies have difficulty nursing and swallowing and can aspirate or quickly become dehydrated. In cattle, excessive salivation has been seen. Even with supportive dietary measures, the prognosis is poor.

Macroglossia, or large tongue, has been described in association with nasopharyngeal dysgenesis in Dachshunds. It has also been seen in double-muscled cattle breeds, such as the Belgian Blue, and can inhibit nursing of calves.

Epitheliogenesis imperfecta is a disorder of the skin in which the epithelium is absent, revealing the dermis. Commonly affected areas include the limbs, back, and oral mucosa and tongue. It is inherited by a simple recessive manner and is well described in cattle and horses, particularly Saddlebreds. Euthanasia is typically elected.

Tight-lip Syndrome of Chinese

Shar-Pei: A small or absent lower anterior lip vestibule is a congenital defect of some Shar-Pei dogs. The lower lip covers the mandibular incisors and canines, disrupting normal occlusion, inhibiting mandibular growth, and leading to the dog biting on the lip (which presents welfare issues). In extreme cases, the mandibular incisors become lingually directed. Surgical correction by chelioplasty has been described using several different mucosal flap techniques. Any animals that have

undergone surgical correction should not be presented for conformation showing and should not be bred.

TEETH

Abnormal Number: Deviation from the dental formula has been seen in several species. Complete lack of development of teeth, or **anodontia**, is rare. **Hypodontia** or **oligodontia** has been described as inherited by a recessive manner in Kerry Blue Terriers and associated with X-linked hypohidrotic ectodermal dysplasia in other breeds. Most cases appear to affect the premolars. **Hyperdontia**, also called polyodontia or supernumerary teeth, is seen most often in the permanent teeth and can affect the incisors, premolars, or molars. Presumably, these teeth arise from overproliferation of the dental lamina during development. Supernumerary teeth tend to cause crowding and malocclusions, which can cause dysphagia, dental disease, and discomfort. In horses, supernumerary incisors are typically not extracted and are managed with regular reduction. For supernumerary cheek teeth, diastema and sinusitis due to oromaxillary sinus fistula formation are possible sequelae. Teeth are either extracted or reduced often to prevent complications.

Irregularities of Shedding: Retention of the deciduous teeth in horses is common. The incisors tend to retain rostrally to the permanent incisors; however, radiographs will help to discern their identity. Incisors retained in other orientations can result in malocclusion and/or displacement of permanent incisors. Retained cheek teeth are called “caps,” which are typically shed as the permanent tooth erupts underneath them. Loose caps can cause discomfort to

the horse, manifest as headshaking, inappetence, quidding, and training issues. Caps can be extracted if they are loose, if the contralateral cap has already been shed, or if there is space between the cap and the permanent tooth below.

Retained deciduous teeth are common in dogs and secondary to the failure of the periodontal ligament to detach from the deciduous tooth, with the permanent canine teeth erupting rostrally. One study showed highest incidence in dogs <2 yr old, with small breeds overrepresented, particularly Toy Poodles. Retention may cause permanent tooth displacement, which can result in malocclusion or food entrapment and subsequent periodontal disease. Therefore, retained deciduous teeth should be removed as soon as possible, taking care not to damage the underlying permanent tooth bud.

Abnormalities in Position, Shape, and Direction:

Displacement or rotation of teeth has been described in many species. In horses, the cheek teeth are affected more commonly than the incisors, with the permanent teeth most often affected rather than the deciduous teeth. Most displacements are due to crowding during eruption. Sequelae include malocclusion, uneven wear and development of sharp points, and diastema with associated feed packing. Treatment includes regular floating of unopposed surfaces, or extraction if severe. Diastema can be addressed by mechanical widening. In dogs, rotation has been described commonly in brachycephalic and large breeds, with the first mandibular premolar or upper third premolar often affected. Abnormally located or directed teeth can result in malocclusions or affect the positioning of adjacent teeth. Extraction can be performed in severely affected animals; many cases are considered incidental findings.

Enamel Lesions: Enamel hypoplasia, hypomineralization, or dysplasia is seen in both large and small animals. Common causes are pyrexia, trauma, malnutrition, toxicosis (eg, fluorosis in cattle), congenital disorders (eg, epitheliogenesis imperfecta in Saddlebred foals), and infections (eg, distemper virus in dogs or bovine viral diarrhea virus in calves) that affect ameloblast and odontoblast activity. Lesions vary, depending on the severity and duration of the insult, from pitted enamel to the absence of enamel with incomplete tooth development. Affected teeth are prone to plaque and tartar accumulation

Retained deciduous incisors in a horse.

and subsequent bacterial penetration and formation of caries. In small animals, resin restoration has been used to cover defects, although diligent dental hygiene and home care is critical to reduce the incidence of complications. Enamel may also develop discoloration. In small animals, administration of tetracyclines to pregnant females or to puppies <6 mo old may result in a permanent brownish yellow discoloration of the teeth. In ruminants, the enamel of some teeth may demonstrate flecks of varying color. The condition is thought to have a genetic etiology but generally is of no clinical significance; however, some believe affected teeth may be prone to more rapid wearing.

CYSTS AND SINUSES OF THE HEAD AND NECK

Congenital cysts, sinuses, or fistulae of the branchial arch apparatus or thyroglossal duct have been reported in horses, dogs, cats, and ruminants, yet are very rare. These structures arise from persistent embryologic pharyngeal pouches, arches, or clefts, or the thyroglossal duct. Animals typically present with nonpainful, fluid-filled masses in the cervical region. Clinical signs are typically due to the space-occupying mass and include dyspnea, respiratory stridor, intermittent esophageal obstruction, and coughing. Animals may present later in life; it is not known why a cyst may suddenly enlarge but may be associated with respiratory infection. Diagnostic imaging includes radiography, ultrasonography, video endoscopy, and contrast CT to determine whether there is communication with the pharynx. **Branchial cysts** (also called lateral cervical cysts) in horses are typically seen on the right side, although a bilateral case has been reported. Surgical excision is curative, although complications include right laryngeal hemiplegia, seroma formation, and pneumonia. Alternatively, some horses have been treated with marsupialization and iodine sclerotherapy with good results. In dogs and cats, few complications have been noted. Embryologic origin of branchial cysts has been mostly of the third pharyngeal pouch, although anatomic location has also suggested origin of the fourth and sixth pouches in some cases.

Thyroglossal duct cysts appear similar in appearance to branchial cysts; differentiation is often made histologically by demonstration of thyroid follicles containing colloid or immunohistochemis-

try for presence of thyroglobulin. These cysts arise from the thyroglossal duct, which in the embryo is present from the base of the tongue to the eventual location of the thyroid and which is normally absent by birth. The cyst is solitary and usually located on ventral midline, although a case of a mediastinal thyroglossal duct cyst with ectopic thyroid tissue was reported in a cat and a case of subepiglottic thyroglossal duct cyst was reported in a dog. It is hypothesized that subepiglottic cysts in horses are also of thyroglossal duct origin and may be associated with epiglottic entrapment. In Damascus goats, thyroglossal duct cysts are heritable by an unknown genetic mechanism. Aspiration of the cyst for measurement of thyroxine has not been reliably diagnostic. Surgical resection is curative.

In horses, congenital cystic lesions of the esophagus are typically of two types: **intramural inclusion cysts** and **esophageal duplication cysts**. Both have been described in yearling horses that presented for recurrent choke, dysphagia, and aspiration pneumonia. Both occur in the cervical esophagus and result in compression of the esophageal lumen and its function. Diagnosis is aided by imaging, including video endoscopy, contrast radiography, and ultrasonography. Described treatments include surgical resection and marsupialization with sclerotherapy. Complications after excision have included left laryngeal hemiplegia and esophageal fistula formation. Histologically, esophageal duplication cysts include a layer of muscle, whereas inclusion cysts contain only keratinized squamous epithelium.

Heterotopic polyodontia, or teeth outside the dental arcade, includes both dentigerous cysts, which have been described in most domestic animal species, and the **ear teeth**, or temporal teratoma, of horses. **Dentigerous cysts** contain all or part of at least one tooth (including the crown). The cysts are lined by epithelium and often cause facial swelling or draining tracts, if fistulated. In horses, dentigerous cysts are often seen in association with the wolf teeth or canine teeth of mares; in dogs, commonly of the brachycephalic breeds, with the mandibular first premolars; and in sheep, with the mandibular incisors. They may be bilateral.

Surgical removal of the cyst(s) is required, with definitive diagnosis based on subsequent histopathologic examination. Curettage of extremely large cysts with compromise of the mandible may require bone grafts.

ESOPHAGUS

Clinically significant esophageal disorders generally manifest themselves as swallowing dysfunction and regurgitation, especially when puppies or kittens are weaned and begin to eat solid food. These disorders, found predominantly in small animals, can be classified as congenital megaesophagus, vascular ring entrapment anomalies, and achalasia. **Congenital megaesophagus** is thought to result from developmental anomalies in esophageal neuromuscular innervation that controls dilation and peristalsis. In dogs, incidence is increased in Chinese Shar-Pei, Fox Terriers, German Shepherds, Great Danes, Irish Setters, Labrador Retrievers, Miniature Schnauzers, and Newfoundlanders. In Fox Terriers, it is an autosomal recessive trait, whereas in Miniature Schnauzers, it is autosomal dominant. It is also seen in Siamese cats and Friesian horses. Megaesophagus may also be a component of a more diffuse congenital neuropathy, such as congenital myasthenia gravis. A laryngeal paralysis-polyneuropathy complex that often includes megaesophagus has been reported in Dalmatians and Pyrenees Mountain Dogs. Secondary megaesophagus may develop in association with hypoadrenocorticism, neoplasia, or GI or neuromuscular disorders. **Vascular ring anomalies** occur due to errors in development of the third, fourth, or sixth aortic arch and result in entrapment of the thoracic esophagus and trachea, which lead to the clinical signs. They have been described in dogs, cats, horses, cattle, and camelids. The most common anomaly is persistent right aortic arch, but aberrant right and left subclavian arteries, right ligamentum arteriosum, and double aortic arch have also been reported. In dogs, Boston Terriers, German Shepherds, and Irish Setters have higher breed incidences. In cats, a report associated persistent right aortic arch with axial skeletal abnormalities. Advanced imaging, including 3-D CT, is useful for diagnosis of specific anomalies and surgical planning. **Cricopharyngeal achalasia** is a failure of the upper esophageal sphincter (specifically, the cricopharyngeal muscle) to relax during swallowing, thereby preventing the normal passage of a food bolus from the caudal pharynx to the cranial esophagus. Cocker and Springer Spaniels appear to be at increased risk. Treatment of congenital achalasia is cricopharyngeal myectomy. Acquired achalasia is treated by addressing the inciting cause and implementing dietary management. **Lower**

esophageal sphincter achalasia is considered to be a component of a more generalized esophageal motor disturbance (ie, megaesophagus) and no longer a distinct entity.

Diagnosis of an esophageal disorder is generally based on characteristic clinical signs (eg, regurgitation, ptyalism, dysphagia, aspiration pneumonia) and contrast imaging. Radiography may identify a distended, gas-filled esophagus, or fluoroscopy may identify alterations in esophageal peristalsis and swallowing. Diagnosis of the specific underlying etiology may require further testing, such as endoscopy, endocrine function testing, and elimination of myasthenia gravis. Treatment is directed at the primary etiology. Some mildly affected animals may improve over time; however, in general the prognosis is poor. Aspiration pneumonia is a frequent and often lethal complication. Frequent, elevated feedings of small quantities of a highly digestible, soft diet may be helpful. For horses, feeding a mash at chest height or full-time pasture grazing have been suggested. Owner compliance is essential for successful management. Surgical correction of vascular ring anomalies had an overall survival rate of 72% in dogs in one study, whereas all horses and camelids died or were euthanized in others. In dogs, only 30% were free of clinical signs after surgery. Persistent clinical signs included regurgitation and aspiration pneumonia. Dietary modification is often required for life.

Esophageal diverticula may involve the cervical esophagus just cranial to the thoracic inlet or be epiphrenic (just cranial to the diaphragm). Small diverticula may not cause any clinical signs. In more severe cases, clinical signs may include impaction, esophagitis, and rarely rupture and pyothorax. Treatment (if necessary) is by surgical resection. Esophageal diverticulae just cranial to the thoracic inlet may be seen in English Bulldogs due to thoracic shortening and external compression of the esophagus by other thoracic structures.

HERNIAS

A true hernia is defined as having a hernia ring, sac, and contents. Hernias of the abdominal wall are common in all domestic species and include umbilical hernias and inguinal or scrotal hernias. Hernias may be direct (through a rent in the body wall) or indirect (through an already existing ring, such as the inguinal ring or umbilical ring). Congenital hernias tend to be indirect, although direct, traumatic hernias may arise

during dystocia or obstetrical manipulations. **Umbilical hernias** vary in size and may contain only fat or omentum, or in more severe cases, intestinal loops. In dogs, Weimaraners, Pekingese, Basenjis, and Airedale Terriers are overrepresented. In many cases, umbilical hernia is seen in dogs with concurrent cryptorchidism. Hereditary etiology is suspected but not proved. In cattle, the Holstein Friesian breed is overrepresented. Diagnosis in all animals is by observation of the hernia sac, palpation, ultrasonography, and possibly radiographs. Surgical closure of the body wall defect is indicated in most cases to reduce risk of future intestinal incarceration.

Inguinal or scrotal hernias are common in pigs, horses (particularly draft breeds and warmbloods), and many breeds of dogs and are suspected to be hereditary. Inguinal hernias can occur in bitches and may involve the uterus. Clinical signs vary from nonpainful inguinal or scrotal swelling to acute colic in horses or vomiting in dogs, particularly if the small intestine is strangulated. In horses, palpation per rectum can diagnose intestinal loops in the vaginal ring, which can be gently removed to provide relief before transport to a surgical facility. Any devitalized bowel is resected via midline celiotomy. In stallions, testis-sparing laparoscopic closure of the inguinal rings has been performed in both standing and recumbent horses with good outcome and subsequent fertility. In foals and calves, medical management through reduction of the hernia and placement of a figure-eight bandage has been successful in some cases. Hernias that do not spontaneously resolve early in life should be surgically corrected to prevent later complications.

Hernias between the abdominal and thoracic cavities that involve the diaphragm are of several types and can be congenital or acquired (traumatic) in origin. Congenital **pleuroperitoneal hernias** have been described in small animals, horses, and calves. In horses, a specific type of hernia, a retrosternal or Morgani hernia, has been described in which a hernial sac protrudes into the thorax in the left dorsal tendinous portion of the diaphragm. The sac is characterized by a pleural covering and a peritoneal lining. In described cases, the presenting complaint was colic, and the diagnosis was made during exploratory celiotomy. Defects can be surgically repaired using mesh products to reduce risk of recurrence. The hernial sac is usually left in situ. In cases of direct herniation, clinical signs include dyspnea, exercise intolerance,

lethargy, and weight loss. In cattle, herniation of the reticulum into the thorax has been described, with a right-side diaphragmatic defect. Clinical signs include anorexia, scant manure, tympani, and decreased or no rumination. Diagnosis is by radiography or ultrasonography. **Peritoneopericardial hernias** are defined as an embryologic defect in the failure of fusion of the septum transversum during diaphragmatic development, allowing communication between the abdominal cavity and pericardial sac. Weimaraners and domestic long-haired cats were overrepresented in one study. Clinical signs reflect the contents of the hernia, which may include omentum, liver, gallbladder, or small intestinal loops, and include cardiac tamponade, dyspnea, tachypnea, exercise intolerance, coughing, vomiting, and GI obstruction. In many cases, the diagnosis was an incidental finding during imaging or celiotomy for other reasons. Other congenital defects were found in many cases, including umbilical hernia, cryptorchidism, cleft palate, portosystemic shunt, and sternal or vertebral abnormalities. Animals with clinical signs were treated with surgical herniorrhaphy, whereas animals with no clinical signs tended to be closely monitored. **Hiatal hernias** occur through the esophageal hiatus and are classified into four types. Type I, the sliding hernia, is the most common in small animals and is characterized by intermittent displacement of the lower esophageal sphincter and gastric fundus into the thoracic cavity. Type II is less common and involves only the displacement of the gastric fundus. Brachycephalic breeds are overrepresented, with a hereditary nature suspected in Shar-Pei. Clinical signs include dysphagia, regurgitation, vomiting, ptyalism, and esophagitis due to decreased function of the lower esophageal sphincter. Diagnosis is by radiography or fluoroscopy; however, the intermittent nature can make diagnosis challenging. Medical treatment of esophagitis is required. Surgical correction is by combination of hiatal plication, esophagopexy, and left-side gastropexy.

STOMACH

Besides hiatal hernia, the most common abnormality involving the stomach with a suspected heritable etiology is **pyloric stenosis**, which affects brachycephalic dog breeds (Boxers, Boston Terriers, English Bulldogs) and Siamese cats. Pyloric stenosis or pyloric muscular hypertrophy

results from muscular thickening of the pyloric sphincter, which obstructs pyloric outflow. Clinical signs reflect delayed gastric emptying and usually manifest as vomiting of food several hours after a meal but may also include poor weight gain, aspiration pneumonia, depression, and dehydration. Diagnosis is aided by contrast imaging and endoscopy, which is often combined with biopsy to exclude neoplasia. Surgical treatment is recommended to relieve the obstruction. Medical treatment of esophagitis, acid-base abnormalities, and dehydration should be instituted before surgery.

Abomasal emptying defect of sheep is a dysautonomia characterized by functional obstruction of the pyloric sphincter, possibly due to neurotoxicity of the celicomesenteric ganglia. It is well described in Suffolk sheep with few cases reported in Hampshire, Dorset, and Texel breeds. The etiology is unknown; it may be hereditary or that certain genotypes predispose to the condition. Pedigree analysis of affected flocks does not show a simple inheritance pattern. Clinical signs include weight loss, anorexia, depression, dyspnea, decreased rumen motility, and progressive distention of the right ventral abdomen. Even with abomasotomy, the prognosis is poor to grave.

SMALL AND LARGE INTESTINE

Maldigestion or malabsorption disorders usually manifest as chronic, persistent GI signs, including vomiting, weight loss, small- and/or large-intestinal diarrhea, or a combination of the above. There are many potential etiologies, both heritable and acquired, and most are associated with inflammatory bowel disease (IBD). Congenital conditions may have specific breed predilections.

Soft-coated Wheaten Terriers have a high incidence of **protein-losing enteropathy (PLE)**, which may be seen alone or in association with **protein-losing nephropathy (PLN)**. Although the mode of inheritance is not clear, the etiopathogenesis of PLN is likely different than that of PLE, due to podocytopathy. Dogs with PLE have both food hypersensitivities and IBD, although the pathogenesis is not clear. The demonstration of increased fecal α_1 -protease inhibitor concentrations can help confirm abnormal protein loss through the intestinal tract, although this is more useful as a screening test in animals <3 yr old. A definitive diagnosis is based on intestinal and renal histopathology. Despite

hypoallergenic diet trials and immunosuppressive therapy directed at IBD and/or glomerulonephritis, prognosis is poor.

Gluten-sensitive enteropathy has been shown to be inherited by an autosomal recessive manner in Irish Setters. However, the pathogenesis in dogs appears to be different than that of celiac disease in people. One case has also been described in a horse. The wheat sensitivity is both confirmed and treated through use of gluten-free diets.

Basenjis have been diagnosed as carriers of a severe form of lymphocytic-plasmacytic enteritis called **Basenji enteropathy**, although the mode of inheritance is not known. The stomach may also be affected. Clinical signs include diarrhea and weight loss, with hyperglobulinemia. Diagnosis is based on histopathologic examination of GI biopsies, usually obtained through endoscopy. Treatment trials with immunosuppressive drugs and hypoallergenic diets are usually unsuccessful unless aggressively initiated early in the disease.

Lymphangiectasia is a malformation of the intestinal lymphatic system that results in a protein-losing enteropathy that may be congenital or acquired, with a 50% incidence in Norwegian Lundehunds in the USA. Other affected breeds include Yorkshire Terriers, Maltese, Rottweilers, and Shar-Pei. Lymph vessels become dilated, secreting lymph into the intestines, which results in hypoproteinemia, lymphopenia, and lipogranulomatous inflammation of surrounding tissues. It is diagnosed through exclusion of other protein-losing diseases and confirmed by histopathology of the small-intestinal wall. Most affected animals respond to a combination of dietary manipulation and anti-inflammatory doses of glucocorticoids. Diets should contain minimal fat, be energy dense, and easily digestible. Although remission of clinical signs may be achieved, the longterm outcome is usually poor.

Exocrine pancreatic insufficiency (EPI) has a higher incidence in German Shepherds and Rough Collies, although it has been diagnosed in many breeds. Disease is due to pancreatic acinar atrophy, which is due to immune-mediated destruction and infiltration of lymphocytes. In German Shepherds and Pembroke Welsh Corgis, genome-wide association studies have identified several major histocompatibility complex haplotypes associated with EPI in affected animals, suggesting a complex mode of inheritance. The lack of pancreatic enzymes results in an osmotic diarrhea, in which steatorrhea is a prominent feature.

Affected animals either fail to gain weight or, if EPI is acquired later in life, show a dramatic weight loss. Diagnosis is through measurement of serum trypsin-like immunoreactivity; validated tests are available for both dogs and cats. Treatment involves exogenous replacement of pancreatic enzymes and use of highly digestible diets.

Granulomatous colitis, previously called histiocytic ulcerative colitis, has been diagnosed in Boxers and French Bulldogs, with sporadic cases in a few other breeds. The disease is characterized by granulomatous inflammation of the colonic mucosa in association with infection with adherent and invasive *Escherichia coli*. An autosomal recessive defect in the immune system that predisposes to *E coli* infection is suspected. Clinical signs arise in animals <4 yr old and include diarrhea, hematochezia, tenesmus, and weight loss. Diagnosis is by histologic examination of colonic mucosal biopsies. Successful remission has been achieved in animals treated with enrofloxacin; however, treatment has been unsuccessful in cases in which the *E coli* was resistant to fluoroquinolones.

Ileocolonic agangliosis, or overo lethal white syndrome, occurs in white foals with blue eyes produced by Overo-Overo matings. The condition is fatal. It is due to mutation in the endothelin B receptor and is inherited in an autosomal recessive manner. Although the foals appear normal at birth, they rapidly develop signs of colic and meconium impaction due to hypoinnervation of the intestinal tract, which causes lack of motility. Diagnosis can be confirmed at necropsy by the lack of ganglia in the colon. Adult Overo horses can be screened for genetic status before breeding to reduce incidence. Congenital atresias of either the small- or large-intestinal tracts have been described in most domesticated animal species. **Atresia coli** has been reported in several foals of differing breeds. **Atresia ilei** in Swedish Highland cattle, and **atresia jejuna** in Jersey cattle are likely due to autosomal recessive inheritance. These conditions are invariably fatal. Aggressive manipulation of the bovine conceptus by transrectal palpation early in gestation (<45 days) has been implicated as a cause, although a reduction in incidence through selective breeding indicates a potential genetic predisposition as well.

Atresia ani results when the dorsal membrane separating the rectum and anus fails to rupture. Clinical signs are apparent at birth and include tenesmus, abdominal pain and distention, retention of feces, and

absence of an anal opening. It is rare in dogs but has been reported in several breeds, including Toy Poodles and Boston Terriers, with an increased incidence in females. Concurrent rectovaginal fistula may occur. Euthanasia is recommended in large animals. In small animals, postoperative fecal incontinence may be a complication of surgical intervention.

Segmental aplasia of the rectum (rectal atresia) is seen when the rectum terminates in a blind pouch before reaching the anus. Surgical correction is difficult because the location of the terminal section varies, and iatrogenic damage to nerves in the area may occur.

Enteric duplications are very rare, with only a few cases described in several species, and may include the colon or rectum. Duplications may communicate with the lumen of the patent tract or be separate (duplication cyst). Affected animals may be diagnosed by identification of an abdominal mass, or they may show GI signs. Diagnosis is by ultrasonography or contrast CT. Correction is via surgical removal of the duplication, although some cases have multiple concurrent abdominal developmental anomalies that preclude complete surgical correction.

Rectourethral fistula has been reported primarily in English Bulldogs and is diagnosed clinically as simultaneous urination from both the urogenital and anal orifices along with a history of chronic urinary tract infections. Diagnosis is via cystourethroscopy with concurrent colorectal infusion of contrast material, or by contrast CT. Surgical correction is curative.

Rectovaginal fistula is a fistulous tract that connects the vagina and rectum and usually is seen in conjunction with imperforate anus. Passage of feces through the vulva is suggestive. Diagnosis may be confirmed by barium enema, which outlines the extension of the defect into the vagina, or video endoscopy. Identification of the fistula, surgical correction, and reestablishment of the normal anatomic structures are imperative. Prognosis is usually guarded. Complications are common and include fecal and urinary incontinence.

Urinary and fecal incontinence is often seen in Manx cats as a sequela of heritable spina bifida.

LIVER

Portosystemic shunts (PSSs) are the most common congenital liver anomaly (see p 446). PSSs typically involve single

extra-hepatic or intrahepatic vessels, with extrahepatic shunts more common in toy breeds (Yorkshire Terriers, Cairn Terriers, Havanese, Maltese, Pugs, and Miniature Schnauzers), and intrahepatic shunts more common in large breeds (Irish Wolfhounds, Labrador and Golden Retrievers, Australian Cattle Dogs, and Old English Sheepdogs). They have also been reported in Himalayan and Persian cats. Commonly, extrahepatic shunts occur between the portal vein or its branches, and the caudal vena cava or azygous vein, whereas intrahepatic shunts may be due to failure of closure of the ductus venosus or connections between the portal vein branches and hepatic veins. Clinical signs generally manifest as neurologic disturbances (hepatic encephalopathy) and are usually seen in young animals. Cats may show ptialism. In the later stages, GI signs (including vomiting, anorexia, and diarrhea) as well as ascites may develop secondary to portal hypertension. Other concurrent clinical findings may include renomegaly and urate urolithiasis. Laboratory tests may show increased liver enzymes and erythrocytic microcytosis. Abdominal ultrasonography is reported to be 100% sensitive for intrahepatic PSSs (although some what less for extrahepatic PSSs), but sensitivity depends on the skill of the ultrasonographer. Definitive diagnosis via positive-contrast portography can identify shunt location and whether the shunt is single or multiple. This procedure also allows assessment of feasibility for surgical correction. Multiple shunts have a poor prognosis, because they are often secondary to an underlying, progressive hepatic parenchymal disease (eg, cirrhosis).

Hepatoportal microvascular dysplasia is an intrahepatic circulatory disorder that results in the shunting of portal blood to the systemic circulation yet no discernible large vessel shunt is identified. The disorder has been classified as a variation of primary hypoplasia of the portal vein, which results in noncirrhotic portal hypertension. The syndrome is well defined in Cairn Terriers and Yorkshire Terriers, although it has also been reported in Maltese, Dachshunds, Toy and Miniature Poodles, Bichon Frise, Pekingese, Shih Tzus, Norfolk and Norwich Terriers, Tibetan Spaniels, Havanese, and Lhasa Apsos. Animals may be asymptomatic or show clinical signs similar to those of

PSSs. Dogs that progress to clinical disease are treated medically as described for PSSs. Because there is no macroscopic shunting vessel, surgery is not a therapeutic option.

Copper-associated hepatopathy results either from a metabolic derangement of hepatic copper storage or secondary to hepatobiliary disease (mostly cholestatic disease). In Bedlington Terriers it has been identified as an autosomal recessive disorder, whereas in other breeds that have been identified as susceptible (Dalmatians, Skye Terriers, West Highland White Terriers, and Doberman Pinschers) no genetic basis has been identified. Primary copper toxicosis is very rare in cats. Affected animals may be asymptomatic or show acute signs of hepatobiliary disease, including vomiting, anorexia, depression, hemolytic anemia, and icterus. Older, chronically affected animals may show progressive end-stage liver disease. Treatment is based on dietary reduction of copper and either treatment with zinc salts to prevent GI absorption of copper in asymptomatic animals, or copper chelators to reduce copper in animals with clinical signs. Because copper chelators are not without adverse effects, treatment should be closely monitored.

Congenital hepatic cysts or congenital hepatic fibrosis is seen in both Persian and Persian-cross cats as an autosomal dominant trait and in the Swiss Freiburger horse (also called the Franches-Montagnes horse) as an autosomal recessive trait that can be traced back to one stallion. Both are features of a larger, polycystic organ syndrome that affects the kidneys, liver, and/or pancreas. Clinical signs in cats may not be apparent or manifest as chronic renal insufficiency. In horses, affected foals present in the first year of life with weight loss, jaundice, hepatic encephalopathy, abdominal distention, fever, and colic signs. A report of dogs with congenital hepatic fibrosis described ascites, vomiting, seizures, and portal hypertension but did not draw inferences on heritability.

Primary or idiopathic hyperlipidemias of dogs and cats have been reported. Miniature Schnauzers have a high prevalence of **hypertriglyceridemia**, up to 33% of animals in one study, with or without concurrent hypercholesterolemia and chylomicronemia. There was an effect of age, with higher prevalence in older animals, and a genetic basis is suspected. **Hypercholesterolemia** has been reported

in Briards, Rough Collies, Shetland Sheepdogs, Doberman Pinschers, and Rottweilers. Also in dogs, a syndrome of idiopathic **hyperchylomicronemia** has been reported, with hypertriglyceridemia and normal serum cholesterol. Clinical signs may be absent or may include vomiting, diarrhea, pancreatitis, lipemia retinalis, seizures, peripheral neuropathies, and abdominal pain. Hyperlipidemias also occur secondary to other diseases, including hypothyroidism, diabetes mellitus, and hyperadrenocorticism, and

treatment is aimed at the inciting disease as well as dietary modifications.

In cats, familial hyperlipidemia due to hyperchylomicronemia has been identified as due to an autosomal recessive defect in lipoprotein lipase. Secondary to this disorder, cutaneous and systemic xanthomas have been described, with deposition of lipid-laden macrophages in the dermis, usually around the head and ears. Peripheral neuropathy may develop secondary to nerve compression by the xanthomas, particularly on the limbs and paws.

DENTAL DEVELOPMENT

All domestic animals have a diphyodont dentition, ie, a deciduous and a permanent set of teeth. The morphology as well as the dental formula (see TABLE 3) of mammalian teeth, however, are variable and closely related to the animal's alimentation.

Identification of teeth was formerly based on an anatomic system in which incisors were designated as I, canines as C, premolars as P, and molars as M. Veterinary dentists now most often use the modified Triadan system, which assigns a 3-digit number to a specific tooth. The animal's head is divided into four quadrants, with the upper right quadrant labeled "1" and the remaining quadrants numbered in a counterclockwise direction. Numbers 1–4 are used to identify the quadrant for permanent teeth, and 5–8 are used for the temporary dentition. The second and third digits identify the specific tooth number; eg, in horses, the left lower second premolar is tooth "306" and the last molar on the right mandible is "411."

ESTIMATION OF AGE BY EXAMINATION OF THE TEETH

In horses, which have a hypsodont dentition, age can be estimated by the eruption times and general appearance of the (lower incisor) teeth. In other species with brachyodont incisors, such as cattle and dogs, age determination is less accurate and is mostly based on dental eruption times.

Horses: The most appropriate teeth to estimate age in horses are the (lower) incisors. It must be emphasized, however, that dental appearances are subject to individual and breed variations and to differences in environmental conditions. The deciduous incisors are smaller than the permanent ones, and the surfaces of their crowns are whiter and have several small longitudinal ridges and grooves. Eruption times are listed in TABLE 4. Permanent incisors are larger and more rectangular in shape. Their crown surfaces are largely covered with cement and have a yellowish appearance. The upper incisors have two distinct longitudinal grooves on their labial surface, while the lower incisors have only one.

Equine incisor teeth develop certain wear-related macroscopic features traditionally used to estimate age. The dental star consists of yellowish brown secondary dentin that fills up the pulp cavity and appears at the occlusal surface as the tooth wears. Its shape and position, as well as the appearance of the "white spot" in its center, are related to age. The shape, size, and time of disappearance of both the infundibula or "cups" (funnel-like infoldings in the occlusal surface) and the "marks" (enamel infundibular bottoms) are additional but more variable indicators of age. Progressive dental wear causes an alteration of the occlusal shape of the incisors. The occlusal surfaces of recently erupted incisors are elliptical, but with age they subsequently become trapezoid, round, and then triangular, with the apex toward the lingual side. The curvature of the dental

Horse	$2 \left(\text{Di} \frac{3}{3} \text{Dc} \frac{0}{0} \text{Dp} \frac{3}{3} \right) = 24$	$2 (\text{I} \frac{3}{3} \text{C} \frac{1}{1} \text{P} \frac{3}{3} \text{M} \frac{3}{3}) = 36 (-44)^{a,b}$
Cow ^c Sheep Goat	$2 \left(\text{Di} \frac{0}{3} \text{Dc} \frac{0}{1} \text{Dp} \frac{3}{3} \right) = 20$	$2 (\text{I} \frac{0}{3} \text{C} \frac{0}{1} \text{P} \frac{3}{3} \text{M} \frac{3}{3}) = 32$
Pig	$2 \left(\text{Di} \frac{3}{3} \text{Dc} \frac{1}{1} \text{Dp} \frac{3}{3} \right) = 28$	$2 (\text{I} \frac{3}{3} \text{C} \frac{1}{1} \text{P} \frac{4}{4} \text{M} \frac{3}{3}) = 44$
Dog	$2 \left(\text{Di} \frac{3}{3} \text{Dc} \frac{1}{1} \text{Dp} \frac{3}{3} \right) = 28$	$2 (\text{I} \frac{3}{3} \text{C} \frac{1}{1} \text{P} \frac{4}{4} \text{M} \frac{2}{2}) = 42$
Cat	$2 \left(\text{Di} \frac{3}{3} \text{Dc} \frac{1}{1} \text{Dp} \frac{3}{2} \right) = 26$	$2 (\text{I} \frac{3}{3} \text{C} \frac{1}{1} \text{P} \frac{3}{3} \text{M} \frac{1}{1}) = 30$

^a The canine teeth are usually regressed or absent in mares.

^b Small premolars 1 (wolf teeth) are often present, especially in the upper jaw.

^c The canine tooth of domestic ruminants has commonly been counted as a fourth incisor.

arch formed by the lower incisive tables is also age related. In young horses this arch is semicircular, whereas in older horses it forms a straight line. Additionally, the arch formed by the incisors of the opposing jaws (as they meet) changes as the teeth advance from their alveoli and undergo attrition. In young horses, the upper and lower incisors are positioned in a straight line. With increasing age, the angle between upper and lower incisors becomes more acute. The Galvayne's groove and the "7-year hook," which have traditionally been used as age indicators, are variable, inconsistent, and thus of little value for age determination in horses. The more useful signs are arranged chronologically in the following list:

Birth to 5 yr: See TABLE 4.

5 yr: The corners are erupting. Dental star in the central incisors.

6 yr: Dental star in the middle incisors.

Cups gone from the central incisors.

7 yr: Dental star in the corners.

8 yr: The central incisors are trapezoidal and have a white spot in the dental star.

9 yr: The middle incisors are trapezoidal and have a white spot in the dental star.

10 yr: Cups gone from the middle incisors. Marks on the central incisors are oval-triangular.

11 yr: White spot in the dental star on the corners. Both the central and middle incisors have a lingual apex. The corners are triangular with a labial apex.

12 yr: Cups gone from all lower incisors.

14 yr: Marks on the central and middle incisors are small and round.

Top: occlusal view on lower incisors of a 6-yr-old mare. Dental stars are visible on I1 and I2 (arrows); cups are present as large elliptical infoldings (arrowheads). Occlusal surfaces of the incisors are oval, and curvature of the dental arch is semicircular. Bottom: occlusal view on the lower incisors of a 12-yr-old mare. In the center of the dental stars, a white spot is clearly visible (arrows). Cups have become smaller and more shallow. Occlusal surfaces are more triangular. Courtesy of Dr. Sofie Muylle.

TABLE 4 ERUPTION OF THE TEETH^a

	Horse	Cow	Sheep and Goat	Pig	Dog	Cat

^a Average data, subject to considerable variation^b 2 yr in goats^c 2½–3 yr in goats^d 3–4 mo in sheep

18 yr: Marks disappear from the central incisors.

20 yr: Marks are gone from the middle incisors and the corners.

Cattle: Eruption times of incisors are the most reliable feature for age determination in cattle (see TABLE 4). Although breed-related, eruption dates are more reliable for estimation of age than signs of wear, because macroscopic age-related dental features are scarce (dental stars) or absent (cups and marks) and because rate of wear is largely influenced by nutrition.

Birth to 5 yr: See TABLE 4.

5 yr: All incisors in wear. Occlusal surface of the central incisors beginning to level.

6–7 yr: Central incisors are leveled and neck is visible.

8 yr: Middle incisors are leveled and neck is visible.

9–10 yr: Corners are leveled and neck is visible.

As cattle continue to age, the teeth wear shorter and more neck becomes visible; they loosen in the sockets and eventually drop out.

Dogs: The following data were found reliable in ~90% of large dogs. There is more variation in small dogs (especially toy breeds) and in dogs with undershot or overshot jaws. Even, or level, bites usually result in excessive wear.

Dentition of the horse. Illustration by Dr. Gheorghe Constantinescu.

Dentition of the dog. Illustration by Dr. Gheorghe Constantinescu.

1½ yr: Cusps worn off lower central incisors.

1½–2½ yr: Cusps worn off lower middle incisors.

3½ yr: Cusps worn off upper central incisors.

4½ yr: Cusps worn off upper middle incisors.

5 yr: Cusps of lower corners slightly worn. Occlusal surface of lower central and middle incisors is rectangular. Slight wear of canines.

6 yr: Cusps worn off lower corners. Canines worn blunt. Lower canine shows impression of upper corner.

7 yr: Occlusal surface of lower central incisor becomes elliptical with the long axis sagittal.

8 yr: Occlusal surface of lower central incisor is inclined forward.

10 yr: Lower middle and upper central incisors have elliptical occlusal surfaces.

DENTISTRY

LARGE ANIMALS

Most large animals are herbivores, and efficient dental function is the key to food intake and to the maintenance of normal body condition. The variations in anatomic structure, dental formula, and eruption schedule for deciduous and permanent teeth is fundamental veterinary knowledge and should be reviewed before performing dentistry on any species (see TABLE 3).

The deciduous and permanent dental formula of cows, sheep, and goats are similar. All ruminants lack upper incisor teeth, with the mandibular brachydont (short-crowned) incisors meeting with a maxillary cornified dental pad. In many herbivore species, the forces of almost continuous grazing or rumination leads to dental attrition. Dental crown wear has been matched by the development of hypsodont (long-crowned) teeth with the continuous eruption of the reserve crown. The dental arcades in the horse consist of at least nine teeth (three incisors separated by a diastema [the interdental space], three premolars, and three molars) in each quadrant of the mouth. These hypsodont teeth have regular serrations that expose sharp enamel edges for shredding and crushing cellulose material. At the same time, the brittle nature of the enamel of the tooth is protected by the surrounding dentin and peripheral cementum. In the normal course of masticating forage, the rate of tooth eruption is matched by the rate of occlusal crown wear. Adult male horses have large permanent canine teeth situated in the interdental space. These are absent or very small in mares (sexual dimorphism).

Of the common domestic large animals, horses generally require the most dental care. In the swine industry, removal or amputation of deciduous canine teeth in piglets and tusk amputation in breeding boars may be part of routine management. In New World camelids (llamas, etc), blunting the fighting teeth (ie, the upper single incisor and canine and the lower canine teeth) is done to reduce the danger and consequences of fighting. (See also LLAMAS AND ALPACAS, p 1844, for additional information on dental care.) Exotic species may also have various dental conditions, eg, impacted tusks in young elephants or maxillary dental periostitis and actinomycosis in wallabies and kangaroos.

Signs of Dental Disease

Dental disease (eg, broken teeth, periodontal disease, irregular dental arcade wear) is a common underlying cause of unthriftiness, loss of condition, or poor breeding or nursing performance. The classic signs of dental disease in horses include difficulty or slowness in feeding and a reluctance to drink cold water. During the chewing process, the horse may stop for a few moments and then start again. Sometimes, the head is held to one side as if the horse were in pain. Occasionally, the horse may quid, ie, it may pick up its food, form it into a bolus but drop the bolus from the mouth after it has been partially chewed. Occasionally, the semi-chewed mass of feed may become packed between the teeth and the cheek or become lodged in the esophagus, leading to choke. To avoid using a painful tooth or a sore mouth, the horse may bolt its food and subsequently

suffer indigestion, choke, or colic. There may be a lack of desire to eat hard grain accompanied by uncrushed grain in the feces. Other signs of dental disease in horses include excessive salivation and blood-tinged mucus in the mouth, accompanied by the fetid breath of dental decay. Extensive dental decay and accompanying periostitis and root abscessation may lead to empyema of the paranasal sinuses and intermittent unilateral nasal discharge. There may be facial or mandibular swelling and development of mandibular fistulas from apical infections of the lower cheek teeth.

Horses may be reluctant to take the bit, shake their head when being ridden, or resist training techniques because of irregularly worn cheek teeth and sharp edges on the maxillary cheek teeth and accompanying buccal mucosa laceration. The presence of small upper first premolar "wolf" teeth in horses may or may not be associated with resistance to the bit.

Dental Examination

In most cases, history, age, and clinical signs are correlated. A thorough physical examination should always be performed, followed by a detailed and thorough oral and dental examination. In most large animals, including horses, this may involve the use of sedation; certain animals may require general anesthesia. A thorough oral examination is facilitated by rinsing the mouth with warm water and illuminating the oral cavity with a bright headlamp while using an oral speculum. Most mouth speculums designed for horses or ponies can be modified by replacing the upper incisor plate with a flat padded gum plate for use in ruminants. A dental mirror or endoscopic camera greatly increases the quality of oral examination. The oral dental examination is often aided by radiography or other advanced imaging such as CT, scintigraphy, or MRI.

Routine Dental Prophylaxis and Extractions

Routine dental prophylaxis consisting of a complete oral dental examination and odontoplasty of sharp enamel points is important in the health care of horses. Enamel edges should be removed twice yearly during the establishment of the permanent dentition and thereafter as frequently as needed, depending on the management of the horse. Horses that graze on free range or grass usually require a yearly dental prophylaxis; horses that are stall confined and essentially fed hay and

grain may require twice yearly oral examinations and dental prophylaxis.

The objective of dental prophylaxis is to remove sharp enamel edges of cheek teeth that might be causing soft-tissue irritation and any occlusal surface elongations. This odontoplasty procedure is often referred to as "floating" the teeth. By maintaining the normal occlusal surface, development of irregularities of wear on the dental arcades is inhibited. Dental prophylaxis can usually be done with simple restraint and/or the use of sedatives and analgesics. Power equipment is now being used more frequently than handheld rasps to grind, balance, and realign the occlusal surfaces of the incisors and cheek teeth. Motorized dental instruments should be used carefully to avoid thermal and pressure trauma to dentin and pulp. This means using low speed grinders (6,000–12,000 rpm) with short contact times, light pressure, and intermittent water irrigation, while removing no more than 3–5 mm of occlusal surface every 3–6 mo.

Sharp edges on wolf teeth have been incriminated as a cause of bit resistance in horses. These small teeth, located just rostral to the upper cheek tooth row, are often extracted in performance horses. This procedure can be done in the standing, sedated horse with the aid of local infiltration anesthesia. The gingival attachment to the tooth is elevated, and a dental luxator or elevator is used to loosen the tooth. A small extraction forceps can grasp the crown and pull the tooth from its socket. Minimal aftercare or diet and work restriction are required for socket healing.

Most dental procedures can be performed on the standing, sedated horse with or without regional anesthesia, but some major dental procedures (eg, repulsions and fracture repairs) usually require general anesthesia. Radiographic evaluation and protection of the airway from debris are necessary in most cases. Some decayed teeth can be extracted *per os* using molar separators, extraction forceps, and elevators. However, in some cases, surgical exposure and tooth repulsion or sectioning and elevation is preferred. Tooth preservation by root end resection and endodontic therapy has demonstrated that extraction is not required in all cases of dental decay in horses.

CONGENITAL AND DEVELOPMENTAL ANOMALIES

In horses, the most commonly diagnosed oral congenital deformity is parrot mouth (class 2 malocclusion), in which the maxilla

is relatively longer than the mandible. In early embryonic development, the first branchial arch extends as a solid hyaline cartilaginous rod surrounded by a fibrocellular capsule from the temporal region to the midline of the fused mandibular processes. If the first branchial arch fails to close properly in the equine fetus, tooth germ can displace and result in the formation of a dentigerous cyst in the temporal region and a draining tract from the rostral pinna of the ear. In equids and cattle, many anomalies of dental development may result from exposure to teratogenic toxins. However, underlying genetic factors should always be considered.

Dental irregularities accompany systemic fluorosis in both cattle and sheep. In the milder forms of fluorosis, only the dentition may be involved. In extreme fluorosis (eg, 40 ppm in the diet for several years), other skeletal abnormalities may be seen (phalanx fracture). (See also FLUORIDE POISONING, p 3075.)

Supernumerary teeth (polyodontia) are seen occasionally. In both horses and cattle, double rows of incisor teeth or extra cheek teeth may be seen. Missing teeth (oligodontia) in a dental arcade is less common and can be developmental or secondary to trauma or previous tooth removal. Treatment is determined on a case-by-case basis and may require extraction or frequent crown reduction of the unopposed teeth.

See also CONGENITAL AND INHERITED ANOMALIES OF THE TEETH, p 164.

ABNORMAL TOOTH ERUPTION

Shedding deciduous teeth can be a source of oral irritation in horses that are 2–5 yr old. Deciduous tooth caps can become loosened, displaced, or fractured, leading to problems with mastication and biting. Abnormal eruption of permanent teeth is commonly a sequela of mandibular or maxillary trauma, eg, incisor avulsion fractures in cattle and horses in which the developing dental bud of the permanent tooth is damaged by the fracture itself or by the repair process. In horses, delayed eruption or impaction of cheek teeth is a common cause of periapical infection. This particularly affects the second and third cheek tooth (premolar 3 [Triadan 07s] and premolar 4 [Triadan 08s]) in both the upper and lower arcades and is a sequela of dental overcrowding. Medial displacement of the third cheek tooth is another form of abnormal eruption due to overcrowding.

IRREGULAR WEAR OF THE DENTITION

Except for pigs, most large animals have an intermandibular space that is narrower than the intermaxillary space; ie, they are anisognathic. In horses, this, together with limited natural movement of the mandible, results in the development of enamel points on the buccal edges of the upper arcades and on the lingual edges of the lower arcades. In cattle and sheep, because the temporomandibular joint affords greater lateral movement of the mandible, such irregularities do not develop as frequently. Extreme forms of disease, however, are seen in all species and may be influenced by other skeletal deformities of the face or accompanying infections (eg, *Actinomyces* sp.). Gross shear mouth may result, with exaggerated obliquity of the molar tables. It may be seen in older horses, and treatment is usually unsatisfactory. Dental care should be supplemented by special diets.

Enamel points are best treated by regular dental equilibration in horses (ie, floating). This should be done twice annually while the permanent dentition is developing; at the same time, retained caps should be removed if they cause oral ulceration or discomfort.

Wave mouth, step mouth, and rostral and caudal hooks are dental overgrowths caused by uneven wear of the teeth and are the result of local pain, dental or jaw malalignment, or missing or damaged teeth. In time, this can lead to abnormal spaces forming between the teeth (diastema), which have been shown to cause feed entrapment and secondary gum and socket disease (ie, periodontitis). Such conditions are best prevented by regular, routine dental prophylaxis. Once dental wear abnormalities are severe, results of dental procedures are usually incomplete. Although occlusal surfaces may be realigned, dental care needs to be supplemented by special dietary regimens.

PERIODONTAL DISEASE

In all animals, a degree of inflammatory change occurs during the eruption of both the deciduous and permanent teeth. However, if malocclusion occurs, severe periodontal disease is inevitable. In horses, this is a common sequela of diastema formation, oral trauma, dental fractures, and impactions, and it is usually accompanied by irregular wear.

In sheep, periodontal disease of the mandibular rostral teeth (incisors) is often referred to as broken mouth. Sometimes,

in horses can be corrected by grinding and realigning the arcades every 6-12 mo.

Because of such complications, surgical techniques that preserve the teeth should be considered, at least for horses. The age of the animal and the specifics of local disease should be considered before contemplating root-end resection and endodontic therapy in large animals.

SMALL ANIMALS

PERIODONTAL DISEASE

Etiology and Pathogenesis: The oral cavity supports a rich bacterial microflora, much of which thrives in plaque on tooth surfaces. Bacterial plaque on the crown surface of a tooth constantly presents antigen to the marginal gingiva, stimulating an inflammatory response and resulting in gingivitis. The bacteria in plaque are predominantly nonmotile, gram-positive aerobes, including *Staphylococcus* spp and *Streptococcus* spp, but many others are also present. Although this microbiota does stimulate an immune response, the bacteria in an otherwise healthy mouth exist in relative commensal harmony with the host. They may even be beneficial by helping to limit the numbers of periodontopathogenic bacteria. If the plaque becomes very thick because of poor oral hygiene and oxygen within the plaque is depleted, the bacterial population can become more pathogenic, with a higher percentage of nonmotile, gram-negative anaerobic rods. The bacteria found in the presence of teeth with periodontal disease include *Bacteroides fragilis*, *Peptostreptococcus*, *Porphyromonas gulae*, *Porphyromonas salivosa*, *Porphyromonas denticanis*, *Prevotella intermedia*, *Treponema* spp, *Bacteroides splanchnicus*, and many others. Interestingly, some of the common human periodontopathogens such

as *Haemophilus* (formerly *Actinobacillus*) *actinomycetemcomitans* are notably absent in animals. Subgingival plaque (plaque on the tooth surface below the gingival margin) is also commonly inhabited by these more periodontopathogenic species of bacteria. Periodontitis is caused by the host's response to subgingival plaque. Inflammatory mediators produced by the host directly result in bone and tissue damage around the root. The bacteria themselves and their metabolic products also contribute to the bone damage. Development of periodontitis is also affected by other intrinsic (eg, genetics, tooth crowding, thin alveolar bone, age) and extrinsic (eg, diet, stress, concurrent disease, oral hygiene) factors.

Clinical Findings and Lesions: Periodontal disease is classified in stages. In teeth with healthy periodontal tissues, no gingivitis or periodontitis is evident.

Stage 1: There is gingivitis only, without attachment loss; the height and architecture of the alveolar margin are normal.

Stage 2: There is early periodontitis with <25% of attachment loss or, at most, there is a stage 1 furcation involvement in multirooted teeth (see below). There are early radiographic signs of periodontitis. The loss of periodontal attachment is <25% as measured by probing of the clinical attachment level or by radiographic determination of the distance of the alveolar margin from the cemento-enamel junction relative to the length of the root.

Stage 3: There is moderate periodontitis, with 25%–50% of attachment loss as measured by probing of the clinical attachment level or by radiographic determination of the distance of the alveolar margin from the cemento-enamel junction relative to the length of the root, or there is a stage 2 furcation involvement in multirooted teeth (see below).

Stage 4: There is advanced periodontitis, with >50% of attachment loss as measured by probing of the clinical attachment level or by radiographic determination of the distance of the alveolar margin from the cemento-enamel junction relative to the length of the root, or there is a stage 3 furcation involvement in multirooted teeth (see below).

A stage 1 furcation involvement exists when a periodontal probe extends less than halfway under the crown in any direction of a multirooted tooth with attachment loss. A stage 2 furcation involvement exists when a periodontal probe extends greater than halfway under the crown of a multirooted tooth with attachment loss but not through and through. A stage 3 furcation involvement exists when a periodontal probe

extends under the crown of a multirooted tooth, through and through from one side of the furcation out the other.

A stage 0 mobility up to 0.2 mm is physiologic. A stage 1 mobility is present when tooth mobility is increased in any direction other than axial over a distance of >0.2 mm and up to 0.5 mm. A stage 2 mobility is present when tooth mobility is increased in any direction other than axial over a distance of >0.5 mm and up to 1 mm. A stage 3 mobility is present when tooth mobility is increased in any direction other than axial over a distance >1 mm or any axial movement.

Treatment: Removal of the bacterial plaque on the tooth surfaces is of utmost importance. This can reverse gingivitis, returning the gingiva to a healthy, uninfamed state. This is achieved through professional dental cleaning (scaling and polishing) with power and hand instruments under general anesthesia. Dental cleaning on an awake animal improves the cosmetic appearance of the tooth crowns but does not improve periodontal health. The owner might falsely believe the condition has been treated, while periodontal disease continues to thrive. If the gingivitis does not resolve, further examination should be performed to identify additional complicating conditions such as persistent subgingival plaque and calculus or the presence of predisposing factor(s). Some less common causes of gingivitis, including systemic disease (eg, uremic stomatitis), autoimmune disease, juvenile gingivitis, etc, may require more than only plaque removal.

Periodontitis requires more aggressive periodontal treatment. Root scaling (removing plaque and calculus on exposed root surfaces) and planing (smoothing the root surfaces by removing textural irregularities and diseased cementum) are performed, followed by gingival curettage that removes the infected and inflamed inside layer of a periodontal pocket. Shallow periodontal pockets are treated in a closed fashion, but pockets >6 mm deep require open surgery (creation of a periodontal flap) to expose the root surface and alveolar bone for adequate treatment (root scaling/planing and alveoloplasty). The connective tissue side of the flap needs to be debrided before wound closure to avoid contact of infected and inflamed granulation tissue with the planed root surfaces. Local placement of a gel containing antibiotics (eg, doxycycline) into cleaned periodontal pockets may be helpful. Extraction is often the best treatment for teeth with increased mobility that have a

guarded to poor prognosis. Periodontitis is not as readily reversible as gingivitis. Lost bone may be augmented by use of bone grafts or bone graft substitutes. Barrier membranes should be placed between the bone defect and gingival tissues to achieve guided tissue regeneration. Maxillary canine teeth with pockets on their palatal side that have already progressed to form an oronasal fistula require extraction and oronasal fistula repair. Deep infrabony defects in multirooted teeth with bone loss that undermines a furcation can infect the pulp through a furcation canal, resulting in secondary endodontic disease. Similarly, if periodontitis has progressed apically and reached the apex of the root of a tooth, secondary endodontic disease will develop. Saving such teeth also requires endodontic therapy (*see below*), and the prognosis is determined by the extent of periodontal disease.

Teeth that have become mobile because of loss of attachment should be extracted. They can sometimes be saved through major periodontal surgery procedures, but disease will recur without drastic changes in home oral hygiene. Extraction allows the tissues to heal. A pet dog or cat can function perfectly fine without teeth.

Prevention: Prevention of gingivitis is the same as its treatment: plaque removal and control. Plaque is a typical biofilm, composed of many microorganisms that differ from their planktonic forms. In a biofilm, microorganisms are more resistant to antibiotics, disinfectants, and antibacterial agents. However, biofilms are easily and effectively removed mechanically with a toothbrush. Even large accumulations of supragingival plaque are easily removed by toothbrushing. The teeth should be brushed daily to remove plaque and prevent calculus (tartar) accumulation. Some dogs and cats may not allow regular toothbrushing, so the plaque should be removed by wiping with a gauze pad at least every second or third day. Only the outside (labial and buccal) surfaces of the teeth may be approachable for brushing in most dogs and cats. Plaque that remains on the tooth surface for >3 days mineralizes to form calculus that cannot be removed by brushing. Although calculus gives the appearance of unhealthy teeth, its contribution to periodontal disease is minor.

Texture of the diet, toys, and treats can affect the self-cleansing mechanisms of the teeth. Firm, fibrous items that allow tooth penetration can wipe plaque from the tooth surfaces during chewing. In addition to texture, some diets are formulated to

include ingredients that help decrease oral bacteria or slow plaque mineralization.

Products that slow or prevent the attachment of pellicle or the adhesion of pioneering plaque bacteria may provide some benefit. The Veterinary Oral Health Council website (www.vohc.org) provides further information about products that meet certain requirements for plaque and/or calculus control.

Prevention of periodontitis is more complicated. Regular oral hygiene to remove supragingival plaque provides some protection to help prevent development of subgingival plaque and to minimize the number of periodontopathogens in the mouth. More importantly, predisposing factors should be identified and removed. Severe crowding can be relieved through selective extractions, predisposing anatomy can be modified, diabetes or renal failure can be treated and controlled, and inappropriate behaviors or parafunctional habits that damage the tissues can be addressed.

ENDODONTIC DISEASE

Etiology and Pathogenesis: Endodontic disease occurs when the dental pulp (odontoblasts, fibroblasts, undifferentiated mesenchymal cells, blood vessels, and nerves in the center of the tooth) becomes infected and/or inflamed. The pulp is protected from bacteria by the impervious enamel covering the dentin of the crown. Damage to the enamel, either through trauma or from a developmental abnormality that allows bacteria to reach the pulp, will result in pulpitis and possibly pulp necrosis. Blunt trauma can also injure the pulp beyond its ability to heal. A tooth with direct exposure of the pulp at a fracture site requires endodontic treatment or extraction. Teeth are fractured from external trauma (eg, catching rocks, automobile impacts, aggressive play) or from biting on inappropriate objects (eg, real bones regardless of the state of processing, hooves, antlers, hard nylon toys, rocks, fences, or cages). An inflamed or dead pulp releases inflammatory mediators into the periradicular tissues (through furcation canals into the periodontal ligament at the furcation of a multirooted tooth, through lateral canals into the periodontal ligament at the mid-root level, and through apical foramina into the periapical tissues). The tissues surrounding the apex of a tooth develop a periapical granuloma, cyst, or abscess.

Clinical Findings and Lesions: A discolored tooth (pinkish, purple, or gray) is

evidence of previous trauma and hemorrhage from the pulp into the dentinal tubules. An inflamed pulp can heal after a minor injury. However, more severe trauma will cause irreversible pulpitis, eventually leading to pulp necrosis. Because dental pulp has no collateral circulation, injuries heal less readily, and extravasated blood remains in the dentin, where it deteriorates rather than being removed. The most obvious indication of endodontic disease is a fractured tooth with exposure of the pulp chamber. The exposed pulp bleeds for only a short time. After the initial injury, it may appear as a red dot at the site of the exposure if the pulp remains vital, or as a black hole if it becomes necrotic. Either way, treatment is required. Drainage is most commonly through the fracture site.

However, a periapical abscess can occur if the site becomes occluded. The skin ventral to the medial canthus of the eye is a common site for swelling and purulent drainage from a fistula due to an endodontically diseased maxillary fourth premolar. This can also cause an intraoral red draining fistula near the mucocutaneous junction adjacent to the tooth. An abscessed maxillary canine tooth in dogs can cause swelling along the side of the nose; in cats, the swelling is often immediately rostral to the eye. Veterinary patients often do not give an indication of discomfort, even for conditions that cause severe orofacial pain in people.

On a radiograph of a tooth with a periapical granuloma or cyst, the typical lesion presents as a periapical lucency, ie, an irregular circular lesion with decreased radiopacity around a root tip. A tooth with an acute periapical abscess (painful accumulation of pus around the apex of a nonvital tooth) may not show distinct radiographic signs. Throughout life, the pulp produces dentin on the inside surface of the pulp cavity, resulting in a constantly decreasing cross-sectional width of the pulp chamber in the crown and root canal in the root of the tooth. A necrotic pulp discontinues its normal dentin production, and thus it falls behind that of a normally maturing tooth adjacent to it or on the contralateral side. Conversely, an inflamed pulp produces dentin at an accelerated rate. If there is generalized pulpitis, the effect can be an apparent accelerated aging of the entire tooth with an abnormally narrow root canal space and pulp chamber. Generally, when evaluating a tooth with endodontic and/or periapical disease, the focus should be on structural defects at its crown and root apex, the width of its pulp cavity, and the appearance of the periapical tissues.

Treatment: Teeth with irreversible pulpitis or pulp necrosis require either endodontic treatment (root canal therapy) or extraction. Except in very young animals, one of these options is indicated for every tooth in which a fracture has exposed the pulp chamber. Canine teeth in dogs and cats and carnassial teeth (maxillary fourth premolars and mandibular first molars) in dogs are considered strategic teeth. Root canal therapy of these teeth is much more comfortable for the animal than extraction; it also allows continued function. Military, police, and assistance dogs may require fabrication and placement of a full or partial prosthodontic crown.

TOOTH RESORPTION

(Resorptive lesion, Cervical lesion, Neck lesion, Feline odontoclastic resorption lesion)

Resorption of tooth structure occurs through the action of odontoclasts—cells virtually identical to osteoclasts. It can occur on the external or internal tooth surface (external or internal resorption). Odontoclast activity can be stimulated by inflammation, pressure from adjacent structures, orthodontic tooth movement, as a result of normal processes such as exfoliation of deciduous teeth, or in the absence of these processes (idiopathic). This idiopathic tooth resorption occurs sporadically in many species (including people), but it is most frequently seen in domestic cats.

Etiology and Pathogenesis: Tooth resorption in cats begins with a loss of the normal periodontal ligament architecture and focal damage to the cementum that covers the root surface. Microscopic areas of root resorption often repair uneventfully in cats. Tooth resorption from any cause occurs through the action of odontoclasts that remove tooth structure, creating a resorptive lacuna. In many but not all lesions, concomitant osteoblast and cementoblastic activity replaces the lost tooth with bone or cementum. If repair does not occur, the resorption progresses into dentin and extends coronally into the crown of the tooth where it undermines the enamel to cause clinically apparent defects on the tooth surface (at the “neck” of the tooth). Inflammation from periodontitis is known to cause external resorption and is most likely responsible for tooth resorption in areas of periodontal disease. However, the etiology of idiopathic tooth resorption affecting multiple (possibly all) teeth in cats has not

yet been proved. Excessive intake of dietary vitamin D has been hypothesized as one possible cause among many others.

Clinical Findings and Lesions: The clinical appearance of tooth resorption greatly varies. In cats, the mandibular third premolar (the first cheek tooth) is often the first tooth affected. In dogs, premolar and molar teeth are most commonly involved. Small lesions on the enamel of the tooth crown usually begin somewhere on the root surface but can progress coronally and then appear at the gingival margin as inflamed granulation tissue filling a defect. The margin of the defect has a sharp ledge of enamel. At this stage, the visible part of the lesion is small, with most of the defect affecting the roots. Tooth resorption is characterized by severity (stage) and radiographic appearance (type).

Stage 1 lesions affect the cementum or cementum and enamel but have not yet progressed into the dentin.

Stage 2 lesions affect the dentin but have not yet progressed into the pulp cavity.

Stage 3 lesions affect the pulp cavity, but most of the tooth retains its integrity.

Stage 4 lesions have significant crown or root damage, with most of the tooth having lost its integrity.

Stage 5 lesions have remnants of dental hard tissue visible only as irregular radiopacities, and gingival covering is complete.

Lesions are categorized radiographically as type 1 when a focal or multifocal radiolucency is present in the tooth with otherwise normal radiopacity and normal periodontal ligament space (inflammatory resorption), type 2 when there is narrowing or disappearance of the periodontal ligament space (dentoalveolar ankylosis) in at least some areas and decreased radiopacity of part of the tooth (replacement resorption, moth-eaten "ghost" roots), or type 3 when features of both type 1 and type 2 are present in the same tooth.

Tooth resorption lesions exposed to the oral cavity may cause discomfort. Lesions limited to root surfaces only are unlikely to cause discomfort or other clinical signs unless they are associated with resorption of bone adjacent to the tooth resorption (eg, resorption caused by painful inflammation from periodontal or endodontic disease).

Diagnosis: Marginal gingivitis of individual teeth in the absence of periodontitis may indicate an early subgingival lesion. Lesions under the gingival margin can be identified by sharp dental exploration. Larger lesions are identified by their typical appearance on

the tooth surface. Internal resorption may sometimes appear as pinkish discoloration of the crown but usually is only identifiable radiographically as round to oval-shaped areas of decreased radiopacity.

Treatment and Prevention: Most teeth affected with resorptive lesions should be extracted. Surgical crown amputation with intentional retention of already resorbing dental tissues can be performed on teeth that are radiographically confirmed to be type 2 lesions in the absence of periodontitis, endodontic disease, and stomatitis (see p 361). Oral hygiene prevents inflammatory lesions caused by marginal periodontitis, and root canal therapy or extraction of endodontically involved teeth prevents resorption caused by apical periodontitis. Idiopathic lesions cannot be prevented, because their etiology is unknown.

DEVELOPMENTAL ABNORMALITIES

Proper growth and development of the oral cavity depends on a series of events that must occur normally and in the proper sequence. Genetic abnormalities or trauma that affects either the developing tissues or the timing of their development can cause abnormalities. Defects that decrease comfort, health, or function require treatment; those that result in only an esthetic problem do not. Common developmental problems include persistent deciduous teeth, unerupted teeth, malformed teeth, malocclusion, and malformed jaws.

Persistent Deciduous Teeth

Deciduous teeth of kittens and puppies are designed to function in a small mouth (fewer in number and smaller in size) and for a temporary period. Dental trauma during this time of energetic oral exploration is often compensated for by the exfoliation of the damaged teeth as the permanent teeth erupt. The permanent teeth are larger and more numerous, erupting as the jaws lengthen to accommodate them.

Exfoliation of deciduous teeth is a complex process, part of which involves pressure exerted by the crown of the subjacent permanent tooth against the root of the deciduous tooth. If the permanent tooth does not erupt in the correct position, the deciduous tooth may remain firmly in position. This may be due to hypodontia with no succedaneous permanent tooth, a genetically malpositioned permanent tooth bud, or traumatic displacement of the tooth

bud. Persistence of a deciduous tooth in areas of wide tooth spacing may not cause a problem. However, if the deciduous tooth causes crowding with the permanent tooth (often the case with canine teeth in dogs), then the area is predisposed to periodontitis. Additionally, the displaced permanent tooth can itself result in traumatic occlusion that requires treatment. Timing of deciduous tooth exfoliation and permanent tooth replacement are genetically determined. In rare cases, trauma during tooth development can cause displacement of a tooth bud that affects exfoliation.

Most commonly, two canine teeth (one deciduous and one permanent) are present at the same time. The permanent maxillary canine tooth erupts mesial ("rostral") to the deciduous one, giving the appearance of a wider and more blunt canine tooth rostral to a narrower one with a sharper cusp. The permanent mandibular canine tooth erupts lingual ("medial") to the deciduous one, giving the appearance of a wider and more blunt canine tooth toward the tongue next to a narrower one with a sharper cusp positioned toward the lip. In the premolar area, it is common to see a deciduous tooth in an area with no simultaneous permanent tooth. A smaller than normal premolar should be radiographed for evaluation of its anatomy and root structure to determine whether it is a deciduous tooth.

A deciduous tooth should be extracted when it remains firmly attached (no mobility) after its successor permanent tooth has erupted. Persistent deciduous teeth that do not have a permanent tooth replacement may be left in place if the roots are strong. However, radiographs should be taken to verify there are no embedded or impacted permanent teeth at the site and that the roots are not being resorbed.

Because most persistent deciduous teeth are genetic, pets with this problem should not be bred unless the condition is known to have been caused by trauma.

Unerupted Teeth

Tooth eruption is genetically programmed. Some breeds, particularly small breeds (eg, Maltese), are predisposed to delayed or incomplete eruption. Some brachycephalic breeds are predisposed to malpositioned first premolar teeth that remain unerupted because of their abnormal position. Trauma can also move a tooth bud into a position in which it is unable to erupt because of impact against another structure.

In some breeds (particularly the terrier breeds), missing premolars are considered

a variation of normal. But in most animals, an edentulous area where there should be a tooth is an indication for radiography. An unerupted tooth is easily identified. Embedded refers to an unerupted tooth covered in bone, the eruption of which is compromised by lack of eruptive force. Impacted refers to an unerupted or partially erupted tooth, the eruption of which is prevented by contact with a physical barrier.

Teeth that are incompletely erupted with a persistent gingival covering can be treated with operculectomy (a form of gingivectomy) to sculpt the tissue to a normal architecture. Individual teeth that are completely unerupted after maturity may remain quiet and require only monitoring. However, they can also form dentigerous cysts that can destroy large areas of the jaws. Mandibular first premolars are significantly predisposed to cyst formation, particularly in brachycephalic breeds. For that reason, any missing mandibular first premolar should always be radiographed; any that are discovered should be removed or closely monitored with periodic radiographs. Other unerupted teeth should be removed if they cause a problem. Surgical removal of deeply unerupted mandibular canine teeth can be challenging.

Animals with unerupted teeth should not be bred unless it is known the condition was caused by trauma.

Malformed Teeth

Any interruption during tooth formation can result in a deformed tooth. The insult can be traumatic, metabolic, infectious, or rarely genetic. Insults to epitheliogenesis (eg, parvovirus, distemper virus, high fever) that occur during amelogenesis causes enamel hypoplasia or hypomineralization. Insults to dentin formation can cause deformed or missing roots.

Enamel abnormalities can be regional, with circumferential lines of missing enamel (rough surface with stairing), or generalized with complete loss of enamel. Radicular dysgenesis can present with relatively normal appearing crowns that are mobile. The lack of roots is readily identified on radiographs. An interesting individual tooth abnormality that appears to be genetic is convergent roots of the mandibular first molar. This anomaly less commonly affects other teeth. The crown may appear normal, or it may have a small developmental groove on the buccal surface extending from the gingival margin. On a radiograph, the roots converge apically instead of having their normal divergent position. The crown sometimes appears too large in relation to

the size of the roots. The convergence causes the floor of the pulp chamber to arch dorsally into the main pulp chamber, giving it the radiographic appearance of a "dens-in-dente" or dens invaginatus. These teeth commonly have a communication from the periodontal ligament to the pulp chamber in the furcation area, resulting in an extremely high rate of endodontic disease. Many other individual tooth anomalies are seen occasionally, such as supernumerary teeth, twinning and fusion of teeth, supernumerary roots, and "peg" teeth (short cylindrical teeth).

Enamel hypoplasia or hypomineralization is treated with early dentin sealant to prevent bacterial ingress to the pulp. Composite resin veneers can also protect the softer dentin from abrasion and provide a smooth surface on which plaque is less able to form, but they will eventually wear or chip. Root dysgenesis carries a poor longterm prognosis. The teeth can be maintained for years with strict oral care and avoidance of any dental trauma or overuse. Individual anomalous teeth should be evaluated for associated pathology; many cause no problem and do not require treatment.

Malformed teeth are the result of trauma, infections, or genetics. Routine caution and care during tooth development prevents most of them.

Malocclusion and Malformed Jaws

Malocclusion is nearly always genetic; however, trauma during development can interfere with normal growth. Maxillary length is easier to manipulate than mandibular length through selective breeding. As a result, a preference for longer faces and noses inadvertently selects for mandibular distocclusion (ie, overbite, or lower jaw appears shorter than upper jaw), whereas selecting for a "blockier" head or shorter nose results in mandibular mesiocclusion (ie, underbite, or lower jaw appears longer than upper jaw). The upper and lower jaws develop at different rates, making the timing of tooth eruption critical. If the jaws have an abnormal relationship to each other at the time the permanent teeth gain enough height to occlude, then the dentition is locked into the abnormal position. If this occurs unilaterally, it can allow continued jaw lengthening on one side while arresting it on the other side, resulting in a mismatch of the central incisor midlines (ie, asymmetric skeletal malocclusion such as "wry" bite).

The most common maxillary-mandibular discrepancy is a horizontal symmetric skeletal malocclusion, resulting in mandibu-

lar mesiocclusion (class 3 malocclusion) or mandibular distocclusion (class 2 malocclusion). The latter problem often causes traumatic occlusion when the mandibular canine teeth impact against the most rostral hard palate. Linguoversion of the mandibular canines often accompanies this problem, because they can be directed palatally as they erupt along the palatal surface of the maxillary canines. Individual tooth malposition (dental malocclusion or class 1 malocclusion) can also be genetic, such as mesioversion of the canine teeth (ie, "lance projection") in Dachshunds and Shetland Sheepdogs.

During the deciduous dentition period, interceptive orthodontics can be performed by selectively extracting deciduous teeth. If there is dental interlock, then extracting locked teeth can allow the jaws to grow to their genetic potential. Deciduous rostral crossbite can be treated by extraction of the deciduous maxillary incisors. This not only relieves the interlock but also encourages the permanent incisors to erupt in a more labial angle (they normally erupt on the palatal side of the deciduous incisors) to help correct the malocclusion. Likewise, deciduous mandibular distocclusion can be treated by extraction of the deciduous mandibular canine teeth. Again, this not only relieves the dental interlock but also encourages the permanent mandibular canine teeth to erupt in a more labial angle (they normally erupt on the lingual side of the deciduous canines) to help correct the malocclusion. Whenever deciduous teeth are extracted, touching the tooth bud of the developing permanent teeth must be avoided so as not to damage the enamel organs or developing enamel. This damage can cause brown spots on the crowns of permanent teeth due to focal enamel defects. Instruments should not be inserted on the palatal side of deciduous maxillary incisors or on the lingual side of deciduous mandibular canines. Even with proper technique, enamel damage can occur, because the enamel epithelium can be tugged as the deciduous tooth is extracted from the alveolus.

Mandibular mesiocclusion in the permanent dentition is considered normal for many brachycephalic breeds and does not require treatment unless it results in traumatic occlusion. If the mandibular canines impact against the palatal aspect of the third or second maxillary incisors, then extraction of the maxillary incisors in contact will create a wide diastema into which the canine tooth can fit, resolving the

problem. The rostral crossbite (ie, maxillary incisors positioned lingual to the mandibular incisors) rarely causes discomfort or health problems. In contrast, mandibular distocclusion often requires orthodontic or surgical intervention. Canine teeth can be moved into a nontraumatic (not always normal) position that is comfortable and functional. Alternatively, the tooth can be shortened and the pulp treated with vital pulp therapy. This approach requires sterile technique to avoid introduction of infection into the pulp and followup radiographs throughout life to monitor the need for definitive endodontic treatment.

Only animals with a normal, healthy occlusion should be bred.

DENTOFACIAL TRAUMA

Teeth and jaws play a prominent role in the interaction of animals with their environment. This predisposes them to traumatic injury, most commonly fights with other animals, automobile impacts, getting caught on fences, or falling onto hard surfaces. Mandibles can also suffer spontaneous pathologic fractures due to severe periodontitis around the mandibular first molars or to neoplasia.

A fractured tooth with a red or black spot in the center of an irregular crown surface indicates pulp exposure. A missing tooth after trauma might be avulsed or may be fractured with retained root fragments, which can be determined radiographically. Fractured mandibles cause acute malocclusion and inability to eat. The midline of the mandible is usually displaced toward the side of the fracture. The mouth may be held open, particularly in bilateral mandibular fractures.

Fractured teeth are treated as described above (see p 181). Avulsed teeth can be replaced if treated promptly (within hours). The owner should immediately place the tooth in a tooth transport medium or milk, without touching the root. The alveolus and root surface should be gently flushed with lactated Ringer's solution to remove dirt, and then the tooth placed into the alveolus and stabilized for 1 mo with interdental wiring. Rigid stabilization with acrylic or composite is less ideal for the periodontal ligament repair because it encourages ankylosis, but it may be a good idea to protect against abuse of the recently replaced tooth. Root canal therapy is done when the fixator is removed.

Soft-tissue trauma is repaired using primary closure with absorbable sutures. Oral soft tissues are vascular and heal quickly. Oral flushes with dilute chlorhex-

idine solution every 2 days helps decrease oral bacteria during healing.

Maxillary fractures can be stabilized with wire and sutures. Mandibular fractures can be more challenging; when possible, they can be repaired with interdental wiring and an intraoral splint made of bis-acryl composite resin. Other options include tape muzzling, cerclage wiring, interarch splinting, intra-osseous wiring, external skeletal fixation, or miniplates. Preserving normal occlusion is important. With rigid stabilization, the pet can usually readily eat soft food until the appliance is removed in 6–8 wk.

Caudal mandibular body fractures in the area of or caudal to diseased molars requiring extraction are much more problematic because of the lack of teeth on both sides of the fracture and the thinner bone caudal to the body of the mandible. Plates can be used, but the prognosis is guarded. Interarch splinting (ie, between the upper dental arch to the lower dental arch) can be successful, but there is a risk of aspiration while the splint is in place if the animal vomits. A feeding tube is used until the splint is removed.

DENTAL CARIES

Dental caries, or bacterial infections of the teeth, are common in people, uncommon in dogs, and essentially nonexistent in cats. This may be related to the fact that human saliva is more acidic, human teeth contain many pits and fissures, and the human diet is rich in highly refined carbohydrates. The saliva of dogs and cats is more alkaline than that of people, their teeth contain fewer pits and fissures, and their diet is less rich in carbohydrates. Furthermore, cariogenic bacteria are less common in the mouths of dogs and cats than in those of people. The initial lesion of caries is acidic demineralization of the enamel. This is accomplished by cariogenic bacteria that ferment sugar, thus releasing acids onto the tooth surface.

In dogs, caries usually occurs on the occlusal surfaces of molar teeth. It has the appearance of a brown to black cavitated lesion with a soft surface into which a sharp explorer tip can penetrate and "stick."

The carious tooth structure must be removed using a dental bur until healthy dentin is reached. A radiograph should be taken to determine whether the infection has spread to the pulp, in which case the tooth also requires root canal therapy. The missing tooth structure is then restored using either composite or amalgam.

Dogs that have had dental caries are predisposed to additional lesions; topical treatment with a stannous fluoride product every 2 wk may help prevent future caries in these animals. Because dogs do not expectorate, they swallow

any medications used. Therefore, only small amounts should be placed on the occlusal surfaces of the teeth. Fluoride can cause gastritis, and it can be nephrotoxic if significant amounts are ingested.

PHARYNGEAL PARALYSIS

Pharyngeal paralysis may be the result of a central or peripheral nervous system disorder or may develop secondary to severe local disease that may cause collapse, obstruction, or malfunction of the pharynx. Of the CNS disorders, rabies (*see* p 1302) is the most important of the viral causes of encephalomyelitis, although perhaps not the most frequent. CNS intoxication, lead poisoning, cranial trauma, intracranial abscessation, and neoplasia may also result in pharyngeal paralysis in many species.

Peripheral causes of pharyngeal paralysis include pharyngeal trauma and abnormalities of the pharyngeal adnexa, particularly involving the guttural pouch of horses. Disorders of the guttural pouch resulting in pharyngeal paralysis include guttural pouch mycosis, guttural pouch empyema, guttural pouch neoplasia, and osteoarthropathy of the temporohyoid joint. Equine protozoal myeloencephalitis (*see* p 1309) can also cause pharyngeal paralysis in some horses. The degree of pharyngeal paralysis ranges from complete to incomplete, depending on whether the abnormality is unilateral or bilateral or central versus peripheral. Unilateral lesions may result in partial pharyngeal malfunction. For example, horses with guttural pouch disease may be able to swallow but may still develop clinical signs of dysphagia (eg, nasal discharge of food or water, coughing).

Clinical Findings and Lesions: Clinical signs of pharyngeal paralysis include dysphagia with oral or nasal discharge of food, water, or saliva. Other clinical signs include coughing, dyspnea, ptialism, or bruxism. Affected animals are at risk of inhalation pneumonia, dehydration, and cardiovascular and respiratory shock. Affected animals frequently have one or more signs, including pyrexia, coughing, retching, and signs compatible with esophageal obstruction. Severely affected animals may die or should be considered for euthanasia. Animals with dyspnea may require an emergency

tracheostomy before any clinical diagnostic techniques can be performed.

Diagnosis: The history and clinical signs are usually indicative of pharyngeal paralysis. A baseline CBC and biochemistry profile should be performed. Affected animals typically may be hemoconcentrated, have electrolyte and acid-base disturbances, and may exhibit prerenal azotemia. Serology, skull radiographs, thoracic radiographs to evaluate for aspiration pneumonia, endoscopy, ultrasonography, CT, and MRI (if available) are all valuable aids to determine whether the underlying cause is central or peripheral. The use of CT and MRI has particular value in evaluating CNS causes of pharyngeal paralysis in small animals. Animals suspected of having rabies should be handled appropriately (*see* p 1302).

Treatment: Treatment protocols for pharyngeal paralysis vary depending on the underlying cause. Treatment generally includes the administration of antimicrobial and anti-inflammatory medications. Because of the inability to swallow normally, IV administration is preferred. Animals with hemoconcentration should be administered IV fluids. If the animal is unable to eat without aspiration, extraoral or parenteral nutrition should be strongly considered. Extraoral alimentation with pharyngostomy, esophagostomy, or nasogastric tubes or temporary rumenostomy in ruminants can be an economical and effective way to provide nutritional support. Other treatments include local therapy for pharyngeal abscesses.

The prognosis for pharyngeal paralysis varies with the instigating cause. The prognosis for pharyngeal abscessation can be favorable, whereas the prognosis for guttural pouch disease can be guarded. If affected animals do not improve after 4–6 wk of symptomatic therapy, the prognosis is poor and euthanasia should be considered.

DISEASES OF THE RECTUM AND ANUS

ANAL SAC DISEASE

Anal sac disease is the most common disease entity of the anal region in dogs. Small breeds are predisposed; large or giant breeds are rarely affected. In cats, the most common form of anal sac disease is impaction.

Etiology and Pathogenesis: Anal sacs may become impacted, infected, abscessed, or neoplastic. Failure of the sacs to express during defecation, poor muscle tone in obese dogs, and generalized seborrhea (which produces glandular hypersecretion) lead to retention of sac contents. Such retention may predispose to bacterial overgrowth, infection, and inflammation.

Clinical Findings and Lesions: Signs are related to pain and discomfort associated with sitting. Scooting, licking, biting at the anal area, and painful defecation with tenesmus may be noted. Induration, abscesses, and fistulous tracts are common. In impaction, hard masses are palpable in the area of the sacs; the sacs are packed with a thick, pasty, brown secretion, which can be expressed as a thin ribbon only with a large amount of pressure. When the sacs are infected or abscessed, severe pain and often discoloration of the area are present. Fistulous tracts lead from abscessed sacs and rupture through the skin; these must be differentiated from perianal fistulas. Anal sac neoplasms are usually nonpainful and are associated with perineal edema, erythema, induration, or fistula formation. Apocrine gland adenocarcinomas of the anal sac are typically seen in older female dogs. These dogs may be presented for signs secondary to hypercalcemia, such as polyuria and polydipsia, or for problems related to the perineal mass.

Diagnosis of impaction, infection, or abscessation is confirmed by digital rectal examination, at which time the sacs can be expressed. Microscopic examination of the contents from infected sacs reveals large numbers of polymorphonuclear leukocytes and bacteria. A tumor should be suspected (anal sac apocrine adenocarcinoma) in anal sacs that are firm, enlarged, and nonexpressible even with irrigation. Ultrasonographic examination may be useful to determine whether a firm, nonexpressible anal sac is due to infection/abscessation or neoplastic

disease. In the case of a suspected tumor, the diagnosis should be confirmed by biopsy. Regional and systemic metastasis should be evaluated, and serum calcium measured.

Treatment: Impacted anal sacs should be gently, manually expressed. A softening or ceruminolytic agent or saline can be infused into the sac if the contents are too dry to express effectively. Infected sacs should be cleaned with antiseptic, followed by local and systemic antibiotic therapy. Hot compresses, applied every 8–12 hr for 15–20 min each, are beneficial for abscesses. Repeated weekly flushings combined with infusion of a steroid-antibiotic ointment may be needed. Adding supplemental fiber to the diet may increase fecal bulk, facilitating anal sac compression and emptying. If medical treatment is ineffective, or if neoplasia is present, surgical excision of the sac is indicated. The closed technique for excision is preferred and has the lowest complication rate. However, fecal incontinence, a common complication of anal sac surgery, may result from damage to the caudal rectal branch of the pudendal nerve and may be complete if damage is bilateral. Chronic fistula formation may be seen when sac removal is incomplete or when the sac ruptures. Scar formation in the external anal sphincter may result from surgical trauma and result in tenesmus. (See *also* APOCRINE GLAND TUMORS OF ANAL SAC ORIGIN, p 950.)

PERIANAL FISTULA

Perianal fistula is characterized by chronic, purulent, malodorous, ulcerating, sinus tracts in the perianal tissues. It is most common in German Shepherds and is also seen in Setters and Retrievers. Dogs >7 yr old are at higher risk.

Etiology and Pathogenesis: The cause is unknown, although many theories have been proposed. Contamination of the hair follicles and glands of the anal area by fecal material and anal sac secretions may result in necrosis, ulceration, and chronic inflammation of the perianal skin and tissues. Affected animals may be predisposed to generalized skin problems. Hypothyroidism, an immunologic defect, or an immune-mediated component may contribute to susceptibility. The likelihood of contamina-

tion is greater in dogs with a broad-based tail; deep anal folds may cause feces to be retained within rectal glands and play a major role. The draining tracts are lined with chronic inflammatory tissue and often extend to the lumen of the rectum and anus. Infection may spread to deeper structures involving the external anal sphincter and, therefore, should be treated promptly.

Clinical Findings: In dogs, signs include attitude change, tenesmus, dyschezia, anorexia, lethargy, diarrhea, and attempts to bite and lick the anal area. Signs in cats are similar to those in dogs but may include matting of fur and sitting in the litter box.

Treatment: Historically, management of perianal fistulae was frustrating for both veterinarians and pet owners. Surgical therapy traditionally included anal sacculotomy, in addition to destroying the diseased tissues. Surgical techniques included excision, debridement, fulguration, and cryosurgery. Amputation of the tail at its base was once advocated alone or adjunctively with other therapy. Surgery is now only recommended for fistulae resistant to medical therapy. Sequelae of surgery include fecal incontinence, rectal stricture, and recurrence.

Cyclosporine has been an effective treatment at a dosage of 5–10 mg/kg, bid for 10–20 wk and then for an additional 4 wk after all fistulae appear to be healed. Concurrent administration of ketoconazole (8 mg/kg/day) allows the dosage (and cost) of cyclosporine therapy to be reduced (1–3.5 mg/kg/day). Prompt treatment is recommended early in the course of the disease to reduce the likelihood of recurrence. However, some dogs are intolerant of ketoconazole. Cyclosporine at a dosage of 5 mg/kg/day can effectively decrease the severity of lesions. In one study, the combination of cyclosporine therapy for 12 wk followed by surgical excision of any remaining draining tracts, along with cryptectomy and anal sacculotomy, successfully resolved disease with minimal recurrence. Topical tacrolimus (0.1% ointment applied once to twice daily) in combination with a tapering course of prednisone (2 mg/kg/day for 2 wk, 1 mg/kg/day for 4 wk, and then 1 mg/kg every 2 days for 10 wk) with metronidazole (10 mg/kg, bid for 2 wk) and a novel-protein diet has also been found to be effective in some dogs. Other aspects of medical management include the use of fecal softeners to

reduce dyschezia. Perianal cleansing and antibiotics may reduce inflammation.

PERIANAL TUMORS

See HEPATOID GLAND TUMORS, p 951, and APOCRINE GLAND TUMORS OF ANAL SAC ORIGIN, p 950.

PERINEAL HERNIA

Perineal hernia is a lateral protrusion of a peritoneally lined hernial sac between the levator ani and either the external anal sphincter muscle or the coccygeus muscle. Incidence in intact 6- to 8-yr-old male dogs is disproportionately high, and Welsh Corgis, Boston Terriers, Boxers, Collies, Kelpies and Kelpie crosses, Dachshunds and Dachshund crosses, Old English Sheepdogs, and Pekingese are at higher risk.

Etiology and Pathogenesis: Many factors are involved, including breed predisposition, hormonal imbalance, prostatic disease, chronic constipation, and weakness of the pelvic diaphragm due to chronic straining. The higher incidence among sexually intact males is evidence that hormonal influences probably play a primary role. Prostatic hypertrophy attributed to sex-hormone imbalance has been strongly implicated. Both estrogens and androgens have been cited as causative agents.

Clinical Findings and Diagnosis: Common signs include constipation and obstipation, tenesmus, and dyschezia. Stranguria and urinary obstruction may develop secondary to retroflexion of the bladder and prostate. Visceral strangulation may be seen. A perineal swelling ventrolateral to the anus is evident. Herniation may be bilateral, but two-thirds are unilateral and >80% of these are on the right side.

The mass is soft and fluctuant and may be reduced digitally. A firm, painful swelling may be compatible with retropulsion of the bladder and prostate. Determination of contents is often made by rectal examination and perineal centesis (to determine whether urine is present). More than 90% of perineal hernias contain a rectal deviation, which is a sacculation of the rectum into the hernial sac, where the layers of the rectal wall remain intact.

Treatment: Perineal hernia is rarely an emergency, except when the bladder has strangulated and the animal is unable to urinate. If catheterization cannot be done, the urine should be removed by cystocente-

sis and an attempt made to reduce the hernia. An indwelling urinary catheter may be necessary to ensure urethral patency and prevent recurrence of obstruction.

Surgical correction is always indicated, and concurrent castration to reduce recurrence is recommended. The prognosis is guarded because of the high incidence of recurrence (10%–46%) and postoperative complications such as infection, rectocutaneous fistula, anal sac fistula, ischiatic and pudendal nerve entrapment, and rectal prolapse.

RECTAL AND ANORECTAL STRICTURES

Strictures are a narrowing of the lumen due to cicatricial tissue. Injury may result from foreign bodies or trauma (eg, bite wounds, accidents) or as a complication of inflammatory disease (eg, perianal fistula disease, histoplasmosis, inflammatory bowel disease, anal sacculitis).

Neoplasia, enlarged prostate, and scar tissue after perianal fistula or anal sac abscess may all predispose to extraluminal constriction. In small animals, anorectal stricture is more common than rectal strictures, but neither is frequent. Strictures are more common in German Shepherds, Beagles, and Poodles.

Rectal stricture in cattle may result from trauma, neoplasia, or fat necrosis impinging on or within the lumen, or from defects associated with rectal and vaginal strictures. Rectal strictures in pigs are seen secondary to enterocolitis, after repair of rectal prolapse, and as a sequela of ulcerative proctitis induced by salmonellae. Treatment in small animals includes general anesthesia followed by balloon dilation of the stricture, combined with intralesional injections of long-acting corticosteroids (triamcinolone). Treatment in large animals may include resection of the strictured area or rectal pull-through.

RECTAL NEOPLASMS

Malignant rectal neoplasms are usually adenocarcinomas in dogs and lymphosarcomas in cats. Adenocarcinomas are slow growing and infiltrative. Local or systemic metastasis may develop before tenesmus, dyschezia, hematochezia, or diarrhea is seen. Surgery is the treatment of choice for adenocarcinomas, but it may be unrewarding because metastasis has usually occurred before the diagnosis. Cats and dogs with rectal lymphosarcoma are treated medically with antineoplastic drugs.

RECTAL POLYPS

Rectal adenomatous polyps are an infrequent, usually benign disease, primarily of small animals. The larger the polyp, the greater the potential for malignancy. Signs include tenesmus, hematochezia, and diarrhea. The polyp is usually palpable per rectum and bleeds easily with surface ulceration. Periodically, the polyp may prolapse through the anal orifice. Surgical excision is usually followed by rapid clinical recovery and lengthy survival time. New polyps may develop after surgery. A biopsy should always be submitted for histopathologic diagnosis.

RECTAL PROLAPSE

In rectal prolapse, one or more layers of the rectum protrude through the anus due to persistent tenesmus associated with intestinal, anorectal, or urogenital disease. Prolapse may be classified as incomplete, in which only the rectal mucosa is everted, or complete, in which all rectal layers are protruded.

Etiology: Rectal prolapse is common in young animals in association with severe diarrhea and tenesmus. Causal factors include severe enteritis, endoparasitism, disorders of the rectum (eg, foreign bodies, lacerations, diverticula, or sacculations), neoplasia of the rectum or distal colon, urolithiasis, urethral obstruction, cystitis, dystocia, colitis, and prostatic disease. Perineal hernia, or other interruption of normal innervation of the external anal sphincter, may also produce prolapse.

Animals of any age, breed, or sex may be affected. Rectal prolapse is probably the most common GI problem in pigs due to diarrhea or weakness of the rectal support tissue within the pelvis. In cattle, it may be associated with coccidiosis, rabies, or vaginal or uterine prolapse; occasionally, excessive "riding" and associated traumatic injury may be causative in young bulls. It is common in sheep with short tail docking and especially in feedlot lambs, in which high-concentrate rations may be causative. The use of estrogens as growth promotants, or accidental exposure to estrogenic fungal toxins, may also predispose large animals to rectal prolapse.

Clinical Findings, Lesions, and

Diagnosis: An elongated, cylindrical mass protruding through the anal orifice is usually diagnostic. However, it must be differentiated from prolapsed ileocolic intussuscep-

tion by passing a probe, blunt instrument, or finger between the prolapsed mass and the inner rectal wall. In rectal prolapse, the instrument cannot be inserted because of the presence of a fornix.

Ulceration, inflammation, and congestion of the rectal mucosa is common. Early, there is a short, nonulcerated, inflamed segment; later, the mucosal surface darkens and may become congested and necrotic.

Treatment: In all animals, identifying and eliminating the cause of prolapse is of primary importance.

In **small animals**, treatment includes prompt replacement of viable prolapsed tissue to its proper anatomic location, or amputation if the segment is necrotic. Small or incomplete prolapses can be manually reduced under anesthesia by using a finger or bougie. Warm saline lavage and lubrication with a water-soluble gel should be applied to the prolapsed tissue before reduction. Alternatively, hypertonic sugar solution (50% dextrose or 70% mannitol) applied topically may be used to relieve edematous mucosa. The placement of a loose, anal purse-string suture for 5–7 days is indicated. Straining may be prevented by applying a topical anesthetic (1% dibucaine ointment) or by administering a narcotic epidural injection before or after reduction or correction. Postoperatively, a moistened diet and a fecal softener (eg, dioctyl sodium sulfosuccinate) are recommended. Diarrhea after surgery may require treatment.

When questionable viability of tissue prohibits manual reduction, rectal resection and anastomosis are required. When rectal tissue is viable but not amenable to manual reduction, celiotomy followed by colopexy is indicated to prevent recurrence. As in medical management, epidural anesthesia may be used to reduce straining.

In **large animals**, caudal epidural anesthesia is suggested to reduce straining, facilitate repositioning of the prolapse, and permit surgical manipulations. Reduction and retention with a purse-string suture is recommended. The suture should be loose enough to leave a one-finger opening into the rectum in pigs and sheep, and slightly larger in cattle and horses. Rectal prolapse in mares, if neglected, can lead to prolapse of the small colon. The blood supply to the small colon is easily disrupted. Replacement of a rectal prolapse with prolapse of the small colon followed by purse-string suture of the anus has a poor prognosis. More aggressive treatment of the prolapse is dictated by the condition of the rectum.

In general, the prolapse may be salvaged by conservative measures, unless obvious deep necrosis or trauma to the tissue exists, or the everted tissue is firm, indurated, and cannot be reduced. Under these circumstances, submucosal resection or amputation should be considered. Amputation of the rectum should be reserved for severe cases. Complete amputation has a higher incidence of rectal stricture formation, especially in swine. A prolapse ring, syringe case, or plastic tubing may be used as an alternative to surgical amputation in pigs and sheep. Postoperatively, the animal should receive antibiotics. Fecal softeners may be used in horses. Usually, it is not economically feasible to repair rectal prolapses in lambs ready for market.

RECTAL TEARS

A separation, rent, or tear in the rectal or anal mucosa is seen as a result of a laceration inflicted within the lumen. Foreign bodies (eg, sharp bones, needles, and other rough material) have been implicated. Bite wounds and, in large animals, trauma from rectal palpation are common causes. The tear may involve only the superficial layers of the rectum (partial tear) or penetrate all layers (complete tear).

Clinical Findings and Diagnosis:

Constipation and reluctance to defecate are usually attributed to pain. Diagnosis is based on tenesmus and hemorrhage, perineal discoloration, and inspection of the rectum and anus; fresh blood found on a glove or on feces after rectal examination is good evidence of a rectal tear. Edema may be present when the injury has persisted. The integrity of the external anal sphincter should be evaluated carefully.

Treatment: In all species, treatment should be initiated immediately. The anorectal area should be cleaned thoroughly and systemic broad-spectrum antibiotics administered. IV fluids and flunixin meglumine may be given to prevent or treat septic and endotoxic shock. In small animals, lacerations should be debrided and may be sutured through the anal orifice, via laparotomy, or through a combination of both depending on the location and degree of the tear. Antibiotics and fecal softeners should be administered postoperatively.

In cattle and horses, accidental perforation during rectal examination necessitates immediate treatment to reduce the risk of peritonitis and death. Exploration through-

out the abdomen should be slow, deliberate, and smooth. The temptation to use the fingertips excessively or to push the arm through a region of resistance must be avoided. Rectal tears in horses have been classified according to the tissue layers penetrated. Grade I tears involve the mucosa or submucosa. Grade II tears involve rupture of the muscular layers only. Grade III tears involve mucosa, submucosa, and muscular layers, including tears that extend into the mesorectum. Grade IV tears involve perforation of all layers of the rectum and extension into the peritoneal cavity.

Grade I tears may be treated conservatively with broad-spectrum antibiotics and IV fluids. Flunixin meglumine may be given to prevent or treat endotoxic shock. Mineral oil is given via stomach tube to soften feces, and the diet should consist of pasture grasses or alfalfa. Grade II and III tears require immediate and more extensive surgery. A consultation with a specialist is suggested immediately after diagnosis. Grade IV tears carry a grave prognosis; they should be repaired only if small and if treatment is instituted before the peritoneal cavity is grossly contaminated.

ENTERIC CAMPYLOBACTERIOSIS

Campylobacter spp are spiral, microaerobic, gram-negative bacteria that cause gastroenteritis in people and animals. Several *Campylobacter* spp are zoonotic. Many domestic animals develop acute gastroenteritis after ingestion of *Campylobacter* spp, including dogs, cats, calves, sheep, pigs, ferrets, mink, monkeys, and several species of laboratory animals. (See also BOVINE GENITAL CAMPYLOBACTERIOSIS, p 1347, AVIAN CAMPYLOBACTER INFECTION, p 2806, and ZOONOTIC DISEASES, p 2419.) Infection with *C. jejuni* is one of the most common causes of gastroenteritis in people worldwide and is the most extensively studied *Campylobacter* species.

Etiology: *Campylobacter* spp are spiral or curved rods that exhibit a characteristic corkscrew darting motility, mediated by a single polar flagellum. These are slow growing, with a generation time of ~90 min, fastidious, and require enriched medium and microaerobic conditions with increased CO₂ (3%–15% O₂, 3%–10% CO₂, 85% N₂) for growth.

The family Campylobacteraceae consists of three genera, including *Campylobacter* and *Arcobacter* associated with animal and human diseases. Certain species are present commensally in animals as suspected reservoirs for human infections. The thermophilic *Campylobacter* spp, *C. jejuni*, or *C. coli* have the highest prevalence and disease impact. *Campylobacter* species causing diseases in livestock include

C. jejuni subsp. *jejuni* (enteritis and abortion), *C. coli*, *C. mucosalis* (porcine enteritis), *C. upsaliensis*, *C. helveticus* (companion pet enteritis), *C. hyointestinalis* subsp. *hyointestinalis* (porcine and bovine enteritis), *C. sputorum* (abortions in sheep), and *C. fetus* subsp. *fetus* (isolated from intestinal tracts of sheep and cattle, sporadic abortions). Certain species such as *C. jejuni*, *C. hyointestinalis*, and *C. fetus* possess closely related subspecies with different disease foci. Initially, *Arcobacter* spp were considered to be aerotolerant campylobacters and are implicated in reproductive disorders, mastitis, gastric ulcers, and/or diarrhea in livestock, including *A. cryaerophilus* (previously *C. cryaerophila*), *A. skirrowii*, *A. thereius*, and *A. butzleri*.

Transmission and Epidemiology:

Transmission is food- or waterborne or via fecal-oral spread. Animals serve as reservoir hosts for *Campylobacter* spp infections in both animals and people throughout the world. The predominant ecologic niche for *Campylobacter* spp is the GI tract of a wide variety of domesticated and wild vertebrates, and zoonotic transmission from animals to people in meat of animal origin, especially chicken, is a food safety issue. *Campylobacter* spp are also commonly isolated from free-living birds, including migratory birds and waterfowl, crows, gulls, and domestic pigeons, which can contaminate environments of grazing animals. Wild

rodents and insects such as flies have also been reported to harbor and transmit *C jejuni*. Fecal contamination of the environment provides a ubiquitous source of these organisms under appropriate conditions for their survival. *Campylobacter* spp can persist for long periods in feces, milk, water, and urine, especially at temperatures close to 4°C. In adverse conditions, *C jejuni jejuni* converts to a viable nonculturable form that can be reactivated when ingested.

Human foods documented as contaminated with *Campylobacter* include chicken, turkey, beef, pork, fish, and milk. Domesticated poultry are the most significant reservoir of *C jejuni jejuni* for people, causing 50%–70% of cases; chicken meat is the number one source. Dogs and cats are commonly infected similar to their owners when they ingest undercooked poultry.

Pathogenesis: Bacterial motility, mucus colonization, toxin production, attachment, internalization, and translocation are among the processes associated with *C jejuni jejuni* virulence. Infection begins with ingestion of *C jejuni jejuni* in contaminated foods or water. Gastric acid provides a barrier, and the bacteria must reach the small and large intestines to multiply; *C jejuni* invades both epithelial cells and cells within the lamina propria.

Clinical Findings: Abdominal pain, fever, diarrhea, blood in feces, and inflammatory cells in feces demonstrate the inflammatory nature of the infection. Natural infections with *C jejuni jejuni* resulting in enteritis have been reported in juvenile macaques, weaning-age ferrets, dogs, cats, and swine. Chickens, rodents, ferrets, primates, rabbits, and pigs have been inoculated experimentally by various routes with *C jejuni* and subsequently developed enteritis. Clinical reports describe primary infections with systemic spread, infection with mucosal disease, infection without disease but with short-term bacterial persistence, and infection with resistance and no bacterial persistence. These reports support the idea that *C jejuni jejuni* produces a spectrum of disease scenarios, depending on the immune status of the host, bacterial virulence, gene expression, and other factors.

C jejuni jejuni, *C coli*, *C jejuni*, *C upsaliensis*, and *C helveticus* are the *Campylobacter* spp that have been associated with intestinal disease in **companion animals**. *C jejuni jejuni* causes diarrhea in dogs and cats, which

are considered a significant source of the bacterium for the human population. Diarrhea is usually acute but can be recurrent. Diarrhea lasting 515 days is the most common clinical sign in dogs <6 mo old. It may be watery to bloody with mucus and is sometimes bile-stained. Occasionally, the diarrhea becomes chronic and may be accompanied by fever and increased WBC count. Cats <6 mo old commonly have diarrhea, which may be bloody. Some infected cats show no signs. Additionally, *C jejuni jejuni* has been isolated in the profuse and odorless hemorrhagic vaginal discharge from late-pregnancy abortions in dogs.

In **cattle and sheep**, *Campylobacter* spp can cause enteritis and abortion, including *C jejuni jejuni*, *C fetus* subsp *fetus*, *C hyointestinalis* subsp *hyointestinalis*, and *C sputorum* (abortions in sheep). However, in studies that compared *C jejuni* prevalence in healthy cattle and in cattle considered “sick” because of diarrhea, the frequency of *Campylobacter* spp was not significantly different. Beef and dairy cattle can have significant levels of *Campylobacter*, with prevalences of 2.5%–60%. In a number of studies, cattle checked at slaughter harbored *Campylobacter* in gallbladders, large and small intestines, and liver. Fecal shed in cattle leads to contamination of milk and beef.

Campylobacters can contribute to colitis in weaning aged **pigs**. Swine commonly carry *C coli* and *C jejuni jejuni* as intestinal commensals, and studies in the USA, Netherlands, Great Britain, and Germany show that more than half of commercially raised pigs excrete the organisms. *C coli* strains comprise most isolates from pigs, causing first watery, then inflammatory diarrheal disease. Pigs have anorexia, fever, and diarrhea for 1–5 days followed by remission of clinical signs but continue to shed *C jejuni jejuni* in the feces. *C hyointestinalis hyointestinalis* and *C mucosalis* are also implicated as causes of enteritis in pigs. Concurrent infections with viruses, other bacteria (eg, *Escherichia coli*), and parasites increase the disease and pathology caused by *Campylobacter* spp in swine. *C hyointestinalis* subsp *lawsonii* has been isolated from pig stomachs; however, this subspecies has not been implicated in disease.

Birds, including intensively farmed poultry, appear to have a higher infection rate and carriage of *Campylobacter* spp, especially *C jejuni jejuni*, than other animals. In broilers, the organism may

colonize the palatine lymphoid tissues and the crop, leading to extremely rapid transmission through communal water troughs and standard fecal-oral spread. However, the organism has been isolated from the small intestines of clinically ill birds, especially psittacines (parrots) and passeriforms (finches and canaries), with hepatitis, lethargy, loss of appetite, weight loss, and yellow diarrhea. Mortality may be high. *Campylobacter* spp have also been isolated from free-living birds, including migratory birds and waterfowl, crows, gulls, and domestic pigeons; however, disease due to *C. jejuni jejuni*, for example in naturally infected birds, is rare.

Campylobacter GI disease has been reported in **exotic pets** (eg, ferrets, mink, primates, hamsters, guinea pigs, mice, and rats). Although clinical signs vary in these species, they generally include mucoid, watery, bile-streaked diarrhea (sometimes with blood), anorexia, vomiting, and fever. Prolonged infections are possible but uncommon; most infections are self-limiting with mild signs.

The following species have been isolated from birds, shellfish, reptiles, marine mammals, and livestock not known to be associated with disease symptoms:

C. avium, *C. hyointestinalis lawsonii*, *C. fetus subsp. testudinum*, *C. canadensis*, *C. peloridis*, *C. insulaenigrae*, *C. subantarcticus*, *C. volucris*, and *C. ureolyticus* (previously *Bacteroides ureolyticus*). Several of these are implicated in human diseases.

Arcobacter spp infecting animals include *A. cryaerophilus* (livestock abortion), *A. butzleri* (livestock diarrhea, bovine and porcine abortions), *A. skirrowii* (sheep diarrhea, livestock abortions), and *A. thereius* (porcine abortion). Disease status is unknown, although these species have been isolated from food animals: *A. cibarius* (chicken meat, piggery effluent), *A. trophiarum* (fattening pigs), and *A. suis* (pork meat). Approximately 11 additional *Arcobacter* spp found in shellfish, sewage, seawater, sediments, and salt marsh plants are not known to cause diseases in animals or people.

Lesions: *C. jejuni* can stably colonize the small and large intestines, although most animals show cecal and colonic lesions with typhlocolitis. In swine and mice, gross lesions observed in *C. jejuni* enteritis include enlarged and fluid-filled ceca and proximal colons with thickened walls. Lymph nodes (ileocecocolic and mesenteric) draining infected sites become

significantly enlarged. Infection with particular strains of *C. jejuni* produces bloody exudates with mucus. Histopathologic features include a marked inflammation of the lamina propria, dominated by neutrophilic polymorphonuclear cells and mononuclear cells that sometimes extend into submucosa. Immune cells such as plasma cells, macrophages, and mononuclear cells have been found in smaller numbers in the lamina propria. Damage to, sloughing of, and ulceration of the epithelial surface and edema have also been seen in most infected species. In pigs and mice, damage to the epithelial surface is associated with the presence of *C. jejuni* at the basolateral surface of the epithelium, in paracellular junctions of the epithelium, and in erosive and ulcerative lesions of the epithelium; there is often a mucopurulent neutrophilic exudate with sloughed and lysed epithelial cells and erosive or ulcerative lesions where *C. jejuni* is associated with the basolateral aspect of sloughing villous tip cells in the colon. Crypt abscesses and damage to the crypt epithelium are also common findings.

Diagnosis: *Campylobacter* spp can be found in both healthy and diarrheic animals; thus, clinical signs and postmortem findings depend on the species and the host animal and its age. Diagnosis of enteric campylobacteriosis relies on isolation of the causative agent using selective media under microaerophilic conditions. Fresh fecal samples should be collected and transported to the laboratory preferably on the same day and within at least 2 days for processing. If transport to the laboratory is delayed, transport media and storage at 4°C produce the best results. Campylobacters are very sensitive to environmental conditions, including dehydration, atmospheric oxygen, sunlight, and increased temperature. Organisms are thin (0.2–0.8 µm × 0.3–5 µm), gram-negative, motile, curved rods. The cells are S-shaped or curved but are occasionally long (8 µm) spiral rods. They exhibit a typical spiraling motility. In unfavorable growth conditions, spiral rods undergo a degenerate conversion to coccoid forms. Campylobacters can be quickly outgrown by contaminating microbes during prolonged transport to the laboratory, and isolation of pure colonies for downstream testing can be difficult. Filtration using 0.45 µm filters can help because campylobacters will pass through.

Enrichment is required for most clinical sampling unless material can be transported to the laboratory immediately.

When samples are collected in swabs, the use of commercially available transport tubes containing medium, such as Amies, is recommended. The medium can be plain agar or charcoal-based. Several transport media have been described for transport of fecal specimens, including Cary-Blair, modified Cary-Blair, modified Stuart medium, Campy thioglycolate medium, alkaline peptone water, and semisolid motility test medium. Other media are recommended for the isolation of campylobacters associated with reproductive losses.

Campylobacter spp do not ferment carbohydrates, and other biochemical characteristics are thus used to identify different species. Thermophilic/thermotolerant *Campylobacter* spp, including *C. jejuni* *jejuni*, *C. coli*, *C. upsaliensis*, *C. lari*, *C. mucosalis*, *C. sputorum*, *C. hyointestinalis*, and *C. helveticus* grow best at 42°C, although they are capable of growth at 37°C. *C. fetus* do not grow or grow poorly at 42°C. Alternatively, this species grows well at 25°C, whereas the thermophilic campylobacters do not (except *C. mucosalis*, which can grow at 42° and 25°C, weak growth for *C. hyointestinalis* at 25°C). *C. jejuni* is differentiated on its ability to hydrolyze hippurate, and *C. upsaliensis* has negative or weak catalase production and is differentiated from other campylobacters because of its sensitivity to nalidixic acid. *C. helveticus* is also catalase negative but can be difficult to differentiate biochemically from *C. upsaliensis* relying on distinctive colony morphologies.

Differentiation of subspecies can be necessary for identification of significant pathogens. *C. jejuni* subsp *jejuni* is the main cause of enteritis, whereas *C. jejuni* subsp *doylei* has been isolated only from enteritis cases of children and not animals. They can be differentiated by the ability of *C. jejuni* *doylei* to reduce nitrate. Similarly, *C. hyointestinalis* subsp *hyointestinalis* can cause bovine and porcine enteritis; however, *C. hyointestinalis* subsp *lawsonii* has been isolated from the porcine stomach, but it is not known to cause disease. The subspecies can be differentiated by testing the intolerance of *C. hyointestinalis* *lawsonii* to 1.5% bile and/or 0.1% potassium permanganate.

Arcobacter spp (previously known as aerotolerant campylobacters) can also be

associated with human and animal diarrhea and with animal abortions. *Arcobacters* are usually not thermophilic but can be confused with the nonthermophilic *Campylobacter* spp if aerotolerance is confirmed using standardized suspensions of organisms. Although most cases of human enteritis are attributed to *C. jejuni* *jejuni*, *C. coli*, *C. lari*, and *C. upsaliensis*, it has been suggested that the importance of other species also associated with GI illness may be significantly underdiagnosed as a consequence of inappropriate isolation and identification methods.

Immunodiagnosis (ELISA) is unsuitable to diagnose intestinal *Campylobacter* infections.

PCR-based methods effectively identify infection, especially if cultivation is difficult or if the sample has been somewhat mishandled. However, a positive test is not sufficient evidence to determine causation and must be considered in conjunction with clinical signs.

Treatment and Control: Clindamycin, gentamicin, tetracyclines, erythromycin, cephalosporins (eg, cephalothin), and fluoroquinolones (eg, nalidixic acid) are effective against *C. jejuni*, *C. helveticus*, and *C. upsaliensis*. *C. fetus*, *C. hyointestinalis*, *C. mucosalis*, and *C. sputorum* are usually resistant to the fluoroquinolones yet sensitive to cephalosporins. *C. coli* are sensitive to fluoroquinolones but resistant to cephalosporins. Susceptibilities to penicillins and trimethoprim are variable across *Campylobacter* spp. Resistance to the fluoroquinolones, tetracycline, kanamycin, and some other antibiotics has been documented among the *Campylobacter* spp, mediated by both chromosomal and plasmid mechanisms. Culture-dependent diagnosis can provide isolates for antibiotic sensitivity testing. However, some animals remain colonized and become persistent shedders despite antibiotic therapy. If the goal of treatment is to decrease the risk of zoonotic transmission to a susceptible household member, antibiotic treatment alone may be inadequate. Control involves treatment, removal to a clean environment, and prospective fecal testing to ascertain shedding status; even so, low infective doses and the ubiquitous distribution of the organism pose significant challenges.

SALMONELLOSIS

Salmonella, a rod-shaped gram-negative bacterium belonging to the family Enterobacteriaceae, is the causative agent of salmonellosis. Salmonellosis in warm-blooded vertebrates is in most cases associated with serovars of *Salmonella enterica*. The most common type of infection is the carrier state, in which infected animals carry the pathogen for a variable period of time without showing any clinical signs. Clinical disease is characterized by two major syndromes: a systemic septicemia (also termed as typhoid) and an enteritis. Other less common clinical presentations include abortion, arthritis, respiratory disease, necrosis of extremities, and meningitis.

Only a few serotypes produce clinical salmonellosis in healthy animals and typically have a narrow range of host species, a phenomenon termed serovar-host specificity. *Salmonella enterica* serovar Typhi (*S* Typhi) and *S* Paratyphi produce typhoid in people, *S* Gallinarum produces a similar disease in poultry, *S* Abortusovis in sheep, *S* Choleraesuis in pigs, *S* Dublin in cattle, etc.

The remaining serovars (serotypes) rarely produce clinical systemic disease in healthy, adult, nonpregnant animals. However, they colonize in the gut of many species of animals, enter the human food chain, and produce gastroenteritis in people (food poisoning). *S* Typhimurium and *S* Enteritidis are the most frequent causes of enteritis in people (nontyphoidal salmonellosis) but are also able to produce typical typhoid infections in mice; hence, the basis of pathogenicity is unclear. Strains from this latter group may also produce more severe disease, with systemic involvement resembling typhoid in very young animals if they have received insufficient protective antibody from their dam or when they are particularly susceptible, eg, as a result of old age, disease, or pregnancy. The host species from which a serotype is characteristically isolated is not necessarily the only species that can act as a host; thus, epidemiologic factors are important in determining prevalence.

Young calves, piglets, lambs, and foals may develop both the enteritis and septicemic form (see ■DIARRHEA IN NEONATAL RUMINANTS, p 275, ■DIARRHEAL, ■DISEASE IN FOALS,

p 289, and INTESTINAL SALMONELLOSIS, p 296). Adult cattle, sheep, and horses commonly develop acute enteritis, and chronic enteritis may develop in growing pigs and occasionally in cattle (see also the chapters on intestinal diseases in each of the major domestic species, p 266, et seq). Pregnant animals may abort. The clinically normal carrier animal is a serious problem in all host species. Salmonellosis is seen infrequently in dogs and cats and is characterized by acute diarrhea with or without septicemia.

Etiology and Pathogenesis: Salmonellosis has been recognized in all parts of the world but is most prevalent in regions with intensive animal husbandry. Although this facultative intracellular pathogen is primarily an intestinal bacterium, it is commonly found in an environment subject to fecal contamination. Feces of infected animals can contaminate feed and water, milk, fresh and processed meats from abattoirs, plant and animal products used as fertilizers or feedstuffs, pasture and rangeland, and many inert materials. The organisms may survive for months in wet, warm areas such as in feeder pig barns and poultry houses or in water dugouts, but they survive <1 wk in composted cattle manure. Rodents and wild birds are also sources of infection for domestic animals. Pelleting of feeds reduces the level of contamination by salmonellae largely as a result of the heat treatment involved.

Although many other *Salmonella* spp may cause enteric disease, the more common ones (to some extent varying according to geographic location) in each species are as follows: **cattle**—*S* Typhimurium, *S* Dublin, and *S* Newport; **sheep and goats**—*S* Typhimurium, *S* Dublin, *S* Abortusovis, *S* Anatum, and *S* Montevideo; **pigs**—*S* Typhimurium and *S* Choleraesuis; **horses**—*S* Typhimurium, *S* Anatum, *S* Newport, *S* Enteritidis, and *Salmonella* serovar Illa 18:z₄:z₂₃; and **poultry**—*S* Enteritidis, *S* Typhimurium, *S* Gallinarum, and *S* Pullorum.

Although their resulting clinical patterns are not distinct, different species of salmonellae do tend to differ in their epidemiology. Plasmid profile and drug-resistance patterns are sometimes

useful markers for epidemiologic studies. The prevalence of infection varies among host species and countries and is much higher than the incidence of clinical disease, which in food animals is commonly precipitated by stressful situations such as sudden deprivation of feed, transportation, drought, crowding, parturition, surgery, and administration of certain drugs, including oral antibiotics. Greater susceptibility in the very young may be the result of high gastric pH, absence of a stable intestinal flora, and limited immunity.

The usual route of infection in enteritis is fecal-oral, although infection through the upper respiratory tract and the conjunctiva have also been reported. After ingestion, the organism colonizes the digestive tract and invades and multiplies in enterocytes and tonsillar lymphoid tissue. Penetration of bacteria into the lamina propria contributes to gut damage and diarrhea. The complex process involves attachment through fimbrial appendages and the injection by the attached *Salmonella* organisms into epithelial cells of proteins, which induce changes in the actin cytoskeleton that induce membrane ruffling at the cell surface. This entraps the *Salmonella* bacteria and results in fluid secretion and their ingestion by the cell. The cellular infection results in activation of a host alarm process through signalling molecules as a result of the detection of bacterial surface proteins, which in turn induces a strong inflammatory response that generally is able to restrict the bacteria to the intestine. Some serotypes also become localized in the reproductive tract. Serotypes that are able to cause typhoid can modulate the initial host response and suppress the inflammatory response. Cell destruction follows, and the bacteria are ingested by phagocytic cells such as macrophages and neutrophils. Although neutrophils are generally able to kill *Salmonella*, the bacteria can survive and multiply within macrophages, which represent the main host cell type during infection.

As infection progresses, a true septicemia may follow, with subsequent localization in brain and meninges, pregnant uterus, joints and distal aspects of the limbs, and tips of the ears and tails, which can result, respectively, in meningoencephalitis, abortion, osteitis, and dry gangrene of the feet, tail, or ears. The organism also frequently localizes in the gallbladder and mesenteric lymph nodes, and survivors

intermittently shed the organism in the feces.

Calves rarely become carriers but virtually all adults do for variable periods—up to 10 wk in sheep and cattle and up to 14 mo in horses. Adult cattle infected with *S* Dublin may excrete the organism for years. Infection may also persist in lymph nodes or tonsils, with no salmonellae in the feces. Latent carriers may begin shedding the organism or even develop clinical disease under stress. A passive carrier acquires infection from the environment but is not invaded, so that if removed from the environment, it ceases to be a carrier.

Epidemiology: In cattle, *S* Typhimurium is commonly associated with outbreaks of enteritis in calves <2 mo old, whereas *S* Dublin has been associated with the same condition in older calves and adult cattle. In calves and lambs, *S* Dublin is usually endemic on a particular farm, whereas *S* Typhimurium is frequently associated with introduction of calves from infected farms and may cause sporadic explosive outbreaks. Subclinical infection with occasional herd outbreaks may be seen in adult cattle. Stressors that precipitate clinical disease include deprivation of feed and water, minimal levels of nutrition, long transport times, calving and antibiotic prophylaxis, and mixing and crowding in feedlots.

Outbreaks of septicemic salmonellosis in pigs are rare and usually can be traced to a purchased, infected pig. Purchase of feeder pigs from *Salmonella*-free herds and use of the “all-in/all-out” policy in finishing units minimize exposure. Increasing use of extensive outdoor rearing increases the risk of exposure to environmental sources of infection. Passerines, gulls, and pigeons can present a direct source of infection or a source of contamination of feed and water.

Most cases in adult horses develop after the stress of surgery or transport related to sales yards and deprivation of feed and water followed by overfeeding at their destination. Mares may be inapparent shedders and shed the bacteria at parturition, infecting newborn foals. Septicemic salmonellosis may occur in foals, which may be endemic, or there may be outbreaks. (See *INTESTINAL DISEASES IN HORSES AND FOALS*, p 281.)

Many dogs and cats are asymptomatic carriers of salmonellae. Clinical disease is uncommon, but when it is seen, it is often associated with hospitalization, another infection or debilitating condition in adults,

or exposure to large numbers of the bacteria in puppies and kittens, in which enteritis may be common.

Clinical Findings: Infection with localization of the pathogen in tonsils or the GI tract that is not associated with clinical disease is a common form of salmonellosis termed as the carrier state. Carrier animals are chronically infected and may shed salmonellae intermittently into the environment. Carrier animals can develop clinical disease whenever the immune function is compromised or concurrent infection with another pathogen occurs.

Enteritis with septicemia is the usual syndrome in newborn calves, lambs, foals, fowl, and piglets, and outbreaks may occur in pigs up to 6 mo old. When systemic disease occurs with enteritis as a result of insufficient immunity, illness may be acute, with depression, fever (105° – 107° F [40.5° – 41.5° C]), and death in 24–48 hr. Nervous signs and pneumonia may be seen in calves and pigs. Mortality may reach 100%, depending on the host genetic background and strain virulence.

Acute enteritis without extensive systemic involvement is more common in adults as well as in young animals ≥ 1 wk old. Initially, there is fever (105° – 107° F [40.5° – 41.5° C]), followed by severe watery diarrhea, sometimes dysentery, and often tenesmus. In a herd outbreak, several hours may lapse before the onset of diarrhea, at which time the fever may disappear. The feces, which vary considerably in consistency, may have a putrid odor and contain mucus, fibrinous casts, shreds of mucous membrane, and in some cases, blood. Rectal examination causes severe discomfort and tenesmus. Milk production often declines precipitously in dairy cows. Abdominal pain is common and may be severe (colic) in horses. Mortality is variable but may reach 100% depending on strain virulence. A marked leukopenia and neutropenia are characteristic of the acute disease in horses. In dogs and cats, clinical disease takes the form of acute diarrhea with septicemia and is seen occasionally in puppies and kittens or in adults stressed by concurrent disease. Pneumonia may be evident. When the enteritis becomes more chronic, abortion may occur in pregnant dogs, cats, cattle, horses, and sheep, and live progeny may have enteritis as well. Conjunctivitis is sometimes seen in affected cats.

Fur-bearing and zoo carnivores may be affected. Contaminated feed is often the

source of infection. Several rodent species (eg, guinea pigs, hamsters, rats, and mice) and rabbits are susceptible. Rodents commonly act as a source of infection on farms where the disease is endemic. Pet turtles were once a common source of infection in people that has been virtually eliminated by the curtailment of commercial trafficking.

Diagnosis: Diagnosis of salmonellosis depends on clinical signs and isolation of the pathogen from feces, blood, or tissues of affected animals. The presence of organisms may also be sought in feed, water supplies, and feces from wild rodents and birds that may inhabit rearing premises to determine the source of the organism. Bacteria are usually identified by a range of biochemical tests. Identification to serotype may be done, followed by further subdivision on the basis of susceptibility to selected bacteriophages (phage typing).

Serologic tests are available and are increasingly used as a diagnostic tool in salmonellae surveillance and control programs. These tests are normally developed to identify a limited spectrum of salmonellae serovars and serogroups. Serologic tests are difficult to interpret in individual animals, because a seropositive animal may no longer be infected. Furthermore, specificity issues mean that in countries with low infection prevalence, many positive results are false-positive.

The clinical syndromes usually are characteristic but must be differentiated from several similar diseases in each species as follows: **cattle**—diarrhea due to enterotoxigenic *Escherichia coli*, dysentery due to verotoxigenic *E coli*, coccidiosis, cryptosporidiosis, the alimentary tract form of infectious bovine rhinotracheitis, bovine viral diarrhea, hemorrhagic enteritis due to *Clostridium perfringens* types B and C, arsenic poisoning, secondary copper deficiency (molybdenosis), winter dysentery, paratuberculosis, ostertagiosis, and dietetic diarrhea; **sheep**—enteric colibacillosis, septicemia due to *Haemophilus* sp or pasteurellae, and coccidiosis; **pigs**—enteric colibacillosis and *Clostridium difficile* of newborn pigs and weanlings, swine dysentery (*Brachyspira hyodysenteriae*), campylobacteriosis, and the septicemias of growing pigs (which include erysipelas, *Lawsonia intracellularis*, classical swine fever, and pasteurellosis); **horses**—septicemia (due to *E coli*, *Actinobacillus equuli*, or streptococci);

poultry—coliform enteritis and *Yersinia pseudotuberculosis*.

Lesions: Lesions are most severe in the lower ileum, cecum, and spiral colon and vary from shortening of villi with loss of the epithelium to complete loss of intestinal architecture. There is infiltration of the lamina propria with neutrophils and later with macrophages, and thrombi may be seen in capillaries in this region. Hemorrhage and fibrin strands are usually seen, and there may be a fibrinonecrotic crust on the surface of the intestinal mucosa. Culture techniques that involve suppression of fecal *E coli* are usually necessary, and several daily fecal cultures may be necessary to isolate the organism. A nonselective enrichment stage may be required for samples in which bacteria may be present in low numbers, as in foodstuffs. This may be followed by enrichment in selective broth and plating for colonies on a variety of selective agars that suppress other enteric bacteria likely to be present in the gut. Blood cultures in septicemic animals may be rewarding but are costly.

Treatment: Early treatment is essential for septicemic salmonellosis, but there is controversy regarding the use of antimicrobial agents for intestinal salmonellosis. Oral antibiotics may be ineffective and may deleteriously alter the intestinal microflora, thereby interfering with competitive antagonism and prolonging shedding of the organism. There is also concern that antibiotic-resistant strains of salmonellae selected by oral antibiotics may subsequently infect people. By suppressing antibiotic-sensitive components of the normal flora, antibiotics may also promote transfer of antibiotic resistance from resistant strains of *E coli* to *Salmonella*. Use of chemotherapeutic antibiotics for growth stimulation has been banned in many countries for this reason.

Broad-spectrum antibiotics administered systemically are indicated for treatment of septicemia. Initial antimicrobial therapy should be based on knowledge of the drug resistance pattern of the organisms previously found in the area. Nosocomial infections may involve highly drug-resistant organisms. Trimethoprim-sulfonamide combinations may be effective. Alternatives are ampicillin, fluoroquinolones, or third-generation cephalosporins. Resistance to ampicillin, trimethoprim, sulfonamide, tetracyclines, and aminoglycosides is generally plasmid mediated and transfers readily between

different bacteria. Resistance to quinolones is mutational, but random mutations may be selected by antibiotic use and may be transferred by bacteriophages. Treatment should be continued daily for up to 6 days.

If oral medication is chosen, it should be given in drinking water and not mixed into solid feed, because affected animals are thirsty due to dehydration and their appetite is generally poor. Fluid therapy to correct acid-base imbalance and dehydration may be necessary. Calves, adult cattle, and horses need large quantities of fluids. Antibiotics such as ampicillin or cephalosporins lead to lysis of the bacteria with release of endotoxin, and NSAIDs or flunixin meglumine may be used to reduce the effects of endotoxemia.

The intestinal form is difficult to treat effectively in all species. Although clinical cure may be achieved, bacteriologic cure is difficult, either because the organisms become established in the biliary system and are intermittently shed into the intestinal lumen, or because the animals are reinfected from the environment at a time when their normal gut flora, which is inhibitory to colonization by pathogens, is depleted by antibiotic therapy. A concern with antimicrobial therapy is that it may increase the risk of creating carrier animals; in people and other animal species, antimicrobial therapy prolongs the period after clinical recovery during which the pathogen can be retrieved from the GI tract.

Control and Prevention: Carrier animals and contaminated feedstuffs and environment are major problems. Drain swabs or milk filters may be cultured to monitor the salmonellae status of a herd. The principles of control include prevention of introduction and limitation of spread within a herd. In many countries and in the EU, government-backed programs have been introduced to control and reduce levels of infection in food animals, especially poultry and pigs.

Prevention of Introduction: Every effort must be made to prevent introduction of a carrier; ideally, animals should be purchased directly only from farms known to be free of the disease and should be isolated for ≥ 1 wk while their health status is monitored. Ensuring that feed supplies are free of salmonellae depends on the integrity of the source. Some countries also test for contamination of and regulate importation and home production of feedstuffs and feed components.

Limitation of Spread Within a Herd:

In an outbreak of salmonellosis, the following procedures should be implemented: 1) Carrier animals should be identified and either culled or isolated and treated vigorously. Treated animals must be rechecked several times before there can be confidence they are not carriers. 2) The prophylactic use of antibiotics in feed or water supplies may be considered (the hazards are mentioned earlier). 3) Movement of animals around the farm should be restricted to limit infection to the smallest group. Random mixing of animals should be avoided. 4) Feed and water supplies must be protected from fecal contamination. 5) Contaminated buildings must be vigorously cleaned and disinfected. 6) Contaminated material must be disposed of carefully. 7) All persons should be aware of the hazards of working with infected animals and the importance of personal hygiene. A strict farm management program should be introduced. 8) Use of a vaccine should be considered, particularly in an outbreak involving pregnant cattle, pigs, or laying poultry. Commercial killed bacterins or autogenous bacterins may be used. Live attenuated vaccines show considerable promise, but few are available commercially (see below). 9) Stresses should be minimized.

Salmonella Vaccines: Salmonellae are facultative intracellular bacteria, and a live vaccine is therefore expected to be necessary for optimal immune protection against disease; however, there is some evidence that inactivated bacterins can

induce a lower level of protection. In several studies, live attenuated *Salmonella* vaccines in pigs, cattle, and chickens stimulated a strong cell-mediated immune response and protected animals against both systemic disease and intestinal colonization. A live attenuated *S. Choleraesuis* vaccine licensed for use in swine appears to effectively reduce colonization of tissues and protect pigs from disease after challenge with virulent organisms and under field conditions. This vaccine also protected calves against experimental challenge with *S. Dublin* and serogroup C1 salmonellae after intranasal or SC administration. A live *S. Gallinarum* vaccine has been shown to be effective not only against *S. Gallinarum* (fowl typhoid) but also in significantly reducing the infection of laying hens challenged with *S. Enteritidis*.

Zoonotic Risk: Infections with *Salmonella* in food-producing animals present a serious public health concern, because food products of animal origin are considered to be a significant source of human infection. Most common sources of infection are eggs and related products, and meat from poultry and other food animal species (see p 2865). Milk and dairy products have also been associated with outbreaks of salmonellosis in people. In addition, contamination of fruit and vegetables by infected water may also be a source of infection. In Europe, *S. Enteritidis* and *S. Typhimurium*, and in the USA, *S. Typhimurium* are the most prevalent serovars associated with human disease.

TYZZER DISEASE

Tyzzler disease is an enterohepatic syndrome of a wide range of animals (see p 1948) and is seen worldwide. Tyzzler disease was first described in mice in 1917. Several years later, it was reported in laboratory rabbits and then in other small laboratory mammals, including guinea pigs, hamsters, gerbils, and rats. It is a highly fatal disease of young foals. The disease is rare in other domestic animals, including dogs, cats, and calves. It has been reported in a variety of wildlife, including muskrats,

cottontail rabbit, coyote, gray fox, lesser panda, snow leopard, raccoon, marsupials, and white-tailed deer.

The disease primarily affects young, well-nourished animals, especially those fed high-protein diets, during periods of stress. Some species appear resistant unless stressed or immunosuppressed, whereas others appear to be susceptible without immunosuppression. Dietary factors, including excessive nitrogenous diets fed to laboratory animals and to nursing mares,

seemingly may cause immunosuppression and may predispose susceptible animals to the disease. Other immunosuppressive agents and drugs and some antibacterials, especially sulfonamides, may also predispose animals to the disease.

Under laboratory conditions, stress is created by immunosuppressive drugs or other factors that can be easily identified. With many experiments, stress may be involved as part of the protocol, and when the disease develops, it is devastating.

Etiology and Pathogenesis: The disease is caused by *Clostridium piliforme*, a motile, spore-forming, rod-shaped, flagellated, obligate, intracellular bacterium. It does not grow in cell-free media but can be cultured in the yolk sac of chick embryos or tissue culture cells. The vegetative phase is very labile; spores may survive in soiled bedding at room temperature for >1 yr and are resistant to heating up to 60°C for 30 min, or exposure to 70% ethanol, 3% cresol, 4% chlorhexidine, and 0.037% formaldehyde; however, they are sensitive to 0.4% peracetic acid, 0.015% sodium hypochlorite, 1% iodophor, and 5% phenol.

C. piliforme appears to be common in the environment, but because it is difficult to culture, very little knowledge has been accumulated on the epidemiology, pathogenesis, and immunity. Infection most likely results from oral exposure to spores from the environment. The feces of infected and carrier animals are the primary source of spores that contaminate the environment.

C. piliforme infections are often subclinical or asymptomatic but may be severe in many animal species. There may be differences in susceptibility within animal species. B lymphocytes, T lymphocytes, and natural killer cells may play a role in mediating strain susceptibility. Seroanalysis using monoclonal antibody-based competitive inhibition ELISA suggests that Tyzzer disease may be relatively common in horses, which are susceptible to at least two distinct strains.

Some isolates of *C. piliforme* produce toxins, whereas others do not. The role of these toxins in the pathogenesis of infection is unknown, but the toxic isolates are generally more virulent than nontoxic isolates. The toxigenic strains appear more likely to induce hepatic lesions in mice, whereas the nontoxigenic strains do not.

The primary site of infection is the lower intestinal tract with subsequent dissemination via the blood or lymphatics to the liver and heart. The bacterium has an affinity for

the epithelial and smooth muscle cells of the intestines, hepatocytes, and cardiac myocytes. Stress factors such as capture, overcrowding, shipping, and poor sanitation appear to be predisposing. Sulfonamide administration predisposes rabbits to the disease. Mortality is highest at weaning age in rabbits. The disease in foals occurs most often between 1 and 6 wk of age, with most cases occurring between 1 and 2 wk of age. In some species, the disease has been identified concurrently with other diseases, eg, feline infectious peritonitis in cats, distemper and mycotic pneumonia in dogs, and cryptosporidial and coronaviral enteritis in calves.

The disease in foals is more common during the spring when nursing mares are exposed to lush, high-protein pastures. The increase in the availability of nutrients from pasture forages and supplemental diets may encourage the overgrowth of *C. piliforme* in the gut of nursing mares; this seemingly predisposes neonatal foals to the disease when they are exposed to massive numbers of the bacterium after consuming the feces of their dams soon after birth as a mechanism to establish their normal intestinal flora. The immature gut is likely more permeable to pathogens like *C. piliforme*.

The disease in young foals primarily affects the liver, where it induces a massive multifocal necrosis and hepatitis, and foals die of acute liver failure. In contrast, in other animals, which generally are older when infected, the bacterium affects the intestinal tract and to a lesser extent the liver and heart.

Older foals up to 6 wk of age become more resistant to the disease as the gut becomes more mature and immune factors may be involved. The disease is not recognized in older foals and adults, but they carry the bacterium in their gut.

Immune factors appear to be involved with the disease in horses, because many adults have antibodies for *C. piliforme* yet do not develop Tyzzer disease. Only young foals up to 6 wk old develop lesions. The disease is more common in foals when young nursing mares are introduced to a farm where the disease is endemic and is less common in suckling foals on older mares; this suggests that older mares are immune to the disease and may be secreting *C. piliforme* antibodies in the colostrum that protects young foals.

Clinical Findings: The disease often affects apparently healthy, fast-growing foals without previously observed clinical

signs. The incubation period in experimentally infected foals is 4–7 days after oral exposure to bacterial spores. Most foals are found in a coma or dead. Clinical signs, if seen, are of short duration, from a few hours to up to 2 days. Signs are variable but may include depression, anorexia, pyrexia, jaundice, diarrhea, and recumbency. Terminally, there are convulsions and coma. Clinical signs vary between animal species. Laboratory animals may be found dead at the start of an outbreak. As the disease progresses, animals may show depression, ruffled coat, and varying degrees of watery diarrhea.

Clinicopathologic tests are of little value in laboratory animals, because they die so rapidly. In foals, the serum enzymes sorbitol dehydrogenase, AST, alkaline phosphatase, lactate dehydrogenase, and γ -glutamyl-transferase are increased. There is also hyperbilirubinemia, leukopenia, hemoconcentration, and terminally profound hypoglycemia.

Lesions: Characteristic lesions are seen in the liver, myocardium, and intestinal tract. In the liver, white, gray, or yellowish foci of necrosis, 2 mm in diameter, are few to disseminated. The hepatic necrosis is most marked and disseminated in foals in which the multiple necrotic foci with slightly depressed hemorrhagic centers appear to infect almost every hepatic lobule. In addition, there is marked hepatomegaly, and the hepatic lymph nodes are edematous and hyperplastic. In rabbits, severe lesions develop in the intestines and heart. The terminal ileum, cecum, and proximal colon are diffusely reddened. ■ Diffuse ("paint-brush") hemorrhage is frequently seen on the serosa of the cecum. Patchy areas of mucosal necrosis are present in the cecum and colon, together with marked edema of the wall of the cecum. Mesenteric lymph nodes may be enlarged and edematous. White streaks in the myocardium may be present, especially near the apex. Intestinal and heart lesions are generally milder or absent in other animal species.

Microscopically, there are numerous widespread multifocal areas of necrosis and hepatitis. In foals, the hepatic lesions are more pronounced than in other animals. Often the necrotic foci are so numerous that two or more coalesce. The hepatocytes in the center of the necrotic foci are destroyed and replaced by a mixture of mononuclear cells, neutrophils, and red blood cells. The causative bacteria are found in a crisscross pattern in viable hepatocytes at the periphery of the necrotic foci. In the cecum

and colon of rabbits, patchy areas of necrosis extend as deep as the muscularis externa with associated mucosal and submucosal infiltrates of neutrophils. Organisms may be found within the epithelium, muscularis mucosa, and muscularis externa of the affected intestine. When cardiac lesions are present, they consist of foci of fiber fragmentation, vacuolation, loss of cross-striations, and minimal inflammatory cell infiltration.

Diagnosis: Serology of the blood and PCR assay of the feces of suspect infected animals may be used clinically to test for *C piliforme*. However, clinical signs in addition to the commonly available diagnostic methods must be interpreted together for a presumptive clinical diagnosis.

In postmortem specimens, a diagnosis is based on demonstration of organisms in tissue sections with special stains. *C piliforme* stains poorly with H&E and Gram stains. With Giemsa stain, the bacillus stains well in the liver and intestinal epithelium and in smears of infected organs but poorly in smooth muscles and cardiac muscle cells. The Warthin-Starry or Levaditi silver stains are preferable to other stains, because the bacillus stains well in the cytoplasm of all infected cells. In addition to special histochemical stains, the PCR assay can be used to detect *C piliforme* gene sequences in liver tissues from infected animals.

Treatment and Control: Little is known about the effectiveness of antibiotics for treatment. Some antibiotics are known to aggravate the disease. *C piliforme* is sensitive to tetracycline and partially sensitive to streptomycin, erythromycin, penicillin, and chlortetracycline. It is resistant to sulfonamides and chloramphenicol.

In neonatal foals, the disease seems to be nearly 100% fatal, although it is likely that older foals less severely affected may survive. Once the disease is present on a farm, it may be seen sporadically year after year. Animals suspected of being infected have been treated IV initially with 50% dextrose, followed by 10% dextrose, other fluid therapy, and antibiotics. Most foals respond dramatically to the dextrose therapy but relapse into a coma and die in a few hours. A few presumptive cases of Tyzzer disease in foals have been treated successfully by intensive administration of IV dextrose, sodium bicarbonate, potassium chloride, penicillin, and sulfamethoxazole-trimethoprim.

Because the disease in foals is sporadic and not highly contagious, specific preventive measures are usually not indicated. In areas where endospores are present in the environment, many foals may be exposed; however, only a few that are immunosuppressed become acutely affected. On premises where the disease is prevalent, overfeeding of mares, especially with high-protein diets seemingly predispose neonatal foals. Reducing the nitrogenous dietary compounds, including protein

and nitrate in the diet that may induce immunosuppression in neonatal foals, may lessen the incidence of the disease. In general, factors that cause stress and immunosuppression should also be reduced. When the disease is seen in a colony of laboratory animals, treatment is not recommended because it prolongs the disease and possibly produces carrier animals. It is best to destroy all animals in the colony, decontaminate the environment, and restock with disease-free animals.

AMEBIASIS

(Amebiosis)

Amebiasis is an acute or chronic colitis, characterized by persistent diarrhea or dysentery, that is prevalent in tropical and subtropical areas worldwide. Its prevalence has declined in the USA over the past several decades, but the disease is still important in many tropical areas, particularly in times of disasters. It is common in people and nonhuman primates, sometimes seen in dogs and cats, and rare in other mammals. Several species of amebae are found in mammals, but the only known pathogen is *Entamoeba histolytica*. People are the natural host for this species and the usual source of infection for domestic animals. Mammals become infected by ingesting food or water contaminated with feces containing infective cysts. *E. dispar* is a noninvasive, nonpathogenic ameba that is molecularly distinct but morphologically indistinguishable from the pathogenic species *E. histolytica*. *E. invadens* of reptiles is also morphologically identical to *E. histolytica*, but it is not transmissible to mammals.

Clinical Findings: *E. histolytica* is a pathogen with variable virulence. It lives in the lumen of the large intestine and cecum and may produce no obvious clinical signs, or it may invade the intestinal mucosa and produce mild to severe, ulcerative, hemorrhagic colitis. In acute disease, fulminating dysentery may develop, which may be fatal, progress to chronicity, or resolve spontaneously. Chronic cases may

show weight loss, anorexia, tenesmus, and chronic diarrhea or dysentery, which may be continual or intermittent. In addition to the colon and cecum, amebae may invade perianal skin, genitalia, liver, brain, lungs, kidneys, and other organs. Signs may resemble those of other colonic diseases (eg, trichuriasis, balantidiasis). Invasive amebiasis is exacerbated by immunosuppression.

Diagnosis: Definitive diagnosis depends on finding *E. histolytica* trophozoites or cysts in feces. Trophozoites are best seen in direct saline smears or in stained sections of affected colonic tissue. These parasites are difficult to find, because many animals with extraintestinal amebiasis have no concurrent intestinal infection. Colonoscopy with scraping or biopsy of ulcerations is more effective than fecal examination in diagnosing amebic colitis. In intestinal infections, repeated examinations may be necessary, because parasites may be passed periodically in the feces.

Trophozoites range in size from 10 to 60 μm but usually are $>20 \mu\text{m}$ in diameter, have a single vesicular nucleus (usually with a central karyosome), are motile, and may contain ingested RBCs. Feces should be examined promptly, because the trophozoites die quickly once outside the body. Fecal leukocytes may be mistaken for amebae, so fixed and stained fecal smears (iodine, trichrome, iron hematoxylin, or periodic acid-Schiff reaction) may be necessary for identification.

Cysts range from 10 to 20 μm in diameter; the usual size is 12–15 μm . Mature cysts have four nuclei, whereas immature cysts may have one or two. In primates, the cysts may be recovered and identified on zinc sulfate flotations or in fixed and stained preparations (iodine, trichrome, or iron hematoxylin); however, *E. histolytica* cysts are seldom, if ever, excreted by dogs or cats. An ELISA-based antigen test, available for diagnosis in people, may also aid diagnosis in other mammals. Immunostaining may also be useful.

Treatment: Scant information on treatment in animals is available. Metroni-

dazole (10–25 mg/kg, PO, bid for 1 wk) or furazolidone (2–4 mg/kg, PO, tid for 1 wk) has been suggested. Dogs may continue to shed trophozoites after therapy. Treatment recommendations for people are available from the CDC Web site. For asymptomatic infections in people, the CDC lists iodoquinol, paromomycin, or diloxanide furoate (not commercially available in the USA) as drugs of choice, and for symptomatic intestinal disease or extraintestinal infections in people (eg, hepatic abscess), the drugs of choice are metronidazole or tinidazole, immediately followed by treatment with iodoquinol, paromomycin, or diloxanide furoate.

COCCIDIOSIS

Coccidiosis is usually an acute invasion and destruction of intestinal mucosa by protozoa of the genera *Eimeria* or *Isospora*. Clinical signs include diarrhea, fever, inappetence, weight loss, emaciation, and in extreme cases, death. However, many infections are subclinical. Coccidiosis is an economically important disease of cattle, sheep, goats, pigs, poultry (see p 2791), and also rabbits, in which the liver as well as the intestine can be affected (see p 1952). In dogs, cats, and horses, coccidiosis is less often diagnosed but can result in clinical illness. Other genera, of both hosts and protozoa, can be involved (see CRYPTOSPORIDIOSIS, p 209, SARCOCYSTOSIS, p 1058, and TOXOPLASMOSIS, p 685).

Etiology and Epidemiology: *Eimeria* and *Isospora* typically require only one host in which to complete their life cycles. Some species of *Isospora* have facultative intermediate (paratenic or transfer) hosts, and a new genus name, *Cystoisospora*, has been proposed for these species of *Isospora*. Coccidia are host-specific, and there is no cross-immunity between species of coccidia.

Coccidiosis is seen universally, most commonly in young animals housed or confined in small areas contaminated with oocysts. Coccidia are opportunistic pathogens; if pathogenic, their virulence may be influenced by various stressors. Therefore, clinical coccidiosis is most

prevalent under conditions of poor nutrition, poor sanitation, or overcrowding, or after the stresses of weaning, shipping, sudden changes of feed, or severe weather.

In general, for most species of farm animals, the infection rate is high and rate of clinical disease is low (5%–10%), although up to 80% of animals in a high-risk group may show clinical signs. Most animals acquire *Eimeria* or *Isospora* infections of varying severity when between 1 mo and 1 yr old. Older animals usually are resistant to clinical disease but may have sporadic inapparent infections. Clinically healthy, mature animals can be sources of infection to young, susceptible animals.

Pathogenesis: Infection results from ingestion of infective oocysts. Oocysts enter the environment in the feces of an infected host, but oocysts of *Eimeria* and *Isospora* are unsporulated and therefore not infective when passed in the feces. Under favorable conditions of oxygen, humidity, and temperature, oocysts sporulate and become infective in several days. During sporulation, the amorphous protoplasm develops into small bodies (sporozoites) within secondary cysts (sporocysts) in the oocyst. In *Eimeria* spp, the sporulated oocyst has four sporocysts, each containing two sporozoites; in *Isospora* spp, the sporulated oocyst has two sporocysts, each containing four sporozoites.

When the sporulated oocyst is ingested by a susceptible animal, the sporozoites escape from the oocyst, invade the intestinal mucosa or epithelial cells in other locations, and develop intracellularly into multinucleated schizonts (also called meronts). Each nucleus develops into an infective body called a merozoite; merozoites enter new cells and repeat the process. After a variable number of asexual generations, merozoites develop into either macrogametocytes (females) or microgametocytes (males). These produce a single macrogamete or a number of microgametes in a host cell. After being fertilized by a microgamete, the macrogamete develops into an oocyst. The oocysts have resistant walls and are discharged unsporulated in the feces. Oocysts do not survive well at temperatures below -30°C or above 40°C ; within this temperature range, oocysts may survive ≥ 1 yr.

Of the numerous species of *Eimeria* or *Isospora* that can infect a particular host, not all are pathogenic. Concurrent infections with two or more species, some of which may not normally be considered pathogenic, also influence clinical disease. Within pathogenic species, strains may vary in virulence.

Clinical Findings: Clinical signs of coccidiosis are due to destruction of the intestinal epithelium and, frequently, the underlying connective tissue of the mucosa. This may be accompanied by hemorrhage into the lumen of the intestine, catarrhal inflammation, and diarrhea. Signs may include discharge of blood or tissue, tenesmus, and dehydration. Serum protein and electrolyte concentrations (typically hyponatremia) may be appreciably altered, but changes in Hgb or PCV are seen only in severely affected animals.

Diagnosis: Oocysts can be identified in feces by salt or sugar flotation methods. Finding appreciable numbers of oocysts of pathogenic species in the feces is diagnostic ($>100,000$ oocysts/g of feces in severe outbreaks), but because diarrhea may precede the heavy output of oocysts by 1–2 days and may continue after the oocyst discharge has returned to low levels, it is not always possible to find oocysts in a single fecal sample; multiple fecal examinations of one animal or single fecal examinations of animals housed in the same environment may be required. The number of oocysts present in feces is influenced by the genetically determined reproductive potential of the species, the number of

infective oocysts ingested, stage of the infection, age and immune status of the animal, prior exposure, consistency of the fecal sample (free water content), and method of examination. Therefore, the results of fecal examinations must be related to clinical signs and intestinal lesions (gross and microscopic). Furthermore, the species must be determined to be pathogenic in that host. The finding of numerous oocysts of a nonpathogenic species concurrent with diarrhea does not constitute a diagnosis of clinical coccidiosis.

Treatment: The life cycles of *Eimeria* and *Isospora* are self-limiting and end spontaneously within a few weeks unless reinfection occurs. Prompt medication may slow or inhibit development of stages resulting from reinfection and, thus, can shorten the length of illness, reduce discharge of oocysts, alleviate hemorrhage and diarrhea, and lessen the likelihood of secondary infections and death. Sick animals should be isolated and treated individually whenever possible to ensure delivery of therapeutic drug levels and to prevent exposure of other animals. However, the efficacy of treatment for clinical coccidiosis has not been demonstrated for any drug, although it is widely accepted that treatment is effective against reinfection and should therefore facilitate recovery.

Most coccidiostats have a depressant effect on the early, first-stage schizonts and are therefore more appropriately used for control instead of treatment. Soluble sulfonamides are commonly administered orally to calves with clinical coccidiosis and are perceived to be more effective than intestinal sulfonamide formulations (boluses). Amprolium is also administered orally to calves, sheep, and goats with clinical coccidiosis. Preventive treatment of healthy exposed animals as a safeguard against additional morbidity is an important consideration when treating individual animals with clinical signs. The FDA is changing the marketing status of drugs, such as the sulfonamides that are used in human medicine, from over-the-counter to (veterinary) prescription for water medication or Veterinary Feed Directive (VFD) for feed medication. Drugs, such as the ionophores, that are not used in human medicine will continue to have an over-the-counter marketing status.

Prevention: Prevention is based on limiting the intake of sporulated oocysts by young animals so that an infection is established to induce immunity but not

clinical signs. Good feeding practices and good management, including sanitation, contribute to this goal. Neonates should receive colostrum. Young, susceptible animals should be kept in clean, dry quarters. Feeding and watering devices should be clean and must be protected from fecal contamination; this usually means feed is placed in troughs above the ground and positioned so that it is difficult for fecal contamination of feed to occur. Stresses (eg, weaning, sudden changes in feed, and shipping) should be minimized.

Preventive administration of coccidiostats is recommended when animals under various management regimens can be predictably expected to develop coccidiosis. In virtually all cases, *Eimeria* spp are implicated. Decoquinate and ionophorous antibiotics are widely used for this purpose in young ruminants. Continuous low-level feeding of decoquinate, lasalocid, monensin, or amprolium during the first month of feedlot confinement has been reported to have preventive value. Ionophorous antibiotics and amprolium have been reported to be effective in goat kids, as have sulfonamides and amprolium in pigs.

COCCIDIOSIS OF CATTLE

Twelve *Eimeria* spp have been identified in the feces of cattle worldwide, but only three (*E. zuernii*, *E. bovis*, and *E. auburnensis*) are most often associated with clinical disease. The other *Eimeria* spp have been shown experimentally to be mildly or moderately pathogenic but are not considered important pathogens.

Coccidiosis is commonly a disease of young cattle (1–2 mo to 1 yr) and usually is sporadic during the wet seasons of the year. “Summer coccidiosis” and “winter coccidiosis” in range cattle probably result from severe weather stress and crowding around a limited water source, which concentrates the hosts and parasites within a restricted area. Although particularly severe epidemics have been reported in feedlot cattle during extremely cold weather, cattle confined to feedlots are susceptible to coccidiosis throughout the year. ● Outbreaks usually occur within the first month of confinement. Cows may contribute to environmental contamination of *E. bovis* oocysts through a periparturient increase in fecal oocyst counts. Time to onset of diarrhea after infection is 16–23 days for *E. bovis* and *E. zuernii* and 3–4 days for *E. alabamensis*; clinical disease due to coccidiosis does not typically occur in the first 3 wk of life. Coccidiosis is therefore not

considered part of the neonatal diarrhea complex in calves.

The most typical syndrome of coccidiosis is chronic or subclinical disease in groups of growing animals. Calves may appear unthrifty and have fecal-stained perineal areas. In light infections, cattle appear healthy and oocysts are present in normally formed feces, but feed efficiency is reduced. The most characteristic sign of clinical coccidiosis is watery feces, with little or no blood, and animals show only slight discomfort for a few days. Severe infections are rare. Severely affected cattle develop thin, bloody diarrhea that may continue for >1 wk, or thin feces with streaks or clots of blood, shreds of epithelium, and mucus. They may develop a fever; become anorectic, depressed, and dehydrated; and lose weight. Tenesmus is common because the most severe enteritis is confined to the large intestine, although pathogenic coccidia of cattle can damage the mucosa of the lower small intestine, cecum, and colon. During the acute period, some calves die; others die later from secondary complications (eg, pneumonia). Calves that survive severe illness can lose significant weight that is not quickly regained or can remain permanently stunted. Calves with concurrent enteric infections (eg, *Giardia*) may be more severely affected than calves with coccidia infections alone. In addition, management factors, such as weather, housing, feeding practices, and how animals are grouped, are important in determining the expression of clinical coccidiosis in cattle.

Nervous signs (eg, muscular tremors, hyperesthesia, clonic-tonic convulsions, with ventroflexion of the head and neck, nystagmus) and a high mortality rate (80%–90%) are seen in some calves with acute clinical coccidiosis. ● Outbreaks of this “nervous form” are seen most commonly during, or after, severely cold weather in midwinter in Canada and the northern USA; there are no reports of the “nervous form” outside this geographic location. Affected calves may die <24 hr after the onset of dysentery and nervous signs, or they may live for several days, commonly in a laterally recumbent position with a mild degree of opisthotonos. Nervous signs have not been reported in experimental clinical coccidiosis in calves, which suggests that the nervous signs may be unrelated to the dysentery or, indeed, even to coccidiosis.

Diagnosis of coccidiosis is by finding oocysts on fecal flotation or direct smear or by the McMaster technique. ● Quantitative oocyst counts on individual rectal samples from at least five calves in a pen are helpful

to confirm coccidiosis as a cause of clinical disease. Differential diagnoses include salmonellosis, bovine viral diarrhea, malnutrition, toxins, or other intestinal parasites.

Coccidiosis is a self-limiting disease, and spontaneous recovery without specific treatment is common when the multiplication stage of the coccidia has passed.

Drugs that can be used for therapy of clinically affected animals include sulfaquinoxaline (6 mg/lb/day for 3–5 days) and amprolium (10 mg/kg/day for 5 days). Sulfaquinoxaline is particularly useful for weaned calves that develop bloody diarrhea after arrival at a feedlot. For prevention, amprolium (5 mg/kg/day for 21 days), decoquinate (22.7 mg/45 kg/day for 28 days) and lasalocid (1 mg/kg/day to a maximum of 360 mg/head/day), or monensin (100–360 mg/head/day) can be used. The major benefits of coccidiostats are through improved feed efficiency and rate of gain.

In an outbreak, clinically affected animals should be isolated and given supportive oral and parenteral fluid therapy as necessary. The population density of the affected pens should be reduced. All feed and water supplies should be high enough off the ground to avoid fecal contamination. Mass medication of the feed and water supplies may be indicated in an attempt to prevent new cases and to minimize the effects of an epidemic. Cattle with coccidiosis and nervous signs should be brought indoors, kept well-bedded and warm, and given fluid therapy orally and parenterally. However, the case fatality rate of calves with coccidiosis and nervous signs is high despite intensive supportive therapy. Parenteral sulfonamide therapy may be indicated to control development of secondary bacterial enteritis or pneumonia, which may be seen in calves with coccidiosis during very cold weather. Corticosteroids are contraindicated, because they increase shedding of oocysts and have induced clinical disease in subclinically infected calves.

Coccidiosis has been difficult to control reliably. ● Overcrowding of animals should be avoided while they develop an immunity to the coccidial species in the environment. Calving grounds should be well drained and kept as dry as possible. All measures that minimize fecal contamination of hair coats and fleece should be practiced regularly. Feed and water troughs should be high enough to avoid heavy fecal contamination. Control of coccidiosis in feeder calves brought into a crowded feedlot depends on management of population density,

presence of appropriate feed bunks, or use of chemotherapeutics, to control the numbers of oocysts ingested by the animals while effective immunity develops.

Coccidiostats are used to control naturally occurring coccidiosis. The ideal coccidiostat suppresses the full development of the life cycle of the coccidia, allows immunity to develop, and does not interfere with production performance. Sulfonamides in the feed at 25–35 mg/kg for ≥15 days are effective to control coccidiosis in calves. Monensin is an effective coccidiostat and growth promotant in calves. Postweaning coccidiosis in beef calves has been controlled using monensin administered via intraluminal continuous-release devices. Lasalocid is related to monensin and is also an effective coccidiostat for ruminants. Mixing lasalocid in the milk replacer of calves beginning at 2–4 days of age is an effective way to control coccidiosis. Lasalocid is also effective as a coccidiostat when fed free-choice in salt at a level of 0.75% of the total salt mixture. A level of 1 mg/kg is the most effective and rapid and is recommended when outbreaks of coccidiosis are imminent. Decoquinate in the feed at 0.5–1 mg/kg suppressed oocyst production in experimentally induced coccidiosis of calves. Decoquinate is most effective in preventing coccidial infections when fed continually in dry feed at 0.5 mg/kg. Monensin, lasalocid, and decoquinate at the manufacturer's recommended levels are equally effective. Toltrazuril administered at 15 mg/kg as a single oral dose, 14 days after animals are moved into group housing, effectively prevents diarrhea due to coccidiosis. Diclazuril (5 mg/kg) is being investigated as an oral anticoccidial in calves.

Control of infection should include changes in management factors that contribute to development of clinical disease. Inadequate housing and ventilation should be corrected, feeding practices adopted that avoid fecal contamination of feed, calves grouped by size, and an “all-in/all-out” method of calf movement from pen to pen adopted.

COCCIDIOSIS OF SHEEP

Infection with *Eimeria* is one of the most economically important diseases of sheep. Historically, some *Eimeria* spp were thought to be infectious and transmissible between sheep and goats, but the parasites are now considered host-specific. The names of some species of goat coccidia are still erroneously applied to species of similar appearance found in sheep.

E. crandallii and *E. ovinoidalis* (*ninkohlyakimovae*) are pathogens of lambs (usually 1–6 mo old); *E. ovina* appears to be somewhat less pathogenic. Older sheep serve as sources of infection for the young. All other *Eimeria* of sheep are essentially nonpathogenic, even when large numbers of oocysts are present in feces.

Signs include diarrhea (sometimes containing blood or mucus), dehydration, fever, inappetence, weight loss, anemia, wool breaking, and death. The ileum, cecum, and upper colon are usually most affected and may be thickened, edematous, and inflamed; sometimes, there is mucosal hemorrhage. Thick, white, opaque patches containing large numbers of *E. ovina* oocysts may develop in the small intestine. Because oocysts are prevalent in feces of sheep of all ages, coccidiosis cannot be diagnosed based solely on finding oocysts. Peak oocyst counts of >100,000/g of feces have been reported in 8- to 12-wk-old lambs that appeared healthy. However, diarrhea with oocyst counts of a pathogenic species of >20,000/g is characteristic of coccidiosis in sheep. Immune complex glomerulonephritis has also been attributed to coccidiosis. Fly strike and secondary bacterial enteric infections may accompany coccidiosis in lambs.

Lambs 1–6 mo old in lambing pens, intensive grazing areas, and feedlots are at greatest risk as a result of shipping, ration change, crowding stress, severe weather, and contamination of the environment with oocysts from ewes or other lambs. Because occurrence of coccidiosis under these management systems often becomes so predictable, coccidiostats should be administered prophylactically for 28 consecutive days beginning a few days after lambs are introduced into the environment. A concentrated ration containing monensin at 15 g/tonne can be fed to ewes from 4 wk before lambing until weaning, and to lambs from 4–20 wk of age. The toxic level of monensin for lambs is 4 mg/kg. Lasalocid (15–70 mg/head/day, depending on body wt) may be effective. A combination of monensin and lasalocid at 22 and 100 mg/kg of diet, respectively, is an effective prophylactic against naturally occurring coccidiosis in early weaned lambs under feedlot conditions.

Treatment of affected sheep once coccidiosis has been diagnosed is not effective, but severity can be reduced if treatment is begun early. A single treatment of toltrazuril (20 mg/kg) can significantly reduce the oocyst output in naturally infected lambs for ~3 wk after administration. Diclazuril (1 mg/kg) is an effective oral anticcoccidial in lambs and is administered

once at ~6–8 wk of age (most common) or twice (at 3–4 wk of age and again 3 wk later). Sulfaquinoxaline in drinking water at 0.015% concentration for 3–5 days may be used to treat affected lambs. In groups of lambs at pasture, frequent rotation of pastures for parasite control also helps control coccidial infection. However, when lambs are exposed to infection early in life as a result of infection from the ewe and a contaminated lambing ground, a solid immunity usually develops and problems are seen only when the stocking density is extremely high.

COCCIDIOSIS OF GOATS

Numerous species of *Eimeria* are found in goats in North America and elsewhere. The *Eimeria* spp are host specific and are not transmitted from sheep to goats.

E. artoingi, *E. christensenii*, and *E. ovinoidalis* are highly pathogenic in kids. Clinical signs include diarrhea with or without mucus or blood, dehydration, emaciation, weakness, anorexia, and death. Some goats are actually constipated and die acutely without diarrhea. Usually, stages and lesions are confined to the small intestine, which may appear congested, hemorrhagic, or ulcerated, and have scattered pale, yellow to white macroscopic plaques in the mucosa. Histologically, villous epithelium is sloughed, and inflammatory cells are seen in the lamina propria and submucosa. In addition, there have been several reports of hepatobiliary coccidiosis with liver failure in dairy goats. Diagnosis of intestinal coccidiosis is based on finding oocysts of the pathogenic species in diarrheal feces, usually at tens of thousands to millions per gram of feces. It is not unusual to find oocyst counts as high as 70,000/g of feces in kids without overt disease, but weight gain may be affected.

Angora and dairy goats, raised under different management practices, may have similar patterns of exposure of kids. Just after parturition, nursery pens and surrounding areas may be heavily contaminated with oocysts from does. Resistance to infection is decreased just after shipping, changing rations, introducing new animals, or mixing young with older animals. Coccidiostats can be administered to a herd immediately after diagnosis or as a preventive in predictable situations such as those mentioned above.

Diagnosis and treatment are similar to those for cattle and sheep. Sulfadimidine at 55 g/tonne is also effective for control of coccidiosis in goats. In nonlactating goats, adding monensin to the feed at 18 g/tonne is preventive.

COCCIDIOSIS OF PIGS

Eight species of *Eimeria* and one of *Isospora* infect pigs in North America. Piglets 5–15 days old are characteristically infected with only *I suis*, which produces enteritis and diarrhea. These agents must be differentiated from viruses, bacteria, and helminths that also cause scours in neonatal pigs.

I suis is prevalent in neonatal pigs.

Infection is characterized by a watery or greasy diarrhea, usually yellowish to white and foul smelling. Piglets may appear weak, dehydrated, and undersized; weight gains are depressed, and sometimes piglets die. A contributing factor to mortality is that piglets become covered with diarrheic feces and stay damp. Oocysts are usually shed in the feces and can be identified by their size, shape, and sporulation characteristics; however, in peracute infections, diagnosis must be based on finding stages of the parasite in impression smears or histologic sections of the small intestine, because pigs can die before oocysts are formed. In severely affected piglets, histologic lesions confined to the jejunum and ileum are characterized by villous atrophy, blunting of villi, focal ulceration, and fibrinonecrotic enteritis with parasite stages in epithelial cells.

Preventive control by feeding anticoccidials to sows from 2 wk before farrowing through lactation or to neonatal pigs from birth to weaning has been reported; however, effectiveness of the latter has not been confirmed. Although the sow is a logical source of infection for piglets, this has not been well documented. Thorough removal of feces and disinfection of farrowing facilities between litters greatly decreases infection. Piglets that recover from infection are highly resistant to reinfection.

Although less commonly associated with clinical coccidiosis, *E debilecki*, *E neodeblecki*, *E scabra*, and *E spinosa* have been found in pigs 1–3 mo old with diarrhea. Illness may last 7–10 days, with pigs remaining unthrifty.

Treatment of coccidiosis may include sulfamethazine in drinking water. The control of coccidiosis in newborn piglets infected with *I suis* has been unreliable. The use of coccidiostats in the feed of the sow for several days or a few weeks before and after farrowing has been recommended and used in the field, but the results are variable. Amprolium and monensin are ineffective for prevention of experimental coccidiosis in piglets. A control program designed to decrease the number of oocysts has been recommended and consists of

proper cleaning, disinfection, and steam cleaning of the farrowing housing. Amprolium (25% feed grade) at the rate of 10 kg/tonne of sows' feed started 1 wk before farrowing and continued until the piglets are 3 wk of age has been recommended, but the results are unsatisfactory. A single dose of toltrazuril (20 mg/kg, PO) decreased oocyst excretion, the incidence of diarrhea, and weight gain impairment in piglets with experimentally induced coccidiosis. Diclazuril (5 mg/kg) is being investigated as an oral anticoccidial in piglets.

COCCIDIOSIS OF CATS AND DOGS

Many species of coccidia infect the intestinal tract of cats and dogs. All species appear to be host-specific. Cats have species of *Isospora*, *Besnoitia*, *Toxoplasma*, *Hammondia*, and *Sarcocystis*. Dogs have species of *Isospora*, *Hammondia*, and *Sarcocystis*. Neither dogs nor cats have *Eimeria*.

Hammondia has an obligatory two-host life cycle with cats or dogs as final hosts and rodents or ruminants as intermediate hosts, respectively. *Hammondia* oocysts are indistinguishable from those of *Toxoplasma* and *Besnoitia* but are nonpathogenic in either host. (See also BESNOITIOSIS, p 597, SARCOCYSTOSIS, p 1058, and TOXOPLASMOSIS, p 685.)

The most common coccidia of cats and dogs are *Isospora*. Some *Isospora* spp of cats and dogs can facultatively infect other mammals and produce in various organs an encysted form that is infective for the cat or dog. Two species infect cats: *I felis* and *I rivolta*; both can be identified easily by oocyst size and shape. Almost every cat eventually becomes infected with *I felis*. Four species infect dogs: *I canis*, *I ohioensis*, *I burrowsi*, and *I neorivolta*. In dogs, only *I canis* can be identified by the oocyst structure; the other three *Isospora* overlap in dimensions and can be differentiated only by endogenous developmental characteristics.

Clinical coccidiosis, although not common, has been reported in kittens and puppies. In kittens, it is seen primarily during weaning stress. The most common clinical signs in severe cases are diarrhea (sometimes bloody), weight loss, and dehydration. Usually, coccidiosis is associated with other infectious agents, immunosuppression, or stress.

Treatment may be unnecessary in cats, because they usually spontaneously eliminate the infection. In clinically affected

cats, trimethoprim-sulfonamide (30–60 mg/kg/day for 6 days) can be used.

In kennel conditions when the need for prophylaxis might be predicted, amprolium is said to be effective, although it is not approved for use in dogs. In severe cases, in addition to supportive fluid therapy, sulfonamides such as sulfadimethoxine (50 mg/kg the first day and 25 mg/kg/day for

2–3 wk thereafter) can be used. Sanitation is important, especially in catteries and kennels, or where large numbers of animals are housed. Feces should be removed frequently. Fecal contamination of feed and water should be prevented. Runs, cages, and utensils should be disinfected daily. Raw meat should not be fed. Insect control should be established.

CRYPTOSPORIDIOSIS

Cryptosporidiosis is recognized worldwide, primarily in neonatal calves but also in lambs, kids, foals, and piglets. Cryptosporidia cause varying degrees of naturally occurring diarrhea in neonatal farm animals. The parasites commonly act in concert with other enteropathogens to produce intestinal injury and diarrhea.

Etiology and Epidemiology: There are currently 19 species and 40 genotypes of *Cryptosporidium*. *C. hominis* (formerly *C. parvum* type I) is a specific human pathogen. *C. parvum* (formerly *C. parvum* type II) is zoonotic and infective to many animals, including people and calves. Four cryptosporidial species have been isolated from cattle (*C. parvum*, *C. andersoni*, *C. bovis*, and *C. ryanae*). *C. andersoni* infects the abomasum of older cattle; *C. bovis* and *C. ryanae* are cattle adapted (cattle are the major host). *C. parvum* is a common cause of calf diarrhea, and cryptosporidial oocysts have been detected in the feces of 70% of 1- to 3-wk-old dairy calves. Infection can be detected as early as 5 days of age, with the greatest proportion of calves excreting organisms between days 9 and 14. Many reports associate infection in calves with diarrhea occurring at 5–15 days of age.

C. parvum is also a common enteric infection in young lambs and goats. Diarrhea can result from a monoinfection but more commonly is associated with mixed infections. Infection can be associated with severe outbreaks of diarrhea, with high case fatality rates in lambs 4–10 days old and in goat kids 5–21 days old. Cryptosporidial infection in pigs is seen over a wider age range than in ruminants and has been seen in pigs from 1 wk old through market age. Most infections are asymptomatic, and the

organism does not appear to be an important enteric pathogen in pigs, although it may contribute to postweaning malabsorptive diarrhea. Cryptosporidial infection in foals appears less prevalent and is seen at a later age than in ruminants, with excretion rates peaking at 5–8 wk old. Infection is not usually detected in yearlings or adults. Most studies indicate that cryptosporidiosis is not a common disease in foals; infections in immunocompetent foals are usually subclinical. Persistent clinical infections are seen in Arabian foals with inherited combined immunodeficiency. Cryptosporidiosis is also recorded in young deer and can be a cause of diarrhea in artificially reared orphans.

Transmission: The source of cryptosporidial infection is oocysts that are fully sporulated and infective when excreted in the feces. Large numbers are excreted during the patent period, resulting in heavy environmental contamination. Transmission may occur directly from calf to calf, indirectly via fomite or human transmission, from contamination in the environment, or by fecal contamination of the feed or water supply. A periparturient rise in the excretion of oocysts may occur in ewes. *C. parvum* is not host-specific, and infection from other species (eg, rodents, farm cats) via contamination of feed is also possible.

Oocysts are resistant to most disinfectants and can survive for several months in cool and moist conditions. Oocyst infectivity can be destroyed by ammonia, formalin, freeze-drying, and exposure to temperatures <32°F (0°C) or >149°F (65°C). Ammonium hydroxide, hydrogen peroxide, chlorine dioxide, 10% formol saline, and 5% ammonia are effective in destroying oocyst infectivity. Infectivity in calf feces is reduced after 1–4 days of drying.

Concurrent infections with other enteric pathogens, especially rotavirus and coronavirus, are common, and epidemiologic studies suggest that diarrhea is more severe in mixed infections. Immunocompromised animals are more susceptible to clinical disease than immunocompetent animals, but the relationship between disease and failure of passive transfer of colostral immunoglobulins is not clear. Age-related resistance, unrelated to prior exposure, is seen in lambs but not calves. Infection results in production of parasite-specific antibody, but both cell-mediated and humoral antibody are important in protection, as well as local antibody in the gut of the neonate.

Case fatality rates in cryptosporidiosis are generally low unless complicated by other factors (eg, concurrent infections, energy deficits from inadequate intake of colostrum and milk, chilling from adverse weather conditions).

Pathogenesis: The life cycle of *Cryptosporidium* consists of six major developmental events. After ingestion of the oocyst, there is excystation (release of infective sporozoites), merogony (asexual multiplication), gametogony (gamete formation), fertilization, oocyst wall formation, and sporogony (sporozoite formation). Oocysts of *Cryptosporidium* spp can sporulate within host cells and are infective when passed in the feces. Infection persists until the host's immune response eliminates the parasite. In natural and experimentally produced cases in calves, cryptosporidia are most numerous in the lower part of the small intestine and less common in the cecum and colon. Prepatent periods are 2–7 days in calves and 2–5 days in lambs. Oocysts are usually passed in the feces of calves for 3–12 days.

Clinical Findings: Calves with cryptosporidiosis usually have a mild to moderate diarrhea that persists for several days regardless of treatment. The age at onset is later, and the duration of diarrhea tends to be a few days longer than are seen in the diarrheas caused by rotavirus, coronavirus, or enterotoxigenic *Escherichia coli*. Feces are yellow or pale, watery, and contain mucus. The persistent diarrhea may result in marked weight loss and emaciation. In most cases, the diarrhea is self-limiting after several days. Varying degrees of apathy, anorexia, and dehydration are present. Only rarely do severe dehydration, weakness, and collapse occur, in contrast to findings in other causes of acute diarrhea in neonatal calves. Case fatality rates can be high in herds with cryptosporidiosis when the calf

feeder withholds milk and feeds only electrolyte solutions during the episode of diarrhea. The persistent nature of the diarrhea leads to a marked energy deficit in these circumstances, and the calves die of inanition at 3–4 wk old.

Lesions: Calves with persistent diarrhea have villous atrophy in the small intestine. Histologically, large numbers of the parasite are embedded in the microvilli of the absorptive enterocytes. In low-grade infections, only a few parasites are present, with no apparent histologic changes in the intestine. The villi are shorter than normal, with crypt hyperplasia and a mixed inflammatory cell infiltrate.

Diagnosis: Diagnosis is based on detection of oocysts by examination of fecal smears with Ziehl-Neelsen stains, fecal flotation techniques, ELISA, fluorescent-labeled antibodies, a rapid immunochromatographic test, and PCR. Sheather's flotation sedimentation staining is the most sensitive (83%) and specific (99%) of these techniques, with a relatively low cost per test. This technique requires centrifuging a fecal sample in Sheather's solution, aspirating the top layer and diluting the fluid in phosphate buffer saline, centrifuging, and placing the sediment on the slide and performing a modified Ziehl-Neelsen technique to look for cryptosporidial oocysts. It has been suggested that if the diarrhea is caused by cryptosporidia, there should be 10^5 – 10^7 oocysts/mL of feces. The oocysts are small (5–6 mm in diameter) and relatively non-refractile. They are difficult to detect by normal light microscopy but are readily detected by phase-contrast microscopy.

Treatment: There are no currently licensed therapeutics available in the USA for *C parvum* infection in food animals. Anecdotal reports of success with extra-label use of various compounds have not been replicated in controlled trials. Experimental treatments have for the most part been toxic or ineffective. Halofuginone is reported to markedly reduce oocyst output in experimentally infected lambs and naturally and experimentally infected calves; therapy was also reported to prevent diarrhea. Paromomycin sulfate (100 mg/kg/day, PO, for 11 days from the second day of age) proved successful in preventing natural disease in a controlled clinical field trial in goat kids.

Affected calves should be supported with fluids and electrolytes, both orally and parenterally, as necessary until recovery occurs. Cows' whole milk should be given

in small quantities several times daily (to the full level of requirement) to optimize digestion and to minimize weight loss. Several days of intensive care and feeding may be required before recovery is apparent. Parenteral nutrition may be considered for valuable calves.

Control: The disease is difficult to control. Reducing the number of oocysts ingested may reduce the severity of infection and allow immunity to develop. Calves should be born in a clean environment, and adequate amounts of colostrum should be fed at an early age. Calves should be kept separate without calf-to-calf contact for at least the first 2 wk of life, with strict hygiene at feeding. Diarrheic calves should be isolated from healthy calves during the course of the diarrhea and for several days after recovery. Great care must be taken to avoid mechanical transmission of infection. Calf-rearing houses should be vacated and cleaned out on a regular basis; an "all-in/all-out" management system, with thorough cleaning and several weeks of drying between batches of calves, should be used. Rats, mice, and flies should be controlled when possible, and rodents and pets should not have access to calf grain and milk feed storage areas.

Hyperimmune bovine colostrum can reduce the severity of diarrhea and the

period of oocyst excretion in experimentally infected calves. Protection is not related to circulating levels of specific antibody but requires a high titer of *C parvum* antibody in the gut lumen for prolonged periods. Many research groups have attempted to develop effective vaccines against cryptosporidiosis. Unfortunately, to date, vaccinations have not been effective.

Zoonotic Risk: Infections in domestic animals may be a reservoir for infection of susceptible people. *C hominis* and *C parvum* are considered to be relatively common nonviral causes of self-limiting diarrhea in immunocompetent people, particularly children. In immunocompromised people, clinical disease may be severe. The infection is transmitted predominantly from person to person, but direct infection from animals and waterborne infection from contamination of surface water and drinking water by domestic or wild animal feces can also be important. Animal handlers on a calf farm can be at high risk of diarrhea due to cryptosporidiosis transmitted from infected calves. Immunocompromised people should be restricted from access to young animals and possibly from access to farms.

GIARDIASIS

(Giardosis, Lambliasis, Lambliosis)

Giardiasis is a chronic, intestinal protozoal infection seen worldwide in most domestic and wild mammals, many birds, and people. Infection is common in dogs, cats, ruminants, and pigs. *Giardia* spp have been reported in 0.44%–39% of fecal samples from pet and shelter dogs and cats, 1%–53% in small ruminants, 9%–73% in cattle, 1%–38% in pigs, and 0.5%–20% in horses, with higher rates of infection in younger animals. Farm prevalences in production animals vary between 0% and 100%, with the highest prevalence in younger animals. The cumulative incidence on a farm where *Giardia* has been diagnosed is 100% in cattle and goats and nearly 100% in sheep.

Three major morphologic groups have been described: *G muris* from mice, *G agilis* from amphibians, and a third

group from various warm-blooded animals. There are at least four species in this third group, including *G ardeae* and *G psittaci* from birds, *G microti* from muskrats and voles, and *G duodenalis* (also known as *G intestinalis* and *G lamblia*), a species complex with a wide mammalian host range infecting people and domestic animals. Molecular characterization has shown that *G duodenalis* is in fact a species complex, comprising seven assemblages (A to G), some of which have distinct host preferences (eg, assemblage C/D in dogs, assemblage F in cats) or a limited host range (eg, assemblage E in hoofed livestock), whereas others infect a wide range of animals, including people (assemblage A and B). There is increasing evidence that some assemblages (A and B) that infect domestic

animals can also infect people, although transmission patterns are not totally understood. Dogs have mainly assemblages C and D, cats have assemblages A1 and F, and people are infected with assemblages A2 and B; however, some studies have identified human assemblages of *Giardia* in canine fecal samples.

Cycle and Transmission: Flagellate protozoa (trophozoites) of the genus *Giardia* inhabit the mucosal surfaces of the small intestine, where they attach to the brush border, absorb nutrients, and multiply by binary fission. They usually live in the proximal portion of the small intestine. Trophozoites encyst in the small or large intestine, and the newly formed cysts pass in the feces. There are no intracellular stages. The prepatent period is generally 3–10 days. Cyst shedding may be continual over several days and weeks but is often intermittent, especially in the chronic phase of infection. The cyst is the infective stage and can survive for several weeks in the environment, whereas trophozoites cannot.

Transmission occurs by the fecal-oral route, either by direct contact with an infected host or through a contaminated environment. Characteristics that facilitate infection include the high excretion of cysts by infected animals and the low dose needed for infection. *Giardia* cysts are infectious immediately after excretion and are very resistant, resulting in a gradual increase in environmental infection pressure. High humidity facilitates survival of cysts in the environment, and overcrowding favors transmission.

Pathogenesis: *Giardia* infections cause an increase in epithelial permeability, increased numbers of intraepithelial lymphocytes, and activation of T lymphocytes. Trophozoite toxins and T-cell activation initiate a diffuse shortening of brush border microvilli and decreased activity of the small-intestinal brush border enzymes, especially lipase, some proteases, and disaccharidases. The diffuse microvillus shortening leads to a decrease in overall absorptive area in the small intestine and an impaired intake of water, electrolytes, and nutrients. The combined effect of this decreased resorption and the brush border enzyme deficiencies results in malabsorptive diarrhea and lower weight gain. The reduced activity of lipase and the increased production of mucin by goblet cells may explain the steatorrhea and mucous diarrhea that has been described in *Giardia*-infected hosts.

Clinical Findings and Lesions:

Giardia infections in dogs and cats may be inapparent or may produce weight loss and chronic diarrhea or steatorrhea, which can be continual or intermittent, particularly in puppies and kittens. Feces usually are soft, poorly formed, pale, malodorous, contain mucus, and appear fatty. Watery diarrhea is unusual in uncomplicated cases, and blood is usually not present in feces. Occasionally, vomiting occurs. Giardiasis must be differentiated from other causes of nutrient malabsorption (eg, exocrine pancreatic insufficiency [see p 409] and intestinal malabsorption [see p 400]). Clinical laboratory findings usually are normal.

In calves, and to a lesser extent in other production animals, giardiasis can result in diarrhea that does not respond to antibiotic or coccidiostatic treatment. The excretion of pasty to fluid feces with a mucoid appearance may indicate giardiasis, especially when the diarrhea occurs in young animals (1–6 mo old). Experimental infection of goat kids, lambs, and calves resulted in a decreased feed efficiency and subsequently a decreased weight gain.

Gross intestinal lesions are seldom evident, although microscopic lesions, consisting of villous atrophy and cuboidal enterocytes, may be present.

Diagnosis: The motile, pear-shaped trophozoites ($12\text{--}18 \times 7\text{--}10 \mu\text{m}$) are occasionally seen in saline smears of loose or watery feces. They should not be confused with yeast or with trichomonads, which have a single rather than double nucleus, an undulating membrane, and no concave ventral surface. The oval cysts ($9\text{--}15 \times 7\text{--}10 \mu\text{m}$) can be detected in feces concentrated by the centrifugation-flotation technique using zinc sulfate (specific gravity 1.18). Sodium chloride, sucrose, or sodium nitrate flotation media may be too hypertonic and distort the cysts. Staining cysts with iodine aids identification. Because *Giardia* cysts are excreted intermittently, several fecal examinations should be performed if giardiasis is suspected (eg, three samples collected throughout 3–5 days). *Giardia* may be underdiagnosed, because the cysts are intermittently shed.

For the detection of parasite antigen, immunofluorescence assays and ELISA are commercially available. An in-house ELISA available for use in dogs and cats is a useful tool for clinical diagnosis, particularly when coupled with a centrifugal flotation

examination of feces. It is best to test symptomatic animals with a combination of a direct saline smear of feces, fecal flotation with centrifugation, and a sensitive, specific ELISA optimized for use in the animal being tested (eg, ELISA for dogs and cats).

Treatment: No drugs are approved for treatment of giardiasis in dogs and cats in the USA. Fenbendazole (50 mg/kg/day for 5–10 days) effectively removes *Giardia* cysts from the feces of dogs; no adverse effects are reported, and it is safe for pregnant and lactating animals. This dosage is approved to treat *Giardia* infections in dogs in Europe. Fenbendazole is not approved in cats but may reduce clinical signs and cyst shedding at 50 mg/kg/day for 5 days. Albendazole is effective at 25 mg/kg, bid for 4 days in dogs and for 5 days in cats but should not be used in these species, because it has led to bone marrow suppression and is not approved for use in these species. A combination of praziquantel (5.4–7 mg/kg), pyrantel (26.8–35.2 mg/kg), and febantel (26.8–35.2 mg/kg) also effectively decreases cyst excretion in infected dogs when administered for 3 days. A synergistic effect between pyrantel and febantel was demonstrated in an animal model, suggesting that the combination product may be preferred over febantel alone.

Metronidazole (extra-label at 25 mg/kg, bid for 5 days) is ~65% effective in eliminating *Giardia* spp from infected dogs but may be associated with acute development of anorexia and vomiting, which may occasionally progress to pronounced generalized ataxia and vertical positional nystagmus. Metronidazole may be administered to cats at 10–25 mg/kg, bid for 5 days. Metronidazole benzoate is perhaps better tolerated by cats. Safety concerns limit the use of metronidazole in dogs and cats. A possible treatment strategy for dogs would

be to treat first with fenbendazole for 5–10 days or to administer both fenbendazole and metronidazole together for 5 days, being sure to bathe the dogs to remove cysts. If clinical disease still persists and cyst shedding continues, the combination therapy should be extended for another 10 days.

Currently, no drug is licensed for the treatment of giardiasis in ruminants. Fenbendazole and albendazole (5–20 mg/kg/day for 3 days) significantly reduce the peak and duration of cyst excretion and result in a clinical benefit in treated calves. Paromomycin (50–75 mg/kg, PO, for 5 days) was found to be highly efficacious in calves.

Oral fenbendazole may be an option for treatment in some birds.

Control: *Giardia* cysts are immediately infective when passed in the feces and survive in the environment. Cysts are a source of infection and reinfection for animals, particularly those in crowded conditions (eg, kennels, catteries, or intensive rearing systems for production animals). Feces should be removed as soon as possible (at least daily) and disposed of with municipal waste. Infected dogs and cats should be bathed to remove cysts from the hair coat. Prompt and frequent removal of feces limits environmental contamination, as does subsequent disinfection. Cysts are inactivated by most quaternary ammonium compounds, steam, and boiling water.

To increase the efficacy of disinfectants, solutions should be left for 5–20 min before being rinsed off contaminated surfaces. Disinfection of grass yards or runs is impossible, and these areas should be considered contaminated for at least a month after infected dogs last had access. Cysts are susceptible to desiccation, and areas should be allowed to dry thoroughly after cleaning.

DISEASES OF THE MOUTH IN LARGE ANIMALS

LIP LACERATIONS

Wounds of the lips and cheeks occur frequently in horses. The most common cause is external trauma or secondary to the use of inappropriate bits or restraint devices. Lip lacerations may be accompa-

nied by mandibular or incisor bone fractures with or without dental fractures and tooth avulsions. These occur when a horse grasps objects with its mouth and then pulls back when startled. Lip lacerations without bone or teeth involvement can be sutured, usually with a good

result. Healing is rapid because of the good blood supply to the head. Lacerations left to heal by second intention can result in orocutaneous fistula, which may require resection and primary wound closure. Rarely, skin grafts or mucosal flaps are required to manage orocutaneous fistula.

GLOSSOPLÉGIA

Glossoplegia, or paralysis of the tongue, is uncommon. Causes in horses include incorrect placement of obstetric snares in neonates during forced extraction, strangles, upper respiratory tract infections, meningitis, botulism, encephalomyelitis, leukoencephalomalacia, equine protozoal encephalomyelitis, and cerebral abscessation. Any condition that damages the hypoglossal nerve (cranial nerve XII), which is the major motor nerve to the muscles of the tongue, can result in glossoplegia. Neonates with glossoplegia must be monitored carefully to ensure they are able to eat. If necessary in affected foals, a nasogastric tube should be placed for administration of colostrum or IV plasma administered to prevent failure of passive transfer. Foals unable to maintain hydration may require IV fluid therapy and anti-inflammatory medication (eg, phenylbutazone, flunixin meglumine, or dexamethasone). Prophylaxis against gastric ulceration is also indicated. If the condition persists for >10 days after birth, the prognosis for regaining normal function is guarded. Inflammatory diseases and trauma may also result in transient glossoplegia. Occasionally, horses undergoing prolonged dental procedures involving excessive traction on the tongue can develop temporary glossoplegia. The prognosis of glossoplegia depends on the horse's response to treatment for the primary condition.

In cattle, glossoplegia may accompany severe actinobacillosis (see p 589). There may be complete paralysis of the tongue accompanied by necrosis of the tip. Such conditions are occasionally seen in outbreaks in feedlot cattle and may follow a bout of viral stomatitis.

NEOPLASIA

Neoplasia of the mouth and lips other than viral papillomas are uncommon and include melanomas, sarcoids, and squamous cell carcinoma. In gray horses, melanomas may develop and infiltrate the commissures of

the mouth and cause hard, thickened, tumorous plaques that may not be detected until well advanced. Verrucous, fibroblastic, and sessile or flat forms of equine sarcoid can involve the mouth and lips.

Carbon dioxide laser removal of oral and lip melanomas should be considered. Complete removal of oral and lip melanomas is not necessary for a successful outcome. In addition, some horses may respond to oral cimetidine therapy. Surgical resection of sarcoids can be performed successfully with the carbon dioxide laser. Along with laser resection, intratumoral administration of cisplatin can be considered to lessen the chances for recurrence. Cryosurgery is another acceptable method of treatment. Squamous cell carcinoma can be difficult to treat because of its invasive nature. Surgical debulking with the carbon dioxide laser followed by intratumoral injection of cisplatin can be effective in select cases. Regardless of treatment, the prognosis for complete resolution of oral squamous cell carcinoma is guarded to poor. (See also TUMORS OF THE SKIN AND SOFT TISSUES, p 942.)

SLAFRAMINE TOXICOSIS

Causes of slaframine toxicosis include the ingestion of forages, particularly clovers, infected with the fungus *Rhizoctonia leguminicola*, which produces the toxic alkaloid slaframine. Profuse ptialism is often the only clinical sign. Affected animals have no evidence of oral ulceration or other oral lesions. Ptialism resolves once the animal is removed from the affected forage. The differential diagnoses for large animals (particularly ruminants) include blue-tongue, vesicular stomatitis, vesicular exanthema, and foot-and-mouth disease.

An extensive sarcoid involving the lower lip of a horse. Courtesy of Dr. Jan Hawkins.

STOMATITIS

Stomatitis is a clinical sign of many diseases in large animals. Oral trauma or contact with chemical irritants (eg, horses that lick at their legs after having been blistered with caustic agents) may result in transient stomatitis. Traumatic injury from the ingestion of the awns of barley, foxtail, porcupine grass, and spear grass, as well as feeding on plants infested with hairy caterpillars, also will result in stomatitis in horses and cattle.

Clinical signs commonly associated with acute active stomatitis include ptialism, dysphagia, or resistance to oral examination. Oral examination is facilitated by sedation, after which the mouth can be examined carefully with the aid of a mouth speculum and a light source. Ulcers should be visually and digitally evaluated to determine whether embedded foreign material (eg, grass awns) is present. If the etiology is ingestion of foreign material, changing the quality and quantity of the hay or removing the animal from a pasture with grass awns may effect recovery.

Differential diagnoses include actinobacillosis, foot-and-mouth disease, malignant

catarrhal fever, and bovine viral diarrhea. Epidemic diseases such as bluetongue in ruminants, swine vesicular disease, and vesicular stomatitis in horses must be differentiated from other forms of acute noninfectious or contagious stomatitis.

PAPILLAR STOMATITIS

Viral papillomas are found around the lips and mouths of young animals, particularly in cattle from 1 mo to 2 yr old. In some herds, the rate of occurrence may be 100%. The lesions are characteristically white to pink, raised, and appear proliferative. Most papillomas resolve spontaneously. However, in some cases, the lesions may coalesce to form cosmetically unacceptable masses, and owners may request therapy.

Surgical removal of larger masses can be cosmetically acceptable and lessen recovery time. Small masses can also be manually debrided or crushed to stimulate the immune system. Other therapies, including cryosurgery and the use of autologous vaccines, may also be effective. Most papillomas eventually disappear if given time.

DISEASES OF THE ESOPHAGUS IN LARGE ANIMALS

ESOPHAGEAL OBSTRUCTION

(Choke)

Esophageal obstruction (choke) occurs when the esophagus is obstructed by food or foreign objects. It is the most common esophageal disease in large animals. Horses most commonly obstruct on grain, beet pulp, or hay. Esophageal obstruction can also occur after recovery from standing chemical restraint or general anesthesia. Cattle tend to obstruct on a single solid object, eg, apples, beets, potatoes, turnips, corn stalks, or ears of corn.

Clinical Findings: In horses, clinical signs associated with esophageal obstruction include nasal discharge of feed material or saliva, dysphagia, coughing, or ptialism. The horse may appear anxious and/or appear to "retch" by stretching and arching

the neck. Affected horses may continue to eat or drink, worsening the clinical signs.

In cattle, clinical signs include free-gas bloat, ptialism, or nasal discharge of food and water. Ruminants may be bloated and in distress or recumbent, or there may be protrusion of the tongue, extension of the head, bruxism, and ptialism. Acute and complete esophageal obstruction is an emergency because it prohibits eructation of ruminal gases, and free-gas bloat develops. Severe free-gas bloat may result in asphyxia, because the expanding rumen puts pressure on the diaphragm and reduces venous return of blood to the heart.

Diagnosis: The clinical signs of esophageal obstruction are usually diagnostic. Physical examination findings compatible with esophageal obstruction include nasal

discharge of feed material and water, bruxism, ptyalism, and palpable enlargement of the esophagus; in some instances, foreign objects lodged in the cervical esophagus may be located via palpation. Subcutaneous emphysema, cervical cellulitis, and fever may be associated with esophageal rupture. The inability to pass a stomach (ruminants) or nasogastric tube (horses) can also confirm the diagnosis.

An endoscopic examination helps localize the site of esophageal obstruction, type of obstructing material, and extent of esophageal ulceration. Because of the risk of aspiration pneumonia, the respiratory tract should be evaluated carefully, including auscultation of the heart and lungs and thoracic radiography. In complicated or chronic cases, a CBC and serum biochemistry profile should be performed. CBC abnormalities include leukocytosis, left shift, toxic neutrophils, and hyperfibrinogenemia. Biochemical abnormalities include hyponatremia, hypochloremia, and hypokalemia secondary to excessive loss of saliva.

Treatment: In horses, many cases of esophageal obstruction may resolve spontaneously if feed and water are withheld. Spontaneous resolution can be aided by IV administration of sedatives (such as xylazine and detomidine). Oxytocin (0.11–0.22 mg/kg, IV) has proved useful to relax esophageal smooth muscle. To ensure that the esophageal obstruction has resolved completely, all horses with suspected obstruction should have a nasogastric tube passed into the stomach or an endoscopic examination.

Waiting >4–6 hr before passing a nasogastric tube is not recommended because of the risk of esophageal mucosal ulceration and aspiration pneumonia. Horses that do not respond to conservative management (withdrawal of feed and water, IV sedation or oxytocin) should be initially treated with esophageal lavage as follows: After IV sedation, a nasogastric tube is inserted to the level of the obstruction. Water is delivered to the obstruction site with a stomach pump, and the tube is slowly inserted and withdrawn to lavage the esophagus. The head must be lower than the torso to minimize aspiration of water into the lungs. Lavage via nasogastric tube is successful in at least 90% of cases.

For horses unresponsive to standing esophageal lavage, general anesthesia should be considered, with the horse

positioned in lateral recumbency and orotracheally intubated. Again, the head must be positioned lower than the torso to prevent water passing into the lungs. A cuffed endotracheal tube (18–22 mm) is inserted into the esophagus as far as possible or to the level of the esophageal obstruction, and the cuff inflated. A nasogastric tube is inserted through the endotracheal tube, and the esophagus is lavaged as previously described. Again, resolution of obstruction should be confirmed with endoscopy or passage of the nasogastric tube into the stomach. An esophagotomy to resolve esophageal obstruction is rarely required.

All chronic cases of esophageal obstruction should be evaluated endoscopically after successful resolution. These horses frequently have esophageal ulceration that can be circumferential. Severe mucosal ulceration can result in esophageal stricture and repeat obstruction. Endoscopy is also useful to exclude esophageal diverticula, which can predispose to esophageal obstruction. Esophageal diverticula can also be diagnosed with contrast esophagograms.

Horses without mucosal ulceration should be fed water-soaked, complete pelleted feed for at least 7–14 days to minimize the likelihood of repeat esophageal obstruction. Horses with mucosal ulceration should be fed this diet for 60 days, after which follow-up endoscopy should be performed to evaluate whether mucosal ulceration has resolved and esophageal stricture has occurred. Horses with chronic mucosal ulceration with stricture may require surgical management.

Aspiration pneumonia should be managed with IV or oral antimicrobials and anti-inflammatory drugs. Commonly used antimicrobials include potassium or procaine penicillin G (22,000 U/kg, IV [potassium] or IM [procaine], bid-qid), trimethoprim sulfamethoxazole (30 mg/kg, PO, bid), and gentamicin sulfate (6.6 mg/kg/day, IV or IM). Metronidazole (15 mg/kg, PO, qid) is useful for management of anaerobic infections. The most common anti-inflammatory drugs used are phenylbutazone (2.2–4.4 mg/kg, PO or IV, bid) and flunixin meglumine (1.1 mg/kg, IV, bid).

In cattle, esophageal obstruction accompanied by ruminal tympany is an emergency, and if clinical signs of distress indicate, the bloat (*see* p 227) must be relieved by trocarization through the left sublumbar fossa. Once tympany has been relieved, solid objects (eg, potatoes) may

often be massaged free or spontaneously dislodge as their outer surfaces are softened by saliva. Caution should be used if any attempt is made to push an offending object down the esophagus using a probang; esophageal rupture and fatal septic mediastinitis may result.

Esophageal obstruction in ruminants can be managed with standing esophageal lavage via orogastric tube or while under general anesthesia (*see* p 215). Large foreign bodies can often be pushed into the rumen without further problems. Rare cases of esophageal obstruction with foreign bodies may be treated with esophagotomy.

Complications of Esophageal Obstruction

In horses and cattle, aspiration pneumonia (*see* p 1417) and septic pleuropneumonia may be complications of esophageal obstruction, especially in chronic cases. Chronic esophageal obstruction (>24 hr) may be associated with pressure necrosis of the esophageal mucosa due to prolonged contact with the foreign body. Circumferential mucosal damage may contribute to esophageal stricture.

An often fatal complication of chronic esophageal obstruction is esophageal rupture. Cervical esophageal rupture can lead to localized cervical cellulitis or septic mediastinitis or pleuropneumonia. Intrathoracic esophageal rupture is typically fatal. Cervical esophageal rupture can be managed by local drainage, wound lavage, and insertion of a nasogastric tube into the rupture site. A traction diverticulum is allowed to form, and the nasogastric tube is removed. Esophageal rupture managed with extraoral alimentation rarely results in esophageal stricture. In cases of septic mediastinitis or pleuropneumonia, euthanasia should be considered because of the difficulty in successfully resolving the bacterial infection.

Esophageal Obstruction Secondary to Extraesophageal Disease

Cervical and prethoracic trauma may result in periesophageal or esophageal fibrosis involving the muscular layer. This can result in esophageal stricture and intermittent or recurrent esophageal obstruction. In some cases, there is no external evidence of cervical or prethoracic trauma. In cases of suspected extraesophageal trauma, endoscopic examination of the esophagus

and a contrast esophagogram can be useful diagnostic tools. Once the site of esophageal stricture is identified, some cases of muscular stricture can be resolved with esophageal myotomy or removal of fibrous connective tissue surrounding the esophagus.

ESOPHAGEAL STRICTURES

Idiopathic esophageal strictures can occur in foals. Initial diagnosis based on clinical signs may be delayed because of other more frequent causes of dysphagia, including idiopathic dorsal displacement of the soft palate or nasal reflux of milk, cleft palate, or pharyngeal cysts. All cases of nasal discharge of milk in foals should be evaluated with endoscopy. Esophageal stricture in older horses or ruminants typically results from mucosal ulceration secondary to esophageal obstruction. Appropriate treatment depends on whether the stricture is mucosal or mural (involving the muscular wall). Mucosal strictures can be treated conservatively with dietary management (*see* p 215), bougienage with a cuffed endotracheal tube, or surgery. Mural strictures are best managed with esophageal myotomy. Surgical treatment of mucosal strictures may involve esophagotomy through the strictured area with insertion of a nasogastric tube, resulting in a traction diverticulum, mucosal resection and anastomosis, or full-thickness esophageal resection and anastomosis.

ESOPHAGEAL NEOPLASIA

The most common neoplasia of the esophagus in horses is squamous cell carcinoma, which carries a guarded prognosis. Focal neoplastic masses can be managed with esophageal resection and anastomosis. Unfortunately, most cases of squamous cell carcinoma are not amenable to surgery, and euthanasia should be considered.

In ruminants, bovine viral papillomas (ie, warts) occasionally develop in the cranial esophagus and pharynx and, in the presence of other agents, may result in development of esophageal carcinoma. In some areas of the world (eg, Scotland and South America), such disease may follow ingestion of natural bracken fern toxins. There is also a causal relationship between such bracken fern tumors and bladder cancers in cattle. (*See also* BRACKEN FERN POISONING, p 3089.)

GASTROINTESTINAL ULCERS IN LARGE ANIMALS

Gastric ulcers are important in adult horses, foals, and pigs. Abomasal ulcers (*see* p 241) in mature cattle and calves appear to be increasing in importance.

GASTRIC ULCERS IN HORSES

(Equine gastric ulcer syndrome)

Gastric ulcers (equine gastric ulcer syndrome [EGUS]) are common in horses and foals. This syndrome is most closely associated with horses involved in performance disciplines; changes in housing or social interaction; and illness. Prevalence in unmedicated racehorses in active training is at least 90%, whereas that in nonracing performance disciplines exceeds 60%. Neonatal foals are at significant risk for development of perforating peptic ulcers until they are several weeks old, because their gastric mucosa is not developed to full thickness at birth. Although spontaneous healing of peptic ulcer lesions has been noted, if the horse is maintained in the circumstances inciting EGUS, the lesions are unlikely to heal without medical intervention.

EGUS describes a spectrum of inflammatory and disruptive mucosal pathophysiology affecting tissues of the distal esophagus, stomach, and entrance into the duodenum. Endoscopic surveys indicate that ~80% of these lesions are found in the nonglandular squamous mucosa of the stomach, especially on the lesser curvature just proximal to the margo plicatus. However, significant portions of the squamous mucosa along the greater curvature and up into the fundus may also be involved, along with lesions in the antrum or pylorus. Duodenal ulceration in adult horses and foals is considered part of EGUS and, hence, a peptic (acid-induced) disorder. Duodenal ulceration, perforation, and stricture can occur, and it is not known whether these problems develop solely as a result of enteritis (duodenitis) or whether peptic factors have a role. However, once a stricture occurs, gastric and esophageal ulcers are often present and severe, secondary to delayed gastric emptying.

Etiology: Ulcers in the nonglandular squamous mucosa are associated with

repeated direct insult from ultra-low pH fluid normally found in the glandular region of the stomach. Pressure increases inside the abdomen (associated with exercise), collapsing the stomach and forcing the acid gastric contents upward. The more fluid (and highly acidic) contents of the lower stomach come in contact with the nonglandular squamous mucosa, causing inflammation and, potentially, erosions to varying degrees.

The causes of ulcers in the glandular mucosa of the stomach are less well defined. Use of nonselective NSAIDs are known to reduce blood flow to the GI tract, causing decreased production of the mucob carbonate matrix by the gastric glandular mucosa and resulting in ulceration. This is not a consistent finding, however. Additionally, attempts have been made to isolate and/or correlate evidence of *Helicobacter* spp organisms from the stomach of horses with and without gastritis and ulcers. Results of these studies have been equivocal or negative, and the role of this organism in glandular equine gastric ulcers has not been determined.

Clinical Findings: Most foals with gastric ulcers do not exhibit clinical signs. Clinical signs become apparent when the ulceration is widespread or severe. The classic clinical signs for gastric ulcers in foals include diarrhea, bruxism, poor nursing, dorsal recumbency, and ptyalism. These signs are vague and not specific for gastric ulcers. In fact, ptyalism is a sign of esophagitis, which in most foals is secondary to gastric outflow obstruction and gastroesophageal reflux. Other causes, including esophageal obstruction and *Candida* infection, should be considered. Importantly, when a foal exhibits clinical signs, the ulcers are severe and should be diagnosed and treated immediately. Sudden gastric perforation without prior signs occurs sporadically in foals.

Adult horses with ulcers display nonspecific signs, including abdominal discomfort (colic), poor appetite, mild weight loss, poor body condition, and attitude changes. Horses with severe abdominal pain or colic may have gastric ulcers, but they are unlikely to be the primary cause of the abdominal pain. No

strong correlation between the extent of ulceration and the severity of clinical signs has been seen.

Complications related to gastric ulcers are most frequent and severe in foals and include perforation, delayed gastric emptying, gastroesophageal reflux and esophagitis, and megaesophagus secondary to chronic gastroesophageal reflux. Ulcers in the proximal duodenum or at the pylorus can cause fibrosis and stricture. Duodenal and pyloric stricture can lead to delayed gastric emptying in foals and adult horses. In rare cases, severe gastric ulceration causes fibrosis and contracture of the stomach.

Diagnosis: Neither clinical signs nor clinicopathologic laboratory tests are specific for gastric ulcers, and an abnormality in a laboratory test does not preclude the possibility that another disorder may be present. Gastric ulcers can develop secondary to stress due to problems in many organ systems or as a result of hospitalization or stall confinement. Endoscopy and visualization of the ulcers in an empty stomach is the only definitive method of diagnosis. Endoscopes with light sources that can be varied in wavelength may be used to more easily visualize inflammatory stages of this disease before breaching of the epithelium by outright ulceration. A presumptive diagnosis can be reasonably made from significant reduction in clinical signs after several days of treatment with a medication known to be effective in raising gastric pH and allowing healing of gastric mucosa.

Treatment: Suppression of gastric acidity and maintenance of a pH between 4 and 5

are the primary treatment objectives. Studies have examined the use of surface-coating agents, antacids, histamine type-2 receptor antagonists (ranitidine and cimetidine), and the proton pump inhibitor omeprazole in a carrier designed to aid passage through the acid stomach into the small intestine for absorption. Sucralfate binds to the gastric glandular mucosa and may promote healing there, although studies using sucralfate have not shown it to be efficacious in the treatment of gastric ulcers in horses or foals. Thus, its use in horses is questionable. Antacids have yet to be proved effective in either healing or preventing gastric ulcers. They must be administered in relatively high volumes every 2 hr to neutralize stomach acid. Ranitidine (6.6 mg/kg, PO, tid) has been shown to be effective in healing gastric ulcers when horses were removed from training. Studies have not shown cimetidine to be effective. Omeprazole is the only medication approved by the FDA for treatment (4 mg/kg/day, PO) or prevention (1 mg/kg/day, PO) of gastric ulcers in horses, and it has been shown to allow gastric ulcers to heal in horses that continue their normal training.

GASTRIC ULCERS IN PIGS

Ulcers affect the pars esophagea in pigs and cause sporadic cases of acute gastric hemorrhage, resulting in death or slow growth due to chronic ulceration.

Etiology: Ulcers result when the unprotected stratified squamous epithelium of the pars esophagea is subjected to insult from the mixture of acid, bile, and digestive enzymes present in the distal region of the stomach. The mucosa that surrounds the esophageal opening is not protected by mucus and therefore relies on maintenance of a pH gradient between the proximal and distal regions of the pig stomach. Many risk factors are associated with the development of ulcers, most of which are associated with an increase in fluidity of the stomach contents. The most important of these factors relate to feed, particularly the use of finely ground feed (<700 microns average particle size). Consumption of finely ground pelleted feed results in rapid stomach transit time and fluid stomach content. Other important factors tend to be associated with disruption in feed intake, eg, an outbreak of respiratory disease, hot weather, or management errors that lead

Gastric ulcers on endoscopy in a foal. Courtesy of Dr. Thomas Lane.

to empty feeders. Disruption in feed intake results again in fluid stomach contents and lack of a physical barrier between the acidic distal contents and the sensitive pars esophageal region. It is possible that factors that cause increased acid production may influence the prevalence and severity of ulcers, but in general there is little evidence that hyperacidity is a primary cause. Similarly, *Helicobacter*-like organisms can often be identified under the mucus on the surface of the glandular mucosa of the distal stomach, but evidence that these bacteria are a cause of ulcer development in the pars esophagea is lacking, and epidemiologic studies showing an association are inconsistent. The presence of the bacteria in the glandular region and the lesion in the pars esophagea is difficult to explain from a biological standpoint.

Clinical Findings: Sudden death usually involving only a small number of pigs in a grower-finisher barn is a common presentation, but higher numbers can occur sporadically and are usually associated with a triggering event such as feed disruption. Death is caused by acute hemorrhage from the ulcer into the stomach, so the carcass appears notably pale but generally in good body condition. If bleeding is less severe, the clinical signs are those associated with anemia, such as paleness; if bleeding is prolonged, the pig will become weak, lose body condition, and grow slower than its pen-mates. Scant amounts of black tarry feces indicating digested blood may be noted. Vomiting may be seen but diarrhea is generally not present, which helps to differentiate gastric ulceration from other conditions. Other causes of blood loss or anemia need to be excluded. The most common age group to show clinical signs are pigs 2–6 mo old, as well as sows. Most pigs reared in modern confinement systems develop lesions in the pars esophagea. Lesions can both develop and heal quickly. This makes it difficult to determine whether erosions of the pars esophageal mucosa cause slow growth rate if blood loss is minimal and anemia is not present. Scarring can occur and, if severe, can result in narrowing of the esophageal-gastric opening. Clinical signs of esophageal stenosis include regurgitation of a meal shortly after consumption and loss of body condition.

Lesions: Gastric ulcers in pigs involve the mucosa near the esophageal opening

in a rectangular area of white, glistening, nonglandular, squamous epithelium. In a pig that has died suddenly from a gastric ulcer, it is common to find a crater 2.5–5 cm in diameter encompassing the entrance of the esophagus. The crater appears as a cream or gray, punched-out area and may contain blood clots or debris. In acute hemorrhage, the stomach and upper small intestine contain dark blood. Earlier lesions are characterized by hyperkeratosis and parakeratosis of the squamous epithelium in the area of the esophageal opening into the stomach. It is assumed that the thickening of the epithelial surface is a defense against insult. Cracks and erosions can occur, particularly near the pars esophageal border. A deep erosion may result in acute and severe blood loss even while most of the surface of the pars esophagea remains intact. The healed ulcer appears as a stellate scar. Erosion and healing may occur over and over. Severe scarring can create stenosis of the esophageal opening.

Diagnosis: Appearance in a pen of one or two listless, anorectic pigs that show weight loss, anemia, dark feces, and sometimes dyspnea is suggestive of gastric ulceration, as is the sudden death of an apparently healthy pig. Differential diagnoses include hemorrhagic bowel syndrome, porcine proliferative enteropathy (*Lawsonia intracellularis* infection), porcine circovirus-associated disease, and swine dysentery. Gross lesions at necropsy are usually sufficient to confirm a diagnosis of gastric ulceration. Abattoir examination has been used to evaluate the prevalence of stomach lesions but must be interpreted with caution. Pigs are generally held without feed before shipping and may be held overnight at the packing plant before slaughter, and during this time ulcers can form or become more severe. On an individual animal basis, possibly for a valuable breeding boar or a pet, an endoscopic examination could readily identify a gastric ulcer.

Treatment and Prevention: No economically feasible treatments are currently available for commercial swine. For pet pigs or very valuable breeding animals, proton-pump inhibitors have been shown to reduce gastric acidity and allow mucosal healing. For commercial swine production, weak, pale pigs in poor body condition should be euthanized, and milder cases might respond to palliative care. Placing the affected pig in a

hospital pen and initially coaxing it to eat using a highly palatable feed, and possibly administering analgesics, can be attempted. Early marketing of affected pigs should be considered.

Preventing, or reducing the incidence of gastric ulcers should focus on maintaining good feed intake, including management steps such as ensuring feeders do not run out of feed, sufficient feeder space is available, and mixing of pigs is minimized. During hot weather, it is important to make the pigs as comfortable as possible using cooling methods such as water spraying or high ventilation rates. Vaccination and other steps to minimize respiratory and systemic

diseases are important to prevent gastric ulcer deaths. Attention to feed milling practices has a major impact on reducing ulcers. Feed produced using a roller mill is regarded to be less ulcerogenic than feed made with a hammer mill. Fine particle size is associated with more likelihood of ulcers but is also associated with improved feed efficiency, so economic considerations must be understood before a drastic change in particle size is recommended. In general, a coarse feed that will protect pigs from stomach lesions may not be an acceptable solution because of the added feed cost, but in an outbreak situation a short-term feed change may be necessary.

DISEASES OF THE RUMINANT FORESTOMACH

SIMPLE INDIGESTION

(Mild dietary indigestion)

Simple indigestion is a minor disturbance in ruminant GI function that occurs most commonly in cattle and rarely in sheep and goats. Simple indigestion is a diagnosis of exclusion and is typically related to an abrupt change in the quality or quantity of the diet.

Etiology: Almost any dietary factor that can alter the intraruminal environment can cause simple indigestion. The disease is common in hand-fed dairy and beef cattle because of variability in the quality and quantity of their feed. Dairy cattle may suddenly eat excessive quantities of highly palatable feeds such as corn or grass silage; beef cattle may eat excessive quantities of relatively indigestible, poor-quality roughage during winter. During drought, cattle and sheep may be forced to eat large quantities of poor-quality straw, bedding, or grain. Simple indigestion can result from suddenly changing the feed, using spoiled or frozen feeds, introducing urea to a ration, turning cattle onto a lush cereal grain pasture, or introducing feedlot cattle to a high-level grain ration.

Simple indigestion is usually associated with a sudden change in the pH of the ruminal contents, such as a decrease in ruminal pH due to rapid fermentation of ingested carbohydrates or an increase in

ruminal pH due to forestomach hypomotility and putrefaction of ingested feed. It can also result from accumulation of excessive quantities of relatively indigestible feed that may physically impair rumen function. Multiple animals are usually simultaneously affected because simple indigestion has a nutritional basis, although the severity of the clinical signs can vary among animals.

Clinical Findings: Clinical signs depend on the type of animal affected and cause of the disorder. Overfeeding of silage causes anorexia and a moderate drop in milk production in dairy cattle. The rumen is usually full, firm, and doughy; primary contractions are decreased in rate or absent, but secondary contractions may be present although usually decreased in strength. Temperature, pulse, and respiration are normal. The feces are normal to firm in consistency but reduced in amount. Recovery usually is spontaneous within 24–48 hr.

Simple indigestion due to excessive feeding of grain results in anorexia and ruminal hypomotility to atony (stasis). The rumen is not necessarily full and may contain excessive fluid. The feces are usually soft to watery and foul smelling. The mechanism for diarrhea formation is uncertain but is most likely due to increased luminal osmolality as a result of the rapid degradation of ingested carbohydrates. The affected animal is bright and alert and

usually begins to eat within 24 hr. A more severe digestive upset due to excessive feeding of grain is described as grain overload (*see below*).

Diagnosis: A diagnosis of simple indigestion is based on a history of an abrupt change in the nature or amount of the diet, multiple animals being affected, and most importantly the exclusion of other causes of forestomach dysfunction. The diagnosis is confirmed by collection and examination of ruminal fluid, which may have an abnormal pH (<6 or >7), decrease in the numbers and size of protozoa, or prolonged methylene blue reduction time (a measure of bacterial metabolic activity).

The systemic reaction and painful responses to deep palpation of the xiphoid in traumatic reticuloperitonitis are not seen. The history and the absence of ketonuria help eliminate clinical ketosis from consideration. The possibility of left displaced abomasum usually can be eliminated by simultaneous percussion and auscultation.

Vagal indigestion, abomasal volvulus, and cecocolic volvulus become more readily detectable as they progress. Grain overload is differentiated from simple indigestion by its greater severity and the pronounced fall in the pH of the rumen contents to <5.5.

Treatment: Treatment is aimed at correcting the suspected dietary factors. Spontaneous recovery is usual when animals are fed a typical ruminant diet. Administration of ~20 L of warm water or saline via a stomach tube, followed by vigorous kneading of the rumen, may help restore rumen function in adult cattle. Magnesium hydroxide PO may be useful when excessive amounts of grain have been ingested, but magnesium hydroxide should only be administered to cattle documented to have low ruminal pH (<6); otherwise, excessive forestomach and systemic alkalization can result. Purported rumenatorics (eg, nux vomica, ginger, tartar emetic, parasymphathomimetics) are not recommended as ancillary treatments. If too much urea (*see* p 3043) or protein has been ingested, vinegar (acetic acid) may be administered PO to return rumen pH to the normal range. If the number or activity of ruminal microbes is reduced, administration of 4–8 L of ruminal fluid from a healthy cow will help. (*See also* RUMINAL FLUID TRANSFER, p 2562.) Oral or intravenous electrolyte solutions may be needed to correct electrolyte and acid-base abnormalities, particularly in dehydrated cattle.

GRAIN OVERLOAD

(Lactic acidosis, Carbohydrate engorgement, Rumenitis)

Grain overload is an acute disease of ruminants that is characterized by rumen hypomotility to atony, dehydration, acidemia, diarrhea, depression, incoordination, collapse, and in severe cases, death.

Etiology and Pathogenesis: The disease is most common in cattle that accidentally gain access to large quantities of readily digestible carbohydrates, particularly grain. Grain overload also is common in feedlot cattle when they are introduced to heavy grain diets too quickly. Wheat, barley, and corn are the most readily digestible grains; oats are less digestible. Less common causes include engorgement with apples, grapes, bread, batter's dough, sugar beets, potatoes, mangels, or sour wet brewer's grain that was incompletely fermented in the brewery. The amount of feed required to produce acute illness depends on the kind of grain, previous experience of the animal with that grain, the nutritional status and condition of the animal, and the nature of the ruminal microflora. Adult cattle accustomed to heavy grain diets may consume 30–45 lb (15–20 kg) of grain and develop only moderate illness, whereas others may become acutely ill and die after eating 20 lb (10 kg) of grain.

Ingestion of toxic amounts of highly fermentable carbohydrates is followed within 2–6 hr by a change in the microbial population in the rumen. The number of gram-positive bacteria (such as *Streptococcus bovis*) increases markedly, which results in the production of large quantities of lactic acid. The rumen pH falls to ≤5, which destroys protozoa, cellulolytic organisms, and lactate-utilizing organisms, and impairs rumen motility. The low pH allows the lactobacilli to utilize the carbohydrate and to produce excessive quantities of lactic acid. The superimposition of lactic acid and its salts, L-lactate and D-lactate, on the existing solutes in the rumen liquid causes osmotic pressure to rise substantially, which results in the movement of excessive quantities of fluid into the rumen, causing fluid ruminal contents and dehydration.

The low ruminal pH causes a chemical rumenitis, and the absorption of lactate, particularly D-lactate, results in lactic acidosis and acidemia. In addition to metabolic (strong ion) acidosis and

dehydration, the pathophysiologic consequences are hemoconcentration, cardiovascular collapse, renal failure, muscular weakness, shock, and death. Animals that survive may develop mycotic rumenitis in several days and hepatic abscesses several weeks or months later. They may have evidence of ruminal epithelial damage at slaughter. The relationship between grain overload and chronic laminitis in cattle is unclear.

Clinical Findings: Carbohydrate engorgement results in conditions ranging from simple indigestion (*see* p 221) to a rapidly fatal acidemia and strong ion (metabolic) acidosis. The interval between overeating and onset of signs is shorter with ground feed than with whole grain, and severity increases with the amount eaten. A few hours after engorgement, the only detectable abnormality may be an enlarged rumen and possibly some abdominal pain (manifest by belly kicking or treading of the hindlimbs). In the mild form, the rumen movements are reduced but not entirely absent, the cattle are anorectic but bright and alert, and diarrhea is common. The animals usually begin eating again 3–4 days later without any specific treatment.

Within 24–48 hr of the onset of severe overload, some animals will be recumbent, some will be staggering, and others will be standing quietly; all will be completely off feed. Immediately after consuming large quantities of dry grain, cattle may gorge themselves on water, but once ill they usually do not drink at all.

Body temperature is usually below normal, 98°–101°F (36.5°–38.5°C); however, in animals exposed to the sun in hot weather, it may be increased to 106°F (41°C). Respirations tend to be shallow and rapid, up to 60–90/min. The heart rate usually is increased in accordance with severity of the acidemia; the prognosis is poor for cattle with heart rates >120 bpm. Diarrhea is common and usually profuse and malodorous. The feces are soft to liquid, yellow or tan, and have an obvious sweet-sour odor. The feces frequently contain undigested kernels of the feed that has induced the overload. In mild cases, dehydration equals 4%–6% body wt, but losses may reach 10%–12% in severe cases.

In severe grain overload, the primary contractions of the rumen are completely absent, although the gurgling sounds of gas rising through the large quantity of fluid are usually audible on auscultation. Ballotement and auscultation of the left flank may

elicit fluid-splashing sounds in the rumen. The contents of the rumen, as palpated through the left paralumbar fossa, may feel firm and doughy in cattle that were previously on a roughage diet and have consumed a large amount of grain. In cattle that have become ill on smaller amounts of grain, the rumen will feel not necessarily full, but rather resilient because of the excessive fluid. Severely affected animals stagger and may bump into objects; their palpebral reflex is sluggish or absent, and the pupillary light reflex is usually present but slower than normal. The extent of depression of the palpebral reflex is associated with the plasma D-lactate concentration and provides a useful clinical method to categorize severity of lactic acidosis and monitor response to treatment. Affected animals commonly lie quietly, often with the head turned into the flank, and their response to any stimulus is much decreased so that they resemble cases of parturient paresis.

Acute laminitis may be present and is most common in those animals not severely affected; chronic laminitis may develop weeks or months later. Anuria is a common finding in acute cases, and diuresis after fluid therapy is a good prognostic sign.

Death may occur in 24–72 hr, and rapid development of acute signs, particularly recumbency, indicates a need for aggressive treatment. A decrease in heart rate, increase in temperature, return of ruminal movement, and passage of large amounts of soft feces are more favorable signs. However, some animals appear to improve temporarily but become severely ill again 3–4 days later, probably because of severe bacterial and fungal rumenitis; death from acute, diffuse peritonitis usually follows in 2–3 days. In pregnant cattle that survive the severe form of the disease, abortion may occur 10–14 days later.

Diagnosis: The diagnosis is usually obvious if the history is available and multiple animals are affected. The diagnosis can be confirmed by the clinical findings, a low ruminal pH (<5.5 in cattle unaccustomed to a high grain diet), and examination of the microflora of the rumen for presence of live protozoa. When only one animal is involved and there is no history of engorgement, the diagnosis is less obvious, but the clinical signs—a static rumen with gurgling fluid sounds, diarrhea, ataxia, and a normal temperature—are characteristic. Rumen fluid analysis in these animals is required to confirm the diagnosis of grain overload.

Although parturient paresis (*see* p 988) may resemble rumen overload, diarrhea and dehydration are not typical, the intensity of heart sounds is reduced, and the response to calcium injection is usually dramatic. Peracute coliform mastitis and acute diffuse peritonitis may also resemble overload, but usually a careful examination will reveal the cause of the toxemia.

To avoid an increase in pH on exposure to air, the pH of rumen fluid obtained by ororuminalestomach tube or ruminal paracentesis should be checked promptly. Normally, the pH in cattle on roughage is 6–7; in those on a high grain diet, 5.5–6. Values <5.5 are strongly suggestive of grain overload, and a rumen pH <5 indicates severe acidemia and metabolic acidosis. Wide-range (2–11) pH indicator paper is suitable for field use. Ruminal fluid should also be examined microscopically if access to a laboratory is available; fluid from affected cattle will have decreased numbers of protozoa (particularly large and medium-sized protozoa). In grain overload, a Gram stain of ruminal fluid will reveal a change from predominantly gram-negative bacteria (normal) to predominantly gram-positive bacteria, with a concomitant loss in bacterial diversity.

Increased blood D-lactate and L-lactate and inorganic phosphate concentrations, mild hypocalcemia, and reduced urinary pH are also seen, but it is seldom necessary to check such values to make a firm diagnosis. The diagnostic problem is to properly assess which animals require vigorous therapy (or slaughter), which require supportive therapy, which have only a mild indigestion that will correct itself if water and grain intake are restricted and hay and exercise are provided, and which need nothing beyond their routine care and ration. In an outbreak of overload involving several animals, it is necessary to identify those animals that need the most intensive therapy and those that will recover with minimal medical therapy.

If the cattle are found while still eating, it is possible that some of the group will fall into each category, and close monitoring is necessary to minimize losses. Cattle found while engorging or shortly thereafter should be allowed no more concentrate but plenty of good hay for up to 24 hr and should be forced to walk periodically. Cattle that appear normal at the end of the first day are probably in good health, although if even one is ill, all should be monitored closely for 48 hr. Most of those that have eaten enough concentrate to be affected seriously show signs within 6–8 hr.

Treatment: For all cattle suspected of having eaten large quantities of concentrate, it is believed that restricting water intake for the first 18–24 hr is helpful, although this has not been proved. If overload is serious, slaughter for salvage should be considered; in feeders nearing the end of their feeding period, it may well be the most economic choice. Mortality is high in severely affected animals unless aggressive therapeutic measures are started early. In such animals, removal of rumen contents and replacement with ingesta taken from healthy animals is necessary. In animals still standing, rumenotomy is preferred to rumen lavage, because animals may aspirate during the lavage procedure and only rumenotomy ensures that all ingested grain has been removed. Rumen lavage may be accomplished with a large stomach tube if sufficient water is available. A large-bore tube (2.5 cm inside diameter, 3 m long) should be used, and enough water added to distend the left paralumbar fossa; gravity flow is then allowed to empty out what it will. Repeating this 15–20 times achieves the same results (and requires about as much time) as using rumenotomy to empty and wash out the rumen with a siphon.

Emptying the rumen should be followed by rumen inoculation (*see* p 2561) and, if not accomplished before signs of severe illness are evident, by rigorous fluid therapy to correct the metabolic acidosis and dehydration and to restore renal function. Initially, over a period of ~30 min, 5% sodium bicarbonate solution should be given IV (5 L/450 kg). During the next 6–12 hr, a balanced electrolyte solution, or a 1.3% solution of sodium bicarbonate in saline, may be given IV, up to as much as 60 L/450 kg body wt. Urination should resume during this period. Usually, it is unnecessary and even undesirable to also administer antacids PO (or intraruminally), particularly if IV sodium bicarbonate has been administered. Procaine penicillin G (22,000 U/kg/day) should be administered IM to all affected animals for at least 5 days to minimize development of bacterial rumenitis and liver abscesses. Thiamine should also be administered IM to facilitate metabolism of L-lactate via pyruvate and oxidative phosphorylation; animals with grain overload also have low concentrations of thiamine in rumen fluid because of increased production of thiaminase by ruminal bacteria. There is no effective preventive treatment for mycotic rumenitis.

Emptying the rumen is unnecessary in less severe cases. In these cattle, magnesium hydroxide (500 g/450 kg body wt) should be

added to warm water, pumped into the rumen, and mixed therein via kneading the flank. This may be all that is necessary if the rumen pH is >5 and the animal is still standing and reasonably alert several hours after the engorgement. A heart rate of 70–85 bpm, weak ruminal contractions, normal body temperature, and especially willingness to eat are additional reassurances that this therapy will suffice. If any question remains, additional fluids should be given. During the convalescent period, which may last 2–4 days, good-quality hay and no grain should be given, and the grain then reintroduced gradually. If good appetite returns within 3 days, the prognosis is good. However, if treatment was not started early enough to prevent acidification of the ruminal contents, and mycotic infection of the rumen wall ensues, relapse is likely within 3–5 days and the prognosis is grave.

Prevention: Accidental access to concentrates for which cattle have developed an appetite, in quantities to which they are unaccustomed, should be avoided. Feedlot cattle should be introduced gradually to concentrate rations over a period of 2–3 wk, beginning with a mixture of $\leq 50\%$ concentrate in the milled feed containing roughage.

SUBACUTE RUMINAL ACIDOSIS

(Chronic ruminal acidosis, Subclinical ruminal acidosis)

Ruminant animals are adapted to digest and metabolize predominantly forage diets; however, growth rates and milk production are increased substantially when ruminants consume high-grain diets. One consequence of feeding excessive amounts of rapidly fermentable carbohydrates in conjunction with inadequate fiber to ruminants is subacute ruminal acidosis, which is characterized by periods of low ruminal pH that resolve without treatment and is rarely diagnosed. Dairy cows, feedlot cattle, and feedlot sheep are at risk of developing this condition.

Etiology and Pathophysiology: Ruminal pH fluctuates considerably during a 24-hr period (typically between 0.5–1 pH units) and is determined by the dynamic balance between the intake of fermentable carbohydrates, buffering capacity of the rumen, and rate of acid absorption from the rumen. In general, subacute ruminal acidosis is caused by ingestion of diets high

in rapidly fermentable carbohydrates and/or deficient in physically active fiber. Subacute ruminal acidosis is most commonly defined as repeatedly occurring prolonged periods of depression of the ruminal pH to values between 5.6 and 5.2. The low ruminal pH is caused by excessive accumulation of volatile fatty acids (VFAs) without persistent lactic acid accumulation and is restored to normal by the animal's own physiologic responses.

The ability of the rumen to rapidly absorb organic acids contributes greatly to the stability of ruminal pH. It is rarely difficult for peripheral tissues to utilize VFAs already absorbed from the rumen; however, absorption of these VFAs from the rumen can be an important bottleneck.

Ruminal VFAs are absorbed passively across the rumen wall. This passive absorption is enhanced by finger-like papillae, which project away from the rumen wall and provide massive surface area for absorption. Ruminal papillae increase in length when cattle are fed higher-grain diets; this presumably increases ruminal surface area and absorptive capacity, which protects the animal from acid accumulation in the rumen. Dairy cows are especially at risk in the transition period, because the ruminal mucosa needs several weeks to adjust to high-grain diets, and in peak lactation, when high levels of easily fermentable carbohydrates are fed to avoid excessive negative energy balance.

One mechanism by which affected animals resolve ruminal acidosis and return ruminal pH to normal is by selecting long forage particles, either by choosing to preferentially consume long dry hay or by sorting a mixed ration in favor of longer forage particles. Another mechanism is by reducing overall feed intake. Depressed dry-matter intake becomes especially evident if ruminal pH falls below ~ 5.5 . Intake depression may be mediated by pH receptors and/or osmolality receptors in the rumen. Inflammation of the ruminal epithelium (rumenitis) could cause pain and also contribute to intake depression during subacute ruminal acidosis.

Absorption of VFA inherently increases as ruminal pH drops. These acids are absorbed only in the protonated state. Because they have a pK_a of ~ 4.8 , the proportion of these acids that is protonated increases dramatically as ruminal pH decreases below 5.5. Lactate levels in the ruminal fluid of cattle with subacute ruminal acidosis, if measured, are usually not increased; however, the pathogenesis of excessive lactate produc-

tion in the rumen is well described. Ruminal carbohydrate fermentation shifts to lactate production at lower ruminal pH (mostly due to *Streptococcus bovis* proliferating and shifting to lactate instead of VFA production); this can offset gains from VFA absorption. Ruminal lactate production is undesirable, because lactate has a much lower pK_a than VFAs (3.9 vs. 4.8). For example, lactate is 5.2 times less protonated than VFAs at pH 5. As a result, lactate stays in the rumen longer and contributes to the downward spiral in ruminal pH.

Additional adaptive responses are invoked if lactate production begins. Lactate-utilizing bacteria, such as *Megasphaera elsdenii* and *Selenomonas ruminantium*, begin to proliferate. These beneficial bacteria convert lactate to other VFAs, which are then easily protonated and absorbed. However, the turnover time of lactate utilizers is much slower than that of lactate synthesizers. Thus, this mechanism may not be invoked quickly enough to fully stabilize ruminal pH. Periods of very high ruminal pH, as during feed deprivation, may inhibit populations of lactate utilizers (which are sensitive to higher ruminal pH) and leave them more susceptible to severe ruminal acidosis.

Besides disrupting microbial balance, feed deprivation causes cattle to overeat when feed is reintroduced. This creates a double effect in lowering ruminal pH. Cycles of feed deprivation followed by overconsumption greatly increase the risk of subacute ruminal acidosis.

Low ruminal pH during subacute ruminal acidosis also reduces the number of species of bacteria in the rumen, although the metabolic activity of the bacteria that remain is very high. Protozoal populations are particularly limited at lower ruminal pH; the absence of ciliated protozoa in ruminal fluid is often observed during bouts of subacute ruminal acidosis. When fewer species of bacteria and protozoa are present, the ruminal microflora are less stable and less able to maintain normal ruminal pH during periods of sudden dietary change. Thus, periods of subacute ruminal acidosis leave animals more susceptible to future episodes of ruminal acidosis.

The pathophysiologic consequences of ruminal acidosis have mainly been described in feedlot cattle and in cattle surviving acute ruminal acidosis. Low ruminal pH may lead to rumenitis, erosion, and ulceration of the ruminal epithelium. Once the ruminal epithelium is inflamed, bacteria may colonize the papillae and leak into the portal circulation. These bacteria

may cause liver abscesses, which may eventually lead to peritonitis around the site of the abscess.

Caudal vena cava syndrome is caused by the release of septic emboli from liver abscesses; this septic material then travels via the caudal vena cava to the lungs. These bacteria proliferate in lung tissue and may ultimately invade pulmonary vessels, causing them to rupture. This is observed clinically as hemoptysis and even peracute deaths due to massive pulmonary hemorrhage.

Subacute ruminal acidosis has traditionally been associated with claw horn lesions, assumed to be caused by subacute laminitis. However, this pathophysiologic mechanism has not been experimentally characterized or reproduced. In recent years, alternative explanations for the development of claw horn lesions have been suggested.

Clinical Findings: The main clinical signs attributed to subacute ruminal acidosis are reduced or cyclic feed intake, decreased milk production, reduced fat, poor body condition score despite adequate feed intake, and unexplained diarrhea. High rates of culling or unexplained deaths may be noted in the herd. Sporadic cases of caudal vena cava syndrome may also be seen. The clinical signs are delayed and insidious. Actual episodes of low ruminal pH are not identified; in fact, by the time an animal is observed to be off-feed, its ruminal pH has probably been restored to normal. Diarrhea may follow periods of low ruminal pH; however, this finding is inconsistent and may be related to other dietary factors as well.

Diagnosis: Subacute ruminal acidosis is diagnosed on a group rather than individual basis. Measurement of pH in the ruminal fluid of a representative portion of apparently healthy animals in a group has been used to help make the diagnosis of subacute ruminal acidosis in dairy herds. Animal selection should be from highest-risk groups: cows between ~15–30 days in milk in component-fed herds and cows between ~50–150 days in milk in herds fed total mixed rations. Ruminal fluid is collected by rumenocentesis, and its pH is determined on a pH meter. Twelve or more animals are typically sampled at ~2–4 hr after a grain feeding (in component-fed herds) or 6–10 hr after the first daily feeding of a total mixed ration. If >25% of the animals tested have a ruminal pH <5.5, then the group is considered to be at high risk of subacute ruminal acidosis. This type of diagnostic tool should be used in conjunction

with other factors such as ration evaluation, evaluation of management practices, and identification of health problems on a herd basis.

Milk fat depression is a poor and insensitive indicator of subacute ruminal acidosis in dairy herds.

Treatment and Prevention: Because subacute ruminal acidosis is not detected at the time of depressed ruminal pH, there is no specific treatment for it. Secondary conditions may be treated as needed.

The key to prevention of subacute ruminal acidosis is allowing for ruminal adaption to high-grain diets, as well as limiting intake of readily fermentable carbohydrates. This requires both good diet formulation (proper balance of fiber and nonfiber carbohydrates) and excellent feed bunk management. Animals consuming well-formulated diets remain at high risk of this condition if they tend to eat large meals because of excessive competition for bunk space or after periods of feed deprivation.

Field recommendations to feed component-fed concentrates to dairy cattle during the first 3 wk of lactation are usually excessive. Feeding excessive quantities of concentrate and insufficient forage results in a fiber-deficient ration likely to cause subacute ruminal acidosis. The same situation may be seen during the last few days before parturition if the ration is fed in separate components; as dry-matter intake drops before calving, dry cows preferentially consume concentrates instead of forage and develop acidosis.

Subacute ruminal acidosis may also be caused by errors in delivery of the rations or by formulation of rations that contain excessive amounts of rapidly fermentable carbohydrates or a deficiency of fiber. Recommendations for the fiber content of dairy rations are available in the National Research Council report, *Nutrient Requirements of Dairy Cattle* (see p 2250). Dry-matter content errors in total mixed rations are commonly related to a lack of adjustment for changes in moisture content of forages.

Including long-fiber particles in the diet reduces the risk of subacute ruminal acidosis by encouraging saliva production during chewing and by increasing rumination after feeding. The provision of adequate long-fiber particles reduces the risk of ruminal acidosis but cannot eliminate it. If a total mixed ration is fed, it is important that the long-fiber particles not be easily sorted away from the rest of the diet; this could

delay their consumption until later in the day or cause them to be refused completely. Sorting can be prevented by providing long-fiber particles less than ~5 cm in length, by having adequate (~50%–55%) moisture in the mixed ration, and by including ingredients such as liquid molasses that help ration ingredients stick together.

Ruminant diets should also be formulated to provide adequate buffering. This can be accomplished by feedstuff selection and/or by addition of dietary buffers such as sodium bicarbonate or potassium carbonate. The dietary cation-anion difference (DCAD) is used to quantify the buffering capacity of a diet; diets for animals at high risk of ruminal acidosis should be formulated to provide a DCAD of >250 mEq/kg of diet dry matter, using the formula $(Na + K) - (Cl + S)$ to calculate DCAD.

Supplementing the diet with direct-fed microbials that enhance lactate utilization in the rumen may reduce the risk of subacute ruminal acidosis. Yeasts, propionobacteria, lactobacilli, and enterococci have been used for this purpose. Ionophore (eg, monensin sodium) supplementation may also reduce the risk by selectively inhibiting ruminal lactate producers and by reducing meal size.

BLOAT

(Ruminal tympany)

Bloat is an overdistention of the rumenoreticulum with the gases of fermentation, either in the form of a persistent foam mixed with the ruminal contents, called primary or frothy bloat, or in the form of free gas separated from the ingesta, called secondary or free-gas bloat. It is predominantly a disorder of cattle but may also be seen in sheep. The susceptibility of individual cattle to bloat varies and is genetically determined.

Death rates as high as 20% are recorded in cattle grazing bloat-prone pasture, and in pastoral areas, the annual mortality rate from bloat in dairy cows may approach 1%. There is also economic loss from depressed milk production in nonfatal cases and from suboptimal use of bloat-prone pastures. Bloat can be a significant cause of mortality in feedlot cattle.

Etiology and Pathogenesis: In primary ruminal tympany, or frothy bloat, the cause is entrapment of the normal gases of fermentation in a stable

foam. Coalescence of the small gas bubbles is inhibited, and intraruminal pressure increases because eructation cannot occur. Several factors, both animal and plant, influence the formation of a stable foam. Soluble leaf proteins, saponins, and hemicelluloses are believed to be the primary foaming agents and to form a monomolecular layer around gas rumen bubbles that has its greatest stability at about pH 6. Salivary mucin is antifoaming, but saliva production is reduced with succulent forages. Bloat-producing pastures are more rapidly digested and may release a greater amount of small chloroplast particles that trap gas bubbles and prevent their coalescence. The immediate effect of feeding is probably to supply nutrients for a burst of microbial fermentation. However, the major factor that determines whether bloat will occur is the nature of the ruminal contents. Protein content and rates of digestion and ruminal passage reflect the forage's potential for causing bloat. Over a 24-hr period, the bloat-causing forage and unknown animal factors combine to maintain an increased concentration of small feed particles and enhance the susceptibility to bloat.

Bloat is most common in animals grazing legume or legume-dominant pastures, particularly alfalfa, ladino, and red and white clovers, but also is seen with grazing of young green cereal crops, rape, kale, turnips, and legume vegetable crops. Legume forages such as alfalfa and clover have a higher percentage of protein and are digested more quickly. Other legumes, such as sainfoin, crown vetch, milk vetch, fenugreek, and birdsfoot trefoil, are high in protein but do not cause bloat, probably because they contain condensed tannins, which precipitate protein and are digested more slowly than alfalfa or clover. Leguminous bloat is most common when cattle are placed on lush pastures, particularly those dominated by rapidly growing leguminous plants in the vegetative and early bud stages, but can also be seen when high-quality hay is fed.

Frothy bloat also is seen in feedlot cattle, and less commonly in dairy cattle, on high-grain diets. The cause of the foam in feedlot bloat is uncertain but is thought to be either the production of insoluble slime by certain species of rumen bacteria in cattle fed high-carbohydrate diets or the entrapment of the gases of fermentation by the fine particle size of ground feed. Fine particulate matter, such as in finely ground grain, can markedly affect foam stability, as

can a low roughage intake. Feedlot bloat is most common in cattle that have been on a grain diet for 1–2 mo. This timing may be due to the increase in the level of grain feeding or to the time it takes for the slime-producing rumen bacteria to proliferate to large enough numbers.

In **secondary ruminal tympany**, or **free-gas bloat**, physical obstruction of eructation is caused by esophageal obstruction due to a foreign body (eg, potatoes, apples, turnips, kiwifruit), stenosis, or pressure from enlargement outside the esophagus (as from lymphadenopathy or sporadic juvenile thymic lymphoma). Interference with esophageal groove function in vagal indigestion and diaphragmatic hernia may cause chronic ruminal tympany. This also occurs in tetanus. Tumors and other lesions, such as those caused by infection with *Actinomyces bovis*, of the esophageal groove or the reticular wall are less common causes of obstructive bloat. There also may be interference with the nerve pathways involved in the eructation reflex. Lesions of the wall of the reticulum (which contains tension receptors and receptors that discriminate between gas, foam, and liquid) may interrupt the normal reflex essential for escape of gas from the rumen.

Ruminal tympany also can be secondary to the acute onset of ruminal atony that occurs in anaphylaxis and in grain overload; this causes a decrease in rumen pH and possibly an esophagitis and rumenitis that can interfere with eructation. Ruminal tympany also develops with hypocalcemia. Chronic ruminal tympany is relatively frequent in calves up to 6 mo old without apparent cause; this form usually resolves spontaneously.

Unusual postures, particularly lateral recumbency, are commonly associated with secondary tympany. Ruminants may die of bloat if they become accidentally cast in dorsal recumbency or other restrictive positions in handling facilities, crowded transportation vehicles, or irrigation ditches.

Clinical Findings: Bloat is a common cause of sudden death. Cattle not observed closely, such as pastured and feedlot cattle and dry dairy cattle, usually are found dead. In lactating dairy cattle, which are observed regularly, bloat commonly begins within 1 hr after being turned onto a bloat-producing pasture. Bloat may develop on the first day after being placed on the pasture but more commonly develops on the second or third day.

In primary pasture bloat, the rumen becomes obviously distended suddenly, and the left flank may be so distended that the contour of the paralumbar fossa protrudes above the vertebral column; the entire abdomen is enlarged. As the bloat progresses, the skin over the left flank becomes progressively more taut and, in severe cases, cannot be "tent ed." Dyspnea and grunting are marked and are accompanied by mouth breathing, protrusion of the tongue, extension of the head, and frequent urination. Rumen motility does not decrease until bloat is severe. If the tympany continues to worsen, the animal will collapse and die. Death may occur within 1 hr after grazing began but is more common ~3–4 hr after onset of clinical signs. In a group of affected cattle, there are usually several with clinical bloat and some with mild to moderate abdominal distention.

In secondary bloat, the excess gas is usually free on top of the solid and fluid ruminal contents, although frothy bloat may be seen in vagal indigestion when there is increased ruminal activity. Secondary bloat is seen sporadically. There is tympanic resonance over the dorsal abdomen left of the midline. Free gas produces a higher pitched ping on percussion than frothy bloat. The distention of the rumen can be detected on rectal examination. In free-gas bloat, the passage of a stomach tube or trocarization releases large quantities of gas and alleviates distention.

Lesions: Necropsy findings are characteristic. Congestion and hemorrhage of the lymph nodes of the head and neck, epicardium, and upper respiratory tract are marked. The lungs are compressed, and intrabronchial hemorrhage may be present. The cervical esophagus is congested and hemorrhagic, but the thoracic portion of the esophagus is pale and thoracic—the demarcation known as the "bloat line" of the esophagus. The rumen is distended, but the contents usually are much less frothy than before death. The liver is pale because of expulsion of blood from the organ.

Diagnosis: Usually, the clinical diagnosis of frothy bloat is obvious. The causes of secondary bloat must be ascertained by clinical examination to determine the cause of the failure of eructation.

Treatment: In life-threatening cases, an emergency rumenotomy may be necessary; it is accompanied by an explosive release of ruminal contents and, thus, marked relief

for the cow. Recovery is usually uneventful, with only occasional minor complications.

A trocar and cannula may be used for emergency relief, although the standard-sized instrument is not large enough to allow the viscous, stable foam in peracute cases to escape quickly enough. A larger bore instrument (2.5 cm in diameter) is necessary, but an incision through the skin must be made before it can be inserted through the muscle layers and into the rumen. If the cannula fails to reduce the bloat and the animal's life is threatened, an emergency rumenotomy should be performed. If the cannula provides some relief, an antifoaming agent can be administered through the cannula, which can remain in place until the animal has returned to normal, usually within several hours.

When the animal's life is not immediately threatened, passing a stomach tube of the largest bore possible is recommended. A few attempts should be made to clear the tube by blowing and moving it back and forth in an attempt to find large pockets of rumen gas that can be released. In frothy bloat, it may be impossible to reduce the pressure with the tube, and an antifoaming agent should be administered while the tube is in place. If the bloat is not relieved quickly by the antifoaming agent, the animal must be observed carefully for the next hour to determine whether the treatment has been successful or whether an alternative therapy is necessary.

A variety of antifoaming agents are effective, including vegetable oils (eg, peanut, corn, soybean) and mineral oils (paraffins), at doses of 250–500 mL. Dioctyl sodium sulfosuccinate, a surfactant, is commonly incorporated into one of the above oils and sold as a proprietary antibloat remedy, which is effective if administered early. Poloxalene (25–50 g, PO) is effective in treating legume bloat but not feedlot bloat. Placement of a rumen fistula provides short-term relief for cases of free-gas bloat associated with external obstruction of the esophagus.

Control and Prevention: Prevention of pasture bloat can be difficult. Management practices used to reduce the risk of bloat include feeding hay, particularly orchard grass, before turning cattle on pasture, maintaining grass dominance in the sward, or using strip grazing to restrict intake, with movement of animals to a new strip in the afternoon, not the early morning. Hay must constitute at least one-third of the diet to

effectively reduce risk of bloat. Feeding hay or strip grazing may be reliable when the pasture is only moderately dangerous, but these methods are less reliable when the pasture is in the pre-bloom stage and the bloat potential is high. Mature pastures are less likely to cause bloat than immature or rapidly growing pastures.

The only satisfactory method available to prevent pasture bloating is continual administration of an antifoaming agent during the risk period. This is widely practiced in grassland countries such as Australia and New Zealand. The most reliable method is drenching twice daily (eg, at milking times) with an antifoaming agent. Spraying the agent onto the pasture is equally effective, provided the animals have access only to treated pasture. This method is ideal for strip grazing but not when grazing is uncontrolled. The antifoaming agent can be added to the feed or water or incorporated into feed blocks, but success with this method depends on adequate individual intake. The agent can be "painted" on the flanks of the animals, from which it is licked during the day, but animals that do not lick will be unprotected.

Available antifoaming agents include oils and fats and synthetic nonionic surfactants. Oils and fats are given at 60–120 mL/head/day; doses up to 240 mL are indicated during dangerous periods. Poloxalene, a synthetic polymer, is a highly effective nonionic surfactant that can be given at 10–20 g/head/day and up to 40 g/head/day in high-risk situations. It is safe and economical to use and is administered daily through the susceptible period by adding to water, feed grain mixtures, or molasses. Pluronic agents facilitate the solubilization of water-insoluble factors that contribute to formation of a stable foam. A pluronic detergent (Alfasure®) and a water-soluble mixture of alcohol ethoxylate and pluronic detergents (Blocare 4511) also are effective but are not approved by the FDA. Ionophores effectively prevent bloat, and a sustained-release capsule administered into the rumen and releasing 300 mg of monensin daily for a 100-day period protects against pasture bloat and improves milk production on bloat-prone pastures.

The ultimate aim in control is development of a pasture that permits high production, while keeping incidence of bloat low. The use of pastures of clover and grasses in equal amounts comes closest to achieving this goal. Bloat potential varies between cultivars of alfalfa, and low-risk LIRD (low initial rate of digestion) cultivars

are available commercially. The addition of legumes with high condensed tannins to the pasture seeding mix (10% sainfoin) can reduce the risk of bloat where there is strip grazing, as can the feeding of sainfoin pellets.

To prevent **feedlot bloat**, rations should contain ≥10–15% cut or chopped roughage mixed into the complete feed. Preferably, the roughage should be a cereal, grain straw, grass hay, or equivalent. Grains should be rolled or cracked, not finely ground. Pelleted rations made from finely ground grain should be avoided. The addition of tallow (3%–5% of the total ration) may be successful occasionally, but it was not effective in controlled trials. The nonionic surfactants, such as poloxalene, have been ineffective in preventing feedlot bloat, but the ionophore lasalocid is effective in control.

TRAUMATIC RETICULOPERITONITIS

(Hardware disease, Traumatic gastritis)

Traumatic reticuloperitonitis develops as a consequence of perforation of the reticulum. It is important as a differential diagnosis of other diseases marked by stasis of the GI tract, because it causes similar signs. Traumatic reticuloperitonitis is most common in mature dairy cattle, occasionally seen in beef cattle, and rarely reported in other ruminants.

Cattle commonly ingest foreign objects, because they do not discriminate against metal materials in feed and do not completely masticate feed before swallowing. The disease is common when green chop, silage, and hay are made from fields that contain old rusting fences or baling wire, or when pastures are on areas or sites where buildings have recently been constructed, burned, or torn down. The grain ration may also be a source because of accidental addition of metal.

Etiology: Swallowed metallic objects, such as nails or pieces of wire, fall directly into the reticulum or pass into the rumen and are subsequently carried over the ruminoreticular fold into the cranioventral part of the reticulum by ruminal contractions. The reticulo-omasal orifice is elevated above the floor, which tends to retain heavy objects in the reticulum, and the honeycomb-like reticular mucosa traps sharp objects. Contractions of the reticulum promote penetration of the wall by the

foreign object. Compression of the ruminoreticulum by the uterus in late pregnancy and straining during parturition increase the likelihood of an initial penetration of the reticulum and may also disrupt adhesions caused by an earlier penetration.

Perforation of the wall of the reticulum allows leakage of ingesta and bacteria, which contaminates the peritoneal cavity. The resulting peritonitis is generally localized and frequently results in adhesions. Less commonly, a more severe diffuse peritonitis develops. The object can penetrate the diaphragm and enter the thoracic cavity (causing pleuritis and sometimes pulmonary abscessation) and the pericardial sac (causing pericarditis, sometimes followed by myocarditis). Occasionally, the liver or spleen may be pierced and become infected, resulting in abscessation, or septicemia can develop.

Clinical Findings: The initial penetration of the reticulum is characterized by the sudden onset of ruminoreticular atony and a sharp fall in milk production. Fecal output is decreased. The rectal temperature is often mildly increased. The heart rate is normal or slightly increased, and respiration is usually shallow and rapid. Initially, the

cow exhibits an arched back; an anxious expression; a reluctance to move; and an uneasy, careful gait. Forced sudden movements as well as defecating, urinating, lying down, getting up, and stepping over barriers may be accompanied by groaning. A grunt may be elicited by applying pressure to the xiphoid or by firmly pinching the withers, which causes extension of the thorax and lower abdomen. The grunt can be detected by placing a stethoscope over the trachea and applying pressure or pinching the withers at the end of an inspiration. Tremor of the triceps and abduction of the elbow may be seen.

In chronic cases, feed intake and fecal output are reduced, and milk production remains low. Signs of cranial abdominal pain become less apparent, and the rectal temperature usually returns to normal as the acute inflammation subsides and peritoneal contamination is walled off. Some cattle develop vagal indigestion syndrome (*see* p 233) because of the adhesions that form after foreign body perforation, particularly those on the ventromedial reticulum.

Cows with pleuritis or pericarditis due to foreign body perforation usually are depressed, tachycardic (>90 bpm), and pyrexic (104°F [40°C]). Pleuritis is manifest

The relationship between the reticulum, diaphragm, and heart and pericardium in large ruminants. *Illustration by Dr. Gheorghe Constantinescu.*

by fast, shallow respiration; muffled lung sounds; and possibly pleuritic friction rubs. Thoracentesis may yield several liters of septic fluid. Traumatic pericarditis is most commonly characterized by muffled heart sounds; however, early in the disease process pericardial friction rubs or gas and fluid splashing sounds (washing machine murmur) can be heard on auscultation. Jugular vein distention and congestive heart failure with marked submandibular and brisket edema is a frequent sequela of traumatic reticulopericarditis. Prognosis is grave with these complications. Penetration through the pericardium into the myocardium usually results in extensive hemorrhage into the pericardial sac or ventricular arrhythmias and sudden death.

Diagnosis: This can be based on history (when available) and clinical findings if the cow is examined when signs initially appear. Without an accurate history and when the condition has been present for several days or longer, diagnosis is more difficult. Other causes of peritonitis, particularly perforated abomasal ulcers, can be difficult to distinguish from traumatic reticuloperitonitis. Differential diagnoses should include conditions that can produce variable or nonspecific GI signs, eg, indigestion, lymphosarcoma, or intestinal obstruction. Abomasal displacement or volvulus should be excluded by simultaneous auscultation and percussion. Pleuritis or pericarditis of nontraumatic origin produces signs similar to those associated with foreign body perforation.

Although not always necessary, laboratory tests may be helpful. In many cases, there is a neutrophilia with a left shift. Plasma fibrinogen concentrations may be increased, and serum haptoglobin, amyloid A, and total plasma protein concentrations may be markedly increased. Severely affected cattle may have coagulation abnormalities, as evidenced by prolonged prothrombin time, thrombin time, and activated partial thromboplastin time. The acid-base status and serum electrolyte levels are typically normal, because abomasal and small-intestinal absorption can remain normal. However, marked hypokalemic, hypochloremic metabolic alkalosis can be seen, presumably because adynamic ileus from peritonitis can affect abomasal and GI motility and resorption of abomasal secretions. The metabolic alkalosis can be created or exacerbated by treatment with alkalinizing agents such as magnesium hydroxide used as a laxative. Peritoneal fluid analysis can help determine

whether peritonitis is present, particularly the concentration of D-dimer and the neutrophil percentage in the peritoneal fluid. However, the peritonitis frequently becomes walled off, and in these cases peritoneal fluid may be within the reference range unless obtained from within the lesion. The presence of a magnet in the reticulum can be determined by movement of a magnetic compass in the region of the cranioventral abdomen; the presence of a magnet in the reticulum makes traumatic reticuloperitonitis very unlikely unless the penetrating object is not magnetic.

Ultrasonography of the ventral abdomen using a 3-MHz transducer is the most accurate way to diagnose localized peritonitis near the reticulum and characterize the reticular contraction frequency. It rarely identifies the presence of a penetrating object. Ultrasonography of the heart and thorax is very useful in the diagnosis of pleuritis and pericarditis as a sequelae of traumatic reticuloperitonitis and has replaced radiography in the diagnosis of reticuloperitonitis.

Lateral radiographs of the cranioventral abdomen can detect metallic material in the reticulum but should be taken only after oral administration of a magnet. To determine whether the reticulum is currently perforated, the foreign body must be visible beyond the border of the reticulum, unattached to the magnet in the reticulum, or positioned off the floor of the reticulum. A depression in the cranioventral aspect of the reticulum or identification of an abscess (by gas accumulation outside a viscus), soft-tissue masses, or a fluid line in the cranial abdomen are also reliable radiographic findings of penetration. Portable radiographic units cannot penetrate the reticular area of standing adult cattle, and the cow may need to be transported to where there is equipment with sufficient power. The cow should not be placed in dorsal recumbency to obtain radiographs, because such manipulation places stress on adhesions and may lead to a localized peritonitis becoming a diffuse peritonitis due to gravitational spread of infection.

Electronic metal detectors can identify metal in the reticulum but do not distinguish between perforating and nonperforating foreign bodies.

Treatment: Treatment of the typical case seen early in its course may be surgical or medical. Either approach improves the chances of recovery from ~60% in untreated cases to 80%–90%. Surgery involves

rumenotomy with manual removal of the object(s) from the reticulum; if an abscess is adhered to the reticulum, it should be aspirated (to confirm it is an abscess) and then drained into the reticulum. Antimicrobials should be administered perioperatively. Medical treatment involves administration of antimicrobials to control the peritonitis and a magnet to prevent recurrence. Because of the mixed bacterial flora in the lesion, a broad-spectrum antimicrobial agent such as oxytetracycline (16 mg/kg/day, IV) should be used. Penicillin (22,000 IU/kg, IM, once to twice daily) is widely used and effective in many cases despite its limited spectrum. Affected cows should be confined for 1–2 wk; placing them on an inclined plane (elevated in front) is believed by some to limit further penetration of the foreign object, but supporting studies are lacking. Supportive therapy, such as oral or occasionally IV fluids and SC calcium borogluconate or calcium gluconate, should be administered as needed. Rumen inoculation (4–8 L of ruminal fluid from a healthy donor) is beneficial in some cases with prolonged ruminal stasis and loss of normal flora.

More advanced cases, those with obvious secondary complications, or those that do not respond to initial medical or surgical therapy should be evaluated from an economic perspective; if the cow is of limited value, slaughter should be considered if the carcass is likely to pass inspection.

Prevention: Preventive measures include avoiding the use of baling wire, passing feed over magnets to remove metallic objects, keeping cattle away from sites of new construction, and completely removing old buildings and fences. Additionally, bar magnets may be administered PO, preferably after fasting for 18–24 hr. Usually, the magnet remains in the reticulum and holds any ferromagnetic objects on its surface. There is good evidence that giving magnets to all herd replacement heifers and bulls at ~1 yr of age minimizes the incidence of traumatic reticuloperitonitis.

VAGAL INDIGESTION SYNDROME

(Chronic indigestion)

Vagal indigestion syndrome is characterized by the gradual development of abdominal distention secondary to ruminoreticular distention. The distention was originally thought to be the result of lesions affecting

the ventral vagus nerve. Vagal indigestion syndrome is seen most commonly in cattle but has been reported in sheep.

Etiology and Pathogenesis: Diseases that result in injury, inflammation, or pressure on the vagus nerve can result in clinical signs of vagal indigestion syndrome. However, vagal nerve damage is not present in most cases of vagus indigestion, and the most common cause is traumatic reticuloperitonitis (see p 230). Conditions resulting in mechanical obstruction of the cardia or reticulo-omasal orifice (eg, papillomas or ingested placenta) can also result in vagal indigestion if ruminoreticular distention is present and the condition is subacute to chronic.

Historically, there were four types of vagal indigestion described based on the purported site of the functional obstruction. Type I was failure of eructation or free-gas bloat, type II was a failure of omasal transport, type III was secondary abomasal impaction, and type IV was indigestion of late gestation. Types I and IV are rare, and this categorization system has minimal clinical relevance.

Type I vagal indigestion, or failure of eructation, results in free-gas bloat and has been attributed to inflammatory lesions in the vicinity of the vagus nerve, such as localized peritonitis, adhesions (usually after an episode of traumatic reticuloperitonitis), or chronic pneumonia with anterior mediastinitis. Other potential causes for type I vagal indigestion include pharyngeal trauma, which affects a more proximal part of the vagus nerve, and esophageal compression by abscesses or neoplasia, such as lymphosarcoma. Vagal indigestion can develop in cattle after abomasal volvulus without abomasal impaction. These cases would presumably fall into the category of type I vagal indigestion with damage to the vagal nerve near the reticulum and omasum.

Type II vagal indigestion, more correctly termed failure of omasal transport, develops as a result of any condition that prevents ingesta from passing through the omasal canal into the abomasum. Adhesions and abscesses (reticular or single liver abscesses) are the most common cause of failure of omasal transport and are usually located on the right or medial wall of the reticulum near the route of the vagus nerve. Reticular abscesses and adhesions are almost invariably the result of traumatic reticuloperitonitis. Mechanical obstruction of the omasal canal by ingested material (eg,

plastic bags, rope, placenta) or masses (eg, lymphosarcoma, squamous cell carcinoma, granulomas, or papillomas) can also cause chronic ruminoreticular distention due to failure of omasal transport.

Type III vagal indigestion is a secondary abomasal impaction. Primary abomasal impaction develops due to feeding of dry, coarse roughage, such as straw, in a chopped or ground form with restricted access to water and usually during extremely cold temperatures (*see p 244*). Secondary abomasal impaction is seen most commonly after an episode of traumatic reticuloperitonitis or occasionally as a sequela of abomasal volvulus. Mechanical fixation of the reticulum to the ventral abdominal floor in cows with reticuloperitonitis interferes with the normal sieving action of the reticulum, with passage of large fiber particles (>2 mm long) into the abomasum. The abomasum has difficulty in emptying the larger particles of food because of the increased viscosity, and they accumulate in the abomasum, resulting in abomasal impaction.

Type IV vagal indigestion, or partial forestomach obstruction, is poorly defined. It typically develops in cattle during gestation and is more appropriately termed indigestion of late gestation. The condition is thought to be related to the enlarging uterus shifting the abomasum to a more cranial position, which inhibits normal abomasal emptying.

Clinical Findings: The clinical signs vary to some extent with the location of the obstruction. In all cases, there is a gradual development (over days to weeks) of abdominal distention secondary to ruminoreticular distention. Distention of the dorsal and ventral sacs of the rumen results in an "L-shaped" rumen on rectal examination. Left dorsal and left and right ventral distention of the abdomen causes a "papple" (pear plus apple) shape as viewed from behind.

Cattle with vagal indigestion syndrome have a diminished appetite, which typically improves temporarily if distention is relieved. Milk production gradually decreases, fecal output is reduced, and the rumen develops a "splashy" fluid consistency. The feces are characteristically very scant and sticky and may contain longer than normal particles. The strength of rumen contractions is decreased; however, rumen motility is often increased (3–4 contractions/min). It is commonly possible to see movements of the left abdominal wall

that mirror the movements of the hyperactive rumen. However, rumen contraction sounds are not audible because the contents have become frothy due to the prolonged contractions and failure of the rumen to empty.

Temperature and respiratory rate are usually normal; however, these can be increased depending on the cause. Bradycardia is present in 25%–40% of cases and is due to decreased feed intake rather than a direct stimulation of the vagus nerve. Tachycardia develops as the disease progresses and cattle become dehydrated. Over time, the animal develops a rough hair coat, loses condition, and becomes weak (in some cases to the point of recumbency), with marked clinical signs of dehydration.

On rectal palpation, the rumen is distended with gas or froth that occupies the entire left abdomen, pushing the left kidney to the right of the midline. The ventral sac of the rumen is enlarged and palpable to the right of the midline (the characteristic "L-shaped" rumen). It is important to recognize that diagnosis of vagal indigestion syndrome requires the presence of a markedly increased ruminoreticular volume. Palpation of the lower half of the right side of the abdomen below the costochondral junction may detect an impacted abomasum that feels doughy. Hematologic findings vary. The PCV can be increased because of dehydration or decreased because of bone marrow depression (anemia of chronic disease). The WBC may be normal, increased, or decreased. If an inflammatory condition such as peritonitis is present, the neutrophil to lymphocyte ratio is typically reversed, and a neutrophilia may be present. Lymphocytosis can be seen with vagal indigestion due to lymphosarcoma. Leukopenia may be present with diffuse peritonitis. Increased serum globulin and total protein can be seen with abscesses.

Metabolic status is normal, or metabolic alkalosis may be present. The serum chloride concentration varies with the site of the obstruction. It is usually normal if the lesion is proximal to the abomasum. A low serum chloride concentration is consistent with reflux of chloride from the abomasum into the rumen (internal vomiting) and obstruction at the level of the abomasum (type III). Metabolic alkalosis is typically present if serum chloride is decreased. Rumen chloride concentration is increased in type III vagal indigestion and provides a useful method to differentiate type II from type III vagal indigestion. The serum

potassium concentration is usually low due to decreased potassium intake in the feed. Serum calcium concentration is often moderately decreased because of ongoing milk production, but it is rarely low enough to cause recumbency. Serum urea and creatinine concentrations increase with dehydration due to prerenal azotemia.

Diagnosis: Diagnosis is based on the presence of subacute to chronic ruminoreticular and abdominal distention. Because vagal indigestion is by definition a subacute to chronic disease, this diagnosis should not be made in cattle that have not been sick for at least several days, which excludes acute rumen tympany and acute frothy bloat. Other causes of abdominal distention, such as ascites and uterine enlargement, are included in the differential diagnosis and can almost invariably be excluded by rectal palpation because of the absence of ruminoreticular distention. Occasional cases of longstanding obstruction of the cecum or small intestine can cause severe ruminoreticular and abdominal distention; however, palpable cecal or small-intestinal distention is also palpable rectally. In addition, the rumen is distended but not L-shaped, and a characteristic ping is present in the case of cecocolic volvulus.

Diagnosing the specific cause of vagal indigestion is more difficult but is important because of differences in treatment and prognosis. Physical examination, rectal examination, CBC, blood acid-base determination, and serum biochemical values are often useful. Peritoneal fluid analysis can support the diagnosis of peritonitis if total protein or nucleated cells are increased. Lateral radiographs of the reticulum should be taken to identify an opaque linear foreign body (eg, wire) or reticular abscess. Ultrasonography of the cranioventral abdomen can indicate the presence of focal peritonitis and the reticular contraction rate. Definitive diagnosis often requires exploratory surgery (left paralumbar fossa laparotomy and rumenotomy).

Treatment and Prognosis: If the value of the animal justifies treatment, surgery is almost always needed to identify and potentially correct the underlying cause. Medical management alone is usually ineffective. A left paralumbar fossa laparotomy and rumenotomy provides the opportunity for definitive treatment in some cases. Emptying the rumen at the time of surgery may help restore normal rumen

motility. Stimulation of low-threshold tension receptors in the reticulum occurs under normal circumstances and causes reflex reticuloruminar contractions. However, severe distention causes stimulation of high-threshold receptors that have the opposite effect and inhibit contractions.

Supportive or symptomatic therapy should be provided in all cases, which typically involves correcting dehydration as well as calcium and electrolyte deficits, commonly with oral fluids and electrolytes. Severely dehydrated animals and those with longstanding disease require IV fluids. Fresh water and normal feed should be available. Transfaunation at surgery or via oroesophageal intubation may help reestablish normal rumen flora in cattle with chronic anorexia. Antimicrobials (procaine penicillin or oxytetracycline) should be given if the underlying cause is infectious or if a rumen fistula is created.

Treatment of type I vagal indigestion (failure of eructation) also typically involves creating a rumen fistula to allow free gas to escape. If surgery is not economically feasible and the underlying cause of vagal indigestion has been identified and treated, a rumen trocar can be placed temporarily. Such trocars are commercially available and must be secure and self-retaining to prevent potentially fatal leakage of rumen contents into the peritoneal cavity. The trocar should not be removed for at least 2 wk to allow firm adhesions to form between the rumen and body wall.

The prognosis for animals with type I vagal indigestion is usually favorable. After creation of a rumen fistula, the signs of vagal indigestion resolve in nearly all cases. However, animals with chronic respiratory disease or pharyngeal trauma may not recover from the underlying condition. Leakage of ingesta from fistulas can cause off-flavored milk. Peritonitis can develop from leakage around the fistula or after rumenotomy; however, this should not happen with good surgical technique.

Type II vagal indigestion (failure of omasal transport) rarely responds to supportive or symptomatic therapy without surgical intervention. Left paralumbar fossa laparotomy and rumenotomy can be used to identify adhesions in the vicinity of the reticulum, reticular or hepatic abscesses, or obstruction of the omasal canal. Removal of foreign bodies, wires, and some masses at surgery and lancing of peritreticular abscesses into the reticulum affords a fair to good prognosis. A diagnosis of lymphosar-

coma at surgery warrants a grave prognosis. Reticular abscesses identified at surgery should be cautiously drained into the reticulum, and antibiotics given for 10–14 days. Reportedly, 83% of cattle with reticular abscesses respond favorably to treatment. Identification of adhesions in the vicinity of the reticulum warrants a fair to good prognosis with surgery, antibiotic therapy, and appropriate supportive treatment. Hepatic abscesses must be drained by a second surgery. Large-bore cannulas placed through the body wall, through the adhesions, and into the abscess will drain the purulent material. However, recurrence is more of a problem with hepatic abscesses than with reticular abscesses.

Animals with type III vagal indigestion (secondary abomasal impaction) diagnosed without surgery usually do not receive further treatment because of the poor prognosis, particularly if there is a history of traumatic reticuloperitonitis or abomasal volvulus. If the diagnosis is made at surgery or if the abomasal impaction is thought to be dietary, dioctyl sodium sulfosuccinate can be infused directly into the abomasum via the reticulo-omasal orifice after emptying the rumen. A nasogastric tube can be passed into the abomasum via the reticulo-omasal orifice at surgery and left in place for continued treatment (3–4 L of mineral oil daily for 3–5 days). If possible, impacted material should be removed manually through the reticulo-omasal orifice. Other lesions, such as abscesses in the medial wall of the reticulum, should be identified and drained. Abomasotomy and removal of abomasal contents, using a right paracostal approach with the cow in left lateral recumbency, can be performed as a last resort. However, recurrence of the impaction is common. Pyloric obstruction in cattle is rare and is most often due to a foreign body obstructing the lumen. Pyloromyotomy is almost never effective in resolving abomasal impactions.

Type III vagal indigestion has a poor prognosis regardless of the cause or the treatment. However, cattle with mild to moderate primary abomasal impactions will respond to therapy, although severely affected animals will not (*see* p 244). Cattle with secondary impactions due to traumatic reticuloperitonitis or as a sequela of abomasal volvulus seldom recover. Animals with foreign bodies (eg, trichobezoars) obstructing the pylorus have a good prognosis if the obstruction is removed.

Therapeutic induction of parturition has been recommended for treatment of cattle with type IV vagal indigestion (indigestion

of late gestation), and some cows have improved with this treatment; however, because type IV vagal indigestion is a poorly defined condition, the prognosis is always guarded. A more specific prognosis is based on response to therapy and identification of a specific lesion at exploratory celiotomy and rumenotomy.

Prevention: The most common cause of vagal indigestion syndrome is traumatic reticuloperitonitis, which causes adhesions and abscesses that interfere with both reticular motility and the appropriate stratification of feed particles for passage through the abomasum. Therefore, prevention of traumatic reticuloperitonitis is important. Good management practices may prevent some cases of vagal indigestion associated with chronic pneumonia. Early diagnosis of abomasal volvulus, with same-day surgical correction, may prevent some cases.

RUMINAL DRINKING

“Ruminal drinking” is caused by failure of the reticular groove reflex, and it results in ruminal acidosis in calves on a liquid diet. The disorder presents as primary chronic disease (ruminal drinking syndrome) in veal calves, and in its acute form as a complication secondary to different neonatal diseases, most commonly neonatal diarrhea. It has also been described in artificially fed lambs.

The reticular groove is a muscular structure extending from the cardia to the reticulo-omasal orifice. Its correct closure is a precondition for the direct passage of ingested milk or milk replacer into the abomasum. When the reticular groove partially or completely fails to close, milk spills into the reticulorumen and is fermented to short-chain fatty acids and/or lactic acid. The subsequent drop in the pH of the ruminal contents to values that occasionally fall below 4 leads to variable degrees of inflammation of the mucosa of the forestomachs and the abomasum. In chronic cases, hyperkeratosis or parakeratosis of the ruminal mucosa can lead to impairment of ruminal motility with chronic or recurrent tympany. Additionally, atrophy of the intestinal villi and a decrease in brush border enzyme activity with maldigestion and malabsorption have been seen.

Systemic consequences of acute ruminal drinking are mainly due to absorption of organic acids from the digestive tract. In particular, the L- and D-isomers of lactic acid may lead to metabolic acidosis with the

accumulation of D-lactate because of an absence of a specific enzyme for its metabolism in mammals. This accumulation of D-lactate has recently been found to be responsible for clinical signs such as depression, ataxia, and general weakness.

Primary dysfunction of the reticular groove occurs as a result of stressful situations (prolonged transport, grouping, change in feeding techniques), especially in bucket-fed veal calves. Clinical signs usually appear some weeks after the arrival of the calves at the fattening units and are characterized by inappetence, depression, poor growth, hair loss, recurrent tympany, ventral abdominal distention, and passing of clay-like feces. Fluid-splashing sounds can be heard on succussion of the left flank. Recovery of fermented ruminal contents via stomach tube is diagnostic. In these advanced, chronic cases the prognosis is poor. If the disease is detected early enough, feeding small volumes of milk from a nipple-bottle or bucket may be successful. Additionally, the closure of the reticular groove can be triggered by allowing the calf to suck a finger before the milk feed is offered.

Acute ruminal acidosis secondary to other disorders is most commonly seen in calves with neonatal diarrhea but occurs also in other painful or weakening diseases. In these cases, the clinical picture is usually dominated by the underlying disease. In cases of severe rumenitis, calves may exhibit teeth grinding, arching of the back, and slight abdominal distention. Force-feeding of inappetent or primarily anorectic calves can also cause ruminal acidosis or worsen the situation by providing substrate for further fermentation.

The prognosis for secondary ruminal drinking depends mainly on the success of treatment of the underlying disease. Calves with metabolic acidosis and dehydration due to neonatal diarrhea usually recover

spontaneously from ruminal drinking after adequate treatment, and the condition will in general remain unrecognized. In calves that were force-fed or that do not respond to treatment as expected, ruminal drinking should be considered, and an examination of the ruminal fluid performed. Removal of the contents and lavage with warm water via stomach tube may be beneficial, especially after prolonged force-feeding. Prophylaxis of ruminal drinking consists of early treatment of diseased calves, adequate feeding techniques, and minimizing stress in purchased calves.

RUMINAL PARAKERATOSIS

Ruminal parakeratosis is a disease of cattle and sheep characterized by hardening and enlargement of the papillae of the rumen. It is most common in animals fed a high-concentrate ration during the finishing period. It also is seen in cattle fed rations of heat-treated alfalfa pellets, as well as in calves with prolonged ruminal acidosis due to ruminal drinking. It does not appear to be related to the feeding of antibiotics or protein concentrates. Incidence in a group may be as high as 40%. The lesions are thought to be caused by the lowered pH and the increased concentration of volatile fatty acids (VFAs) in the ruminal fluid, and do not usually develop in cattle fed unprocessed whole grain (on which animals gain weight as readily). This may be related to the higher pH and higher concentration of acetic acid than those of the longer chain VFAs in the ruminal contents.

Many of the papillae are enlarged and hardened, and several may adhere together to form bundles. The papillae of the anterior ventral sac are commonly affected. In cattle, the roof of the dorsal sac may show multiple foci (each 2–3 cm²) of parakeratosis. In sheep, abnormal papillae may be visible and palpable through the wall of the intact rumen. Affected papillae contain excessive layers of keratinized epithelial cells, particles of food, and bacteria. The rumens of affected cattle are difficult to clean in the preparation of tripe. The abnormal epithelium, by interfering with absorption, may reduce efficiency of feed utilization and rate of gain, although there is little evidence to support this theory.

Ruminal parakeratosis may be prevented by finishing animals on rations that contain unground ingredients in the proportion of 1 part roughage to 3 parts concentrate. The necessity and economics of prevention are not well defined.

Severe rumenitis in a 10-day-old calf after a prolonged course of ruminal drinking. Courtesy of Dr. Ingrid Lorenz.

DISEASES OF THE ABOMASUM

Abomasal disorders include left displaced abomasum (LDA), right displaced abomasum (RDA), abomasal volvulus (AV), abomasal ulceration, and impaction. Displacement or volvulus is seen most commonly in dairy cows but can also be seen in dairy bulls and calves. Except for AV, abomasal displacement is rare in beef cattle and essentially undiagnosed in small ruminants. Abomasal ulcers are seen in dairy and beef cattle and in calves and lambs; they are rarely diagnosed in small ruminants. Impactions can be primary, which is most frequent in beef cattle, or secondary, which develop most often in dairy cows as a form of vagal indigestion. Impactions may have a hereditary basis in some black-faced sheep.

LEFT OR RIGHT DISPLACED ABOMASUM AND ABOMASAL VOLVULUS

Because the abomasum is suspended loosely by the greater omentum and lesser omentum, it can be moved from its normal position on the right ventral part of the abdomen to the left or right side (LDA, RDA), or it can rotate on its mesenteric axis while displaced to the right and lateral to the liver (AV). The abomasum can shift from its normal position to left displacement or to right displacement over a relatively short period. AV can develop rapidly or slowly from an uncorrected RDA.

Etiology: Although LDA, RDA, and AV (previously incorrectly referred to as right torsion of the abomasum) are often considered separately, there is evidence of a common underlying etiology; they may be different manifestations of the same or a similar disease process.

The etiology is multifactorial, although abomasal hypomotility and dysfunction of the intrinsic nervous system are thought to play an important role in development of displacement or volvulus. Important contributing factors include abomasal hypomotility associated with hypocalcemia and possibly hypokalemia, as well as concurrent diseases (mastitis, metritis) associated with endotoxemia and decreased rumen fill, periparturient changes in the position of intra-abdominal organs, and genetic predisposition, particularly in deep-bodied cows. Genetic

predisposition is correlated with milk yield, indicating that current selection practices for milk production are increasing the incidence of abomasal displacement. Hypomotility is also related to ingestion of high-concentrate, low-roughage diets, which reduce abomasal motility through a poorly defined mechanism that may involve hyperinsulinemia or increased concentrations of volatile fatty acids. One of the mechanisms of excessive gas accumulation in cattle with abomasal displacement is reticulum-mediated inflow of ruminal gas into the abomasum that is hypomotile. In addition, high-concentrate diets result in increased gas production in the abomasum (mostly carbon dioxide, methane, and nitrogen). Finally, subclinical and clinical ketosis increase the risk of abomasal displacement through an unknown mechanism that may be associated with decreased rumen fill.

Approximately 80% of displacements are seen within 1 mo of parturition; however, they can be seen at any time. LDA is much more common than RDA (30 LDA to 1 RDA); cases of AV are also more common than RDA (10 LDA to 1 AV). AV is preceded by RDA.

Pathogenesis: In LDA, as a result of abomasal hypomotility and gas production, the partially gas-distended abomasum becomes displaced upward along the left abdominal wall lateral to the rumen. The fundus and greater curvature of the abomasum are primarily displaced, which in turn causes displacement of the pylorus and duodenum. The omasum, reticulum, and liver are also rotated to varying degrees. The abomasal obstruction is partial, and although the segment contains some gas and fluid, a certain amount can still escape, and the distention rarely becomes severe. Because there is minimal interference with blood supply unless the gas distention is marked, the effects of displacement are entirely due to interference with digestion and passage of ingesta, which lead to decreased appetite and dehydration.

A mild metabolic alkalosis with hypochloremia and hypokalemia are common. The hypochloremic metabolic alkalosis is due to abomasal hypomotility, continued secretion of hydrochloric acid into the abomasum, and the partial abomasal outflow obstruction, with sequestration of chloride in the abomasum

and reflux into the rumen. Hypokalemia is due to decreased intake of feeds high in potassium, sequestration of potassium in the abomasum, and dehydration. Secondary ketosis is common and may be complicated by development of hepatic lipidosis (fatty liver disease; *see* p 1018).

In RDA, hypomotility, gas production, and displacement of the partially gas-filled abomasum occur as in LDA. Mild hypokalemic, hypochloremic, metabolic alkalosis develops as well. After this dilatation phase, rotation of the abomasum on its mesenteric axis leads to volvulus and local circulatory impairment and ischemia (hemorrhagic strangulating obstruction). The volvulus is usually in a counterclockwise direction when viewed from the rear and the right side of the animal. The omasum is displaced medially and can be involved in the volvulus with occlusion of its blood supply (called an omasal-abomasal volvulus) and displacement of the liver and reticulum. In rare cases, the reticulum can be involved (called a reticular-omasal-abomasal volvulus).

A large quantity of chloride-rich fluid (up to 50 L) accumulates in the abomasum, and hypochloremic, hypokalemic metabolic alkalosis develops. The blood supply to the abomasum, and often the omasum and proximal duodenum, is compromised, eventually resulting in ischemic necrosis of the abomasum and proximal duodenum as well as dehydration and circulatory failure. As circulatory failure progresses, a metabolic acidosis due to hyper-L-lactatemia and azotemia can become superimposed on the preexisting metabolic alkalosis.

Clinical Findings: The typical history of abomasal displacement includes anorexia (most commonly a lack of appetite for grain with a decreased or normal appetite for roughage) and decreased milk production (usually significant but not as dramatic as with traumatic reticuloperitonitis or other causes of peritonitis). In AV, anorexia is complete, milk production is more markedly and progressively reduced, and clinical deterioration is rapid. In abomasal displacement, temperature, heart rate, and respiratory rate are usually normal. The caudal part of the rib cage on the side of the displacement may appear “sprung.” Hydration appears subjectively normal with displacements except in some chronic cases. Rumen motility may be normal but often is reduced in frequency and strength of contraction. Feces are usually reduced in quantity and more fluid than normal.

The most important diagnostic physical finding is a ping on simultaneous auscultation and percussion of the abdomen, which should be performed in the area marked by a line from the tuber coxae to the point of the elbow, and from the elbow toward the stifle. The ping (detected during simultaneous percussion and auscultation) characteristic of an LDA is most commonly located in an area between ribs 9 and 13 in the middle to upper third of the left abdomen; however, the ping can be more ventral or more caudal, or both. Pings associated with a rumen gas cap are usually more dorsal, less resonant, and extend more caudally through the left paralumbar fossa. Rectal examination can confirm a gas-filled rumen or an extremely empty rumen that correlates with the rumen ping in these cases. Pings associated with pneumoperitoneum typically are less resonant, present on both sides of the abdomen, and are inconsistent in location on repeated evaluation. Frequently, secondary ketosis develops, and ketones are present in the urine or milk. Ketosis that develops in association with abomasal displacement responds only transiently to treatment and recurs (versus in primary ketosis, which develops early in lactation in high-producing cows and responds to therapy permanently if instituted early). (*See also* KETOSIS IN CATTLE, p 1024.)

The ping associated with RDA also is most commonly located in the area between ribs 10 and 13 on the right abdomen. Differentiation between various causes of a right-side ping can be difficult in some cases, although a ping cranial to rib 10 usually indicates the presence of AV because the liver is displaced medially by the distended viscus. A small, right-side ping underlying ribs 12 or 13 and extending as far forward as rib 10 is common in cows with functional ileus from a number of causes. This ping is most often associated with gas in the ascending colon and resolves with correction of the underlying condition. Cecal dilatation and rotation are characterized by a right-side ping. The ping extends through the dorsal paralumbar fossa in cecal dilatation and usually is located more caudally (well into the paralumbar fossa) in cecal rotation than the ping of RDA. Palpation per rectum is helpful in differentiating an RDA from cecal dilatation or rotation. Other right-side pings are produced by pneumoperitoneum or gas in the rectum, descending colon, duodenum, or uterus.

Spontaneous fluid splashing or gas tinkling sounds may be heard on auscultation of the area of the ping or on simultaneous ballottement and auscultation of the

abdomen (succussion). The characteristic rectal examination findings with LDA include a medially displaced rumen and left kidney. The abomasum is rarely palpable in LDA and only occasionally in RDA.

The clinical signs associated with abomasal volvulus are more severe than with simple displacements because of the vascular compromise. However, an early abomasal volvulus can be difficult to distinguish from an RDA except by the presence of a right-side ping cranial to rib 10 (indicating medial displacement of the liver by the abomasal volvulus) and the anatomic position identified at surgery. In contrast to cases of displacement, an animal with AV has tachycardia proportional to the severity of the condition. The area of the ping is usually larger (extending as far forward as rib 8), and the amount of succussible fluid is greater. The animal is more depressed, and signs of weakness, toxemia, and dehydration develop as the disease progresses. The caudal extent of

the abomasum is usually palpable per rectum. Without therapy, the animal often becomes recumbent within 48–72 hr after developing volvulus. Death occurs from shock and dehydration and is sudden if the ischemic abomasum ruptures.

Diagnosis: For displacement or volvulus, diagnosis is based on the presence of the characteristic ping on simultaneous auscultation and percussion and exclusion of other causes of left- or right-side pings. Ultrasonography may be helpful in confirming a diagnosis of LDA, RDA, or AV, but it cannot reliably differentiate RDA from AV. Recent parturition, partial anorexia, and decreased milk production suggest displacement. A ketosis that is only temporarily responsive to treatment is consistent with abomasal displacement, which may be intermittent. The typical signs on physical examination (in addition to the ping), rectal examination, and laboratory evaluation also support the

diagnosis. Melena or signs of peritonitis (eg, fever, tachycardia, localized abdominal pain, pneumoperitoneum) with an LDA may indicate a bleeding or perforated abomasal ulcer, respectively. In cattle with AV, blood L-lactate concentrations ≤ 2 mmol/L indicate a positive outcome with surgical correction, whereas cattle with blood L-lactate concentrations ≥ 6 mmol/L have a high probability of a negative outcome.

Treatment: Open (surgical) and closed (percutaneous) techniques can be used to correct abomasal displacements. Rolling a cow through a 180° arc after casting her on her right side corrects most LDAs; however, recurrence is very likely. LDA can be corrected surgically using right flank pyloric omentopexy, right paramedian abomasopexy, left paralumbar abomasopexy, combined left flank and right paramedian laparoscopy (two-step procedure), or left flank laparoscopy (one-step procedure). Blind suture techniques (toggle-pin fixation or the “big needle” [blind-stitch] method), performed in the right paramedian area, are percutaneous methods for correction of LDA; however, the exact location of the suture is not known. Potentially fatal complications can develop after blind suture techniques, and the reported success rate is less than that of surgical correction by right flank pyloric omentopexy. With toggle-pin fixation, the pH can be checked to confirm that the pin is in the abomasum, which reduces the likelihood of attaching rumen, small intestine, or omentum to the body wall rather than the abomasum. RDA and AV are corrected surgically (using right paralumbar fossa omentopexy) when economically feasible. The right paramedian abomasopexy should be used only to correct RDA and AV in cattle unable to stand.

Ancillary treatment of animals with abomasal displacement include treating any concurrent disease (eg, metritis, mastitis, ketosis). Calcium borogluconate or calcium gluconate SC or calcium gels PO help restore normal abomasal motility in many cases. Administration of erythromycin (10 mg/kg, IM) at the time of surgery increases abomasal emptying rate and milk production in the immediate postoperative period. Because surgical correction of abomasal displacement or volvulus is frequently done on the farm, the prokinetic effect of erythromycin suggests that it might be preferred if antimicrobials are administered to control intraoperative

infection. However, administration of an antimicrobial for a nonantimicrobial effect should not be promoted.

In simple displacement, fluid and electrolyte abnormalities correct spontaneously with access to water and a salt block. Providing electrolyte water (60 g sodium chloride and 30 g potassium chloride in 19 L of water) via stomach tube is helpful in cases of longer duration. Animals with significant dehydration and metabolic derangement require IV therapy, typically administered as hypertonic saline (7.2% NaCl, 5 mL/kg, IV over 5 min).

Occasionally, animals with abomasal displacement or volvulus have atrial fibrillation, thought to be of metabolic origin and primarily due to concurrent hypokalemia and metabolic alkalosis. Correction of the displacement or volvulus almost always results in correction of the atrial fibrillation within 5 days.

Aggressive treatment of ketosis plays an important role in successful treatment of abomasal displacement, because most of the cattle that die after surgical correction of LDA and RDA do so from the metabolic consequences of prolonged anorexia.

The prognosis after correction of simple LDA or RDA is good, with survival rates of 95%. AV has a variable and less favorable prognosis (average survival rate of 70%); a high heart rate, moderate to severe dehydration, a longer period of illness, a large quantity of fluid in the abomasum, increased blood or plasma L-lactate concentration, and the presence of omasal-abomasal or reticulo-omasal-abomasal volvulus are associated with a poorer prognosis.

Prevention: The incidence of abomasal displacements can be decreased by ensuring a rapid increase in rumen volume after calving, feeding a total mixed ration rather than feeding grain twice daily (“slug feeding”), avoiding rapid dietary changes, maintaining adequate roughage in the diet, avoiding postparturient hypocalcemia, and minimizing and promptly treating concurrent disease and ketosis.

ABOMASAL ULCERS

Abomasal ulcers affect mature cattle and calves and have several different manifestations.

Etiology and Pathogenesis: Except for lymphosarcoma of the abomasum and the erosions of the abomasal mucosa that develop in viral diseases such as bovine

viral diarrhea and bovine malignant catarrhal fever, the causes of abomasal ulceration are not well understood. Many different causes have been suggested. Although abomasal ulcers can be seen any time during lactation, they are common in high-producing, mature dairy cows within the first 6 wk after parturition. The most likely cause is prolonged inappetence, which results in sustained periods of low abomasal pH; hence, the adage “no acid, no ulcer.”

Abomasal ulcers may also arise in association with lymphosarcoma, abomasal disorders (displacement or volvulus), or increased luminal pressure causing ischemia of abomasal mucosa; they may also appear to be unrelated to other disease.

Abomasal ulcers are very common in milk-fed calves after they have consumed milk or milk replacer for 4–12 wk. Most of these ulcers are subclinical and nonhemorrhagic. Occasionally, milk-fed calves <2 wk old are affected by acute, hemorrhagic abomasal ulcers that may perforate and cause rapid death. Well-nourished suckling beef calves, 2–4 mo old, may be affected by acute abomasal ulcers. Abomasal trichobezoars are common in these calves but do not appear to increase risk of ulcer formation.

Clinical Findings: The syndrome varies, depending on whether ulceration is complicated by hemorrhage or perforation and by the severity of such hemorrhage or peritonitis.

A system of classification is based on the depth of penetration or the degree of hemorrhage or peritonitis caused by the ulcer: Type I is an erosion or ulcer without hemorrhage, Type II is hemorrhagic, Type III is perforated with acute localized peritonitis, Type IV is perforated with acute diffuse peritonitis, and Type V is perforated with peritonitis within the omental bursa. There may be only a single ulcer or many acute and chronic ulcers.

Cattle with bleeding abomasal ulcers may be asymptomatic except for intermittent occult blood in the feces, or they can die acutely from massive hemorrhage. Common clinical signs include mild abdominal pain, bruxism, sudden onset of anorexia, tachycardia (90–100 bpm), and fecal occult blood or melena that may be intermittent. Signs of blood loss are seen with major hemorrhage and may include tachycardia (100–140 bpm), pale mucous membranes, weak pulse, cool extremities, shallow breaths, tachypnea, and melena. More severe signs include acute rumen

stasis, generalized abdominal pain with a reluctance to move and an audible grunt or groan with each breath, weakness, and dehydration. Melena may not be present in peracute cases, because it takes at least 8 hr for abomasal blood to be detected in the feces. As the condition progresses, body temperature drops, and the animal becomes recumbent and dies within 6–8 hr.

In general, bleeding ulcers do not perforate, and perforating ulcers do not bleed into the GI tract sufficiently to produce melena. However, hemorrhage and perforation are seen together occasionally, usually in cases that are chronic or associated with abomasal displacement.

Calves with abomasal ulceration and hairballs may have a distended gas- and fluid-filled abomasum that is palpable behind the right costal arch. Deep palpation may reveal abdominal pain associated with local peritonitis due to a perforated ulcer. In calves, perforating ulcers are more common than bleeding ulcers.

Lesions: Ulceration is most common in the fundic region in adult cattle and in the pyloric antrum in milk-fed calves. The single or multiple ulcers measure from a few millimeters to 5 cm in diameter. The affected artery is usually visible after ingesta and necrotic tissue are removed from a bleeding ulcerated area. Most cases of perforation are walled off by the omentum, which forms a cavity 12–15 cm in diameter that contains degenerated blood and necrotic debris. Material from this cavity may infiltrate widely through the omental fat. Adhesions may form between the ulcer and surrounding organs or the abdominal wall.

Diagnosis: In cases with only slight bleeding and mild clinical signs, diagnosis of abomasal ulcer is difficult and may require repeated fecal evaluations for occult blood. Other conditions that can cause partial anorexia and decreased milk production should be excluded by physical examination and laboratory tests, including abdominocentesis. In cases with melena, the diagnosis can be based on physical examination alone. The PCV can help to determine the degree of hemorrhage, although it takes at least 4 hr after an acute hemorrhage before the PCV decreases. An occult blood test of the feces can confirm melena. Other conditions that result in blood in the feces should be eliminated. Blood from portions of the GI tract distal to the abomasum reacts on fecal occult blood tests; it is usually bright

red if from the large intestine or raspberry-colored if from the small intestine. Animals with abomasal lymphosarcoma can have a bleeding syndrome similar to that associated with abomasal ulcers but do not respond to therapy. Occasionally, oral, pharyngeal, and laryngeal lesions bleed, and the swallowed blood appears in the feces. Similarly, pulmonary abscesses that form as a sequela of rumenitis by embolization to the lungs and liver can erode blood vessels and result in hemoptysis; if the blood is swallowed, this can also result in melena. Fecal occult blood may also be due to AV or rarely to bloodsucking helminths.

Diagnosis of perforating abomasal ulcers is based on physical examination and excluding other causes of peritonitis. Abomasal ulceration with perforation and local peritonitis may be indistinguishable from chronic traumatic reticuloperitonitis (see p 230). A magnet in the reticulum (confirmed by use of a compass) or an accurate history of having given the cow a magnet before the onset of signs decreases the likelihood of traumatic reticuloperitonitis. Reticular radiographs may confirm or exclude the presence of radiopaque foreign bodies in the reticulum. In some cases, there is a neutrophilia, possibly with a left shift. Evaluation of peritoneal fluid will confirm peritonitis if total protein or γ -dimer concentration and nucleated cell count are increased. Intracellular bacteria or degenerate neutrophils are rarely seen because, in most cases, the infection is rapidly walled off. The diagnosis of diffuse peritonitis due to perforation is based on physical examination and excluding other causes. Rupture of a distended viscus, such as can occur with AV or cecal rotation, produces similar signs. Regardless of the cause of diffuse peritonitis, the prognosis is grave because of overwhelming infection and cardiovascular deterioration. There is neutrophilia with a marked left shift and hemoconcentration. Abdominal fluid is usually readily obtainable in large quantities, and the protein level is increased; the nucleated cell count may be increased, or it may be normal due to dilution or utilization.

Treatment: Most cases of abomasal ulcers are undiagnosed and therefore untreated. Occasionally, a presumptive diagnosis is made and medical treatment instituted. The most important treatment is to get the animal to eat, because food is an excellent buffer and continual flow of forestomach contents (pH 6.0–7.0) into the abomasum helps increase abomasal pH. Broad-spectrum antimicrobial therapy (given for ≥ 5 days or until the rectal temperature is normal for

48 hr) is indicated for perforating ulcers. Antacids effectively increase abomasal pH in milk-fed calves when administered at 4- to 6-hr intervals in a manner that induces esophageal groove closure; however, their efficacy is extremely questionable in adult ruminants because of dilution by the large rumen volume. H_2 -receptor antagonists effectively increase abomasal pH in milk-fed calves; however, the oral dosages required for cimetidine (100 mg/kg, tid) and ranitidine (50 mg/kg, tid) are high, making treatment expensive. Proton pump inhibitors, such as omeprazole (2 mg/kg, IV) effectively increase luminal pH, but again treatment is expensive. The efficacy of oral omeprazole (4 mg/kg) in adult ruminants is unknown, but it has some efficacy in milk-fed calves. Because NSAIDs can contribute to ulceration, their use is contraindicated. The prognosis for localized peritonitis associated with perforating abomasal ulcers is good with medical therapy and dietary alteration. Recovery generally takes 1–2 wk, and animals fully recovered for 1–2 wk generally do not experience recurrence. Surgery is indicated for perforating abomasal ulcers only when the abomasum is displaced; however, significant abdominal contamination can occur in the process of breaking down adhesions and resecting or oversewing the ulcer.

Animals with diffuse peritonitis after perforation of an abomasal ulcer rarely respond to therapy, and the prognosis is grave. Treatment consists of rapid and continued IV fluid therapy (based on the current metabolic status) and IV broad-spectrum antibiotics. The few animals that recover from diffuse peritonitis usually have massive abdominal adhesions.

For bleeding ulcers, blood transfusions and fluid therapy may be necessary in addition to dietary management, stall confinement, and oral antacids. If hemorrhage is acute, the PCV may not reflect the severity because equilibration between intravascular and extravascular fluid after blood loss takes at least 4 hr. Generally, a blood transfusion is required whenever weakness and lethargy are present; a decision regarding transfusion should be based on clinical signs rather than PCV. Cross-matching is not usually necessary; a single transfusion of 4–6 L of blood is required. Some cattle require more than one transfusion over the course of several days. Complete recovery usually takes 1–2 wk. The prognosis is good if weakness and lethargy have not developed before treatment is started.

Prevention: Animals should be encouraged to keep eating to avoid prolonged periods of inappetence and low abomasal pH.

DIETARY ABOMASAL IMPACTION

Impaction of the abomasum develops in pregnant beef cows during cold winter months when cattle have decreased water intake and are fed poor-quality roughage. Impaction also has been seen in feedlot cattle fed a variety of mixed rations containing chopped or ground roughage (straw, hay) and cereal grains and in late-pregnancy dairy cows on similar feeds. Impaction of the pyloric antrum is an underdiagnosed condition in dairy cows in early lactation.

Etiology and Pathogenesis: The cause of dietary abomasal impaction is unknown but considered to be consumption of excess roughage low in both digestible protein and energy. Impaction with sand can occur if cattle are fed hay or silage on sandy soils, or root crops that are sandy or dirty. Outbreaks may affect up to 15% of all pregnant cattle on individual farms when the ambient temperature drops to -14°F (-26°C) or lower for several days. The cause in postparturient dairy cows is probably related to abomasal hypomotility.

The pathogenesis is unknown but is related to diet. Once the abomasum becomes impacted, subacute obstruction of the upper GI tract develops. Ions of hydrogen and chloride are continually secreted into the abomasum in spite of the impaction, and atony and alkalosis with hypochloremia result. Varying degrees of dehydration develop, because fluids are not moving beyond the abomasum into the duodenum for absorption. Sequestration of potassium ions in the abomasum results in hypokalemia. Dehydration, alkalosis, electrolyte imbalance, and progressive starvation are seen. Impaction of the abomasum may be severe enough to cause irreversible abomasal atony.

Clinical Findings and Lesions: Complete anorexia, scant feces, moderate distention of the abdomen, weight loss, and weakness are usually the initial signs of dietary abomasal impaction. Body temperature is usually normal but may be subnormal during cold weather. A mucoid nasal discharge tends to collect at the external nares and on the muzzle; the muzzle is usually dry and cracked, caused by both the failure of the animal to lick its nostrils and the effects of dehydration. The heart rate may be increased, and mild dehydration is common.

Most often, the rumen is static and distended with dry contents, but it may contain excess fluid if the cow has been fed

finely ground feed. The pH of the ruminal fluid is usually normal (6.5–7). Protozoal activity in the rumen ranges from normal to a marked reduction in numbers and activity (assessed microscopically under low power). The impacted abomasum is usually in the right lower quadrant on the floor of the abdomen. Deep palpation and strong percussion of the right flank may indicate the presence of a large, firm mass (impacted abomasum) and elicit a grunt (as is common in acute traumatic reticuloperitonitis), probably because of distention of the abomasum and stretching of its serosa.

Severely affected cattle die 3–6 days after the onset of signs. The abomasum ruptures in some cases, and death from acute, diffuse peritonitis and shock occurs precipitously in a few hours. In sand impaction, there is considerable weight loss, chronic diarrhea with sand in the feces, weakness, recumbency, and death in a few weeks.

Metabolic alkalosis, hypochloremia, hypokalemia, and hemoconcentration are common, as are total and differential WBC counts within the normal range. At necropsy, the abomasum is commonly enlarged (up to 8 times normal size) and impacted with dry rumen-like contents. The omasum may be similarly enlarged and impacted. The rumen is grossly enlarged and filled with dry contents or fluid. The GI tract beyond the pylorus is characteristically empty and has a dry appearance. Varying degrees of dehydration and emaciation are also present. If the abomasum has ruptured, lesions of acute diffuse peritonitis are present. In dairy cattle in early lactation, typically only the pyloric antrum is impacted.

Diagnosis: Clinical diagnosis of dietary abomasal impaction is based on the nutritional history, clinical evidence of impaction, and laboratory results. The disease must be differentiated from secondary abomasal impaction as a form of vagal indigestion.

Impaction of the abomasum as a complication of traumatic reticuloperitonitis usually is seen in late pregnancy, and commonly only in one animal. A mild fever may or may not be present, and there may be a grunt on deep palpation of the xiphoid. The rumen is enlarged and may be hypermotile (early) or atonic (late). In many cases, it is impossible to distinguish between the two causes of impacted abomasum, and a right flank laparotomy may be necessary to explore the abdomen for peritoneal lesions.

Treatment: The challenge is to recognize the cases of dietary abomasal impaction

that will respond to treatment and those that will not, ie, to determine those animals that should be slaughtered immediately for salvage. Cows that are weak, have a severely impacted abomasum, and have a marked tachycardia (100–120 bpm) are poor treatment risks. Medical treatment usually requires a confirmed diagnosis via right-side laparotomy. In cows that are treated, the metabolic alkalosis, hypochloremia, hypokalemia, and dehydration should be corrected. Lubricants can be used in an attempt to move the impacted material; it is necessary to empty the abomasum surgically only in cattle with severe impaction. Balanced electrolyte solutions are infused IV continuously for up to 72 hr at a daily rate of 80–120 mL/kg. Some cows respond well to this therapy and begin ruminating and passing feces in 48 hr.

Mineral oil should be administered at 4 L/day for 3 days. Additionally, dioctyl sodium sulfosuccinate (DSS) can be injected once into the abomasum during standing right flank laparotomy at 60–100 mL of a 25% solution for a 1,000-lb (450-kg) animal. This dose rate should not be administered PO because DSS kills rumen protozoa. A beneficial response cannot be expected in <24 hr; in cattle that respond, improvement is usually seen by the end of day 3 after treatment begins. Erythromycin (10 mg/kg, IM, once to twice daily) can be administered as a prokinetic in cattle that do not improve after surgery, provided that mineral oil has been administered and physical obstructions were not identified at surgery.

Surgery may be considered, but results are often unsuccessful, probably because of abomasal atony, which appears to worsen after surgery. An alternative may be a rumenotomy to empty the rumen and infuse

mineral oil directly into the abomasum through the reticulo-omasal orifice in an attempt to soften and promote evacuation of the abomasal contents. Cattle with secondary impactions that develop as a sequela of traumatic reticuloperitonitis or AV usually show signs of vagal indigestion, and abomasal impaction may be diagnosed at the time of exploratory surgery.

The induction of parturition using dexamethasone (20 mg, IM) may be indicated in affected cattle within 2 wk of term and in which the response to treatment for a few days has been unsuccessful. Parturition may assist recovery because of a reduction in intra-abdominal volume. For sand impaction, affected cattle should be moved off the sandy soil and fed good hay and a grass mixture containing molasses and minerals. Severely affected cattle should be treated with mineral oil (4 L/day for 3 days).

Prevention and Control: Prevention of dietary abomasal impaction is possible by providing the necessary nutrient requirements for wintering pregnant beef cattle. When low-quality roughage is used, it should be analyzed for crude protein and digestible energy. Based on the analysis, grain is usually added to the ration to meet energy and protein requirements.

The nutrient requirements of beef cattle (see p 2248) are guidelines for use under average conditions; higher nutrient levels than those indicated may be necessary, particularly during periods of severe cold stress. Adequate fresh drinking water should be supplied at all times; the practice of forcing wintering cows to obtain their water requirements by eating snow while on low-quality roughage is hazardous.

ACUTE INTESTINAL OBSTRUCTIONS IN LARGE ANIMALS

Intestinal obstructions are seen in all large animal species but are most common in horses. Cattle are the most commonly affected ruminants; diagnosis in sheep and goats is rare, except for intestinal volvulus in lambs. Other than inguinal hernias, intestinal obstructions are infrequently recognized in pigs.

Obstructions interrupt the flow of ingesta and can be mechanical or functional in nature. Mechanical intestinal obstructions are characterized as being luminal or extraluminal. Extraluminal obstructions include hemorrhagic strangulating obstructions in animals with volvulus of the GI tract, or simple extraluminal compression in animals

with an expanding abdominal mass such as lymphosarcoma or fat necrosis. Functional obstructions have no gross abnormality but are characterized by a generalized hypomotility or ileus. In general, functional obstructions occur more often than mechanical obstructions, and they are commonly identified in horses after abdominal surgery.

Etiology and Pathogenesis:

The inciting cause of a functional intestinal obstruction often is not determined. Functional obstructions are associated with altered intestinal motility, often due to dietary or management factors, phyto-bezoars, parasite infection, enteritis, peritonitis, or electrolyte abnormalities. Mechanical obstructions (physical blockage of ingesta) occur due to abnormalities in the bowel lumen, in the wall, or outside the tract. Mechanical obstructions include congenital obstructions (atresia jejuni, coli, recti, and ani in calves; atresia ani in lambs and pigs) that result in the lack of passage of feces since birth.

In horses, transient functional obstructions are common, as are feed impactions, which usually involve the pelvic flexure of the left colon. Parasite infection or migration, dental abnormalities, and dietary or management factors are often implicated in the development of functional obstruction. Impactions and other luminal obstructions can result from coarse feeds, reduced water intake, enteroliths, or ingested foreign material. Sites of impaction other than the pelvic flexure are the small colon, transverse colon, right dorsal colon, cecum, and ileum. Other causes of intestinal obstruction in horses are volvulus (twist on the mesenteric axis), torsion (twist along the long axis of the bowel), displacement of the ascending (large) colon, and volvulus of part or all of the small intestine. Altered motility and possibly strenuous exercise and rolling may be initiating causes. Broodmares may be predisposed to volvulus, torsion, or displacement of the ascending colon during gestation and shortly after parturition. Obstruction occurs either due to incarceration of the intestine (usually small) by herniation through the inguinal canal, diaphragm, mesenteric defects, umbilicus, or epiploic foramen; or because of fibrous bands (adhesions, mesodiverticular bands, or stalks of pedunculated lipomas). Standardbred stallions and colts develop inguinal and scrotal hernias more commonly than other breeds. Diaphragmatic hernias and mesenteric defects may be congenital or traumatically induced. Adhesions in horses

are most often the sequela of parasite migration or abdominal surgery; however, most adhesions are clinically silent. Pedunculated lipomas are common in older horses. Ileocecal, cecocolic, cecocolic, and small-intestinal intussusceptions also are seen. Lymphosarcoma and other abdominal neoplasms as well as abdominal abscesses can cause intestinal obstruction.

In cattle, specific causes of intestinal obstruction include volvulus of the duodenal sigmoid flexure; intussusception of the jejunum and ileum; volvulus of the jejunoileal flange of the small intestine; volvulus at the root of the mesentery; luminal occlusion of the jejunum due to a blood clot secondary to hemorrhagic jejunitis; obstruction of the small intestine or spiral colon due to phyto-bezoars; cecocolic volvulus; and atresia coli, recti, and ani. Intussusceptions are thought to be the result of irregular peristaltic movements related to enteritis, intestinal parasitism, dietary disorders, and mural masses. Altered intestinal motility due to ingestion of a rapidly fermentable substrate may cause intestinal volvulus. Obstructions of the small intestine can develop due to a variety of fibrous bands (eg, adhesions, parovarian bands, falciform ligament, spermatic cord retraction into the abdomen after surgical castration), mural thickening (eg, intestinal adenocarcinoma), extramural masses (eg, lymphosarcoma, fat necrosis, abdominal abscesses), herniation (omental, inguinal, or umbilical), or hemorrhagic jejunitis (which results in luminal blood clots and obstruction). Adhesions and abdominal abscesses can form subsequent to peritonitis, intraperitoneal injections, or previous abdominal surgery. Decreased motility caused by accumulation of volatile fatty acids, possibly related to high-concentrate rations or an abrupt increase in the concentrate:forage ratio, have been suggested as causes of cecocolic volvulus in cattle. They also are associated with advanced pregnancy and ileus from concurrent disease. Atresia coli develops most commonly in Holstein-Friesian calves secondary to in utero ischemia of the developing spiral colon.

Clinical Findings and Diagnosis:

Intestinal obstruction in horses generally manifests as abdominal pain, which is termed colic (*see* p 248). In cattle, signs of abdominal pain include treading of the hindlimbs, stretching, restlessness, and kicking at the abdomen; rolling and bellowing are rarely seen. The signs of intestinal obstruction in cattle are generally

more subtle than in horses and are usually referable to small-intestinal distention, tension on the intestinal mesentery (by the weight of distended bowel), or vascular impairment. Signs of pain are relatively consistent but often transient with intussusceptions and are seen in some cases of cecocolic volvulus. Cattle with volvulus of the small intestine at the root of the mesentery are severely affected.

Usually, cattle with intestinal obstruction are anorectic and pass few or no feces, and milk production in lactating cows drops suddenly. The feces that are passed may be covered with mucus, or mixed or coated with blood. Thick, raspberry-colored blood mixed with scant feces is characteristic of small-intestinal bleeding, particularly that associated with intussusception or hemorrhagic jejunitis. Blood from the colon or rectum is generally brighter red. Melena is typical of abomasal bleeding. Calves with atresia coli are healthy at birth but have progressive abdominal distention and decreased appetite during the first few days of life. (See also CONGENITAL AND INHERITED ANOMALIES OF THE DIGESTIVE SYSTEM, p 162.)

Abdominal distention, usually with a ping on simultaneous auscultation and percussion, in the upper right caudal abdominal quadrant occurs with cecocolic volvulus. Cecal dilatation does not produce abdominal distention, but a ping is generally present in the caudal dorsal paralumbar fossa. In cecocolic volvulus, one or more large, distended loops of large intestine are identified on palpation per rectum. Rumen hypomotility is usually present, and metabolic and cardiovascular derangement tend to be mild except in cecocolic volvulus of long duration.

Abdominal distention in the lower right abdominal quadrant is sometimes seen with small-intestinal distention. Distended loops of bowel may be palpable on rectal examination, and fluid may be heard on simultaneous ballottement and auscultation of the right side of the abdomen. Small areas of tympanic resonance may be heard on simultaneous auscultation and percussion. Intussusceptions and fibrous bands that cause small-intestinal obstruction can be palpated per rectum in ~25% of cases. Ultrasonographic examination of the abdomen via the right paralumbar fossa or per rectum may help identify the presence of small-intestinal distention, ileus, and an increased peritoneal fluid volume. Occasionally, ultrasonography can identify an intussusception.

Profound changes in cardiovascular parameters, such as tachycardia, abnormal

color of the mucous membranes, prolonged capillary refill time, and dehydration, are most commonly associated with hemorrhagic strangulating obstructions such as volvulus of the jejunal-ileal flange of the small intestine. Volvulus of the jejunal-ileal flange and volvulus at the root of the mesentery are characterized by acute onset and rapid cardiovascular deterioration. This is in contrast with cecocolic volvulus or intussusception, which can continue for several days in cattle.

Metabolic derangements range from hypokalemic, hypochloremic metabolic alkalosis in longstanding small-intestinal and duodenal obstructions to severe metabolic acidosis with hemorrhagic strangulating obstructions. Usually, there are no metabolic derangements in mild functional obstructions and early (simple) mechanical obstructions, particularly if a relatively distal part of the intestinal tract is involved. Hypocalcemia can develop, presumably due to decreased calcium absorption from the duodenum.

Peritoneal fluid changes reflect the degree of peritonitis and may aid in the diagnosis in both cattle and horses, although results are more variable in cattle. Hemorrhagic strangulating obstructions are characterized by an increase in the total protein concentration and nucleated cell counts of peritoneal fluid due to extravasation through the bowel wall. Neutrophils become degenerative, and intracellular gram-positive and gram-negative bacteria are seen in peritoneal fluid as the integrity of the bowel wall is lost. Plant material in the peritoneal cavity is indicative of bowel rupture or inadvertent enterocentesis. Peritoneal fluid analysis is normal with most simple mechanical and functional obstructions. When neoplasms are present and causing an extraluminal obstruction, neoplastic cells are sometimes identified in peritoneal fluid.

Treatment: Treatment of intestinal obstruction in horses is covered elsewhere (see p 253). Treatment of functional intestinal obstruction in cattle is generally symptomatic and supportive after identifying and eliminating the inciting cause (eg, hypocalcemia, hypokalemia, excessive grain intake) and allowing time for normal intestinal motility to return. If present, dehydration and electrolyte imbalances should be corrected by appropriate fluid therapy (PO or IV). Lactating cows often benefit from calcium chloride gels administered orally or calcium borogluconate or calcium gluconate

administered SC, and oral potassium chloride (120–240 g twice at 12-hr intervals). Secondary ketosis should be treated if present. Erythromycin (10 mg/kg, IM, bid) is the most effective pharmacologic method to increase abomasal emptying rate in cattle (and presumably increasing intestinal motility), but studies documenting efficacy in functional intestinal obstruction are lacking. Prokinetics should not be administered to cattle with a mechanical obstruction because of the increased risk of intestinal rupture proximal to the obstruction. The prognosis with most functional obstructions is good with appropriate supportive therapy, particularly if the inciting cause is identified and eliminated.

Mechanical obstructions almost always require surgery. Antimicrobial therapy should be started preoperatively; supportive therapy, such as fluids, electrolytes, and calcium, should be administered as needed.

Horses that require exploratory laparotomy to correct an intestinal obstruction have an overall longterm survival rate of 50%. The survival rate is lower for horses with hemorrhagic strangulating obstructions and small-intestinal lesions than for horses with simple

obstructions, but early surgical intervention can improve the prognosis.

In cattle, 70%–80% of those with cecocolic volvulus survive, although 10% of cases recur. For cows with small-intestinal obstruction amenable to resection and anastomosis, 30%–40% survive and lead a productive life. For cows with volvulus of the jejunal-ileal flange of the small intestine or at the root of the mesentery, ~50% survive if surgical correction is performed within a few hours of onset. Less than 30% of calves with atresia coli survive to adulthood. Surgical correction of atresia coli is not recommended in Holstein-Friesian calves because the condition is probably inherited in this breed, although vascular damage secondary to annular vesicle palpation in the first 6 wk of embryonic development can also lead to intestinal ischemia and atresia in calves.

Prevention: Prevention of all, or even most, cases of intestinal obstruction is not possible. However, abrupt changes in feeding and management; inadequate water intake; parasite infection; dental abnormalities; and access to coarse feeds, highly fermentable feedstuffs, and foreign material should be avoided or corrected.

COLIC IN HORSES

In its strictest definition, the term “colic” means abdominal pain. Throughout the years, it has become a broad term for a variety of conditions that cause a horse to exhibit clinical signs of abdominal pain. Consequently, it is used to refer to conditions of widely varying etiologies and severity. To understand these etiologies, make a diagnosis, and initiate appropriate treatments, veterinarians must first appreciate the clinically relevant aspects of equine GI anatomy, the physiologic processes involved in movement of ingesta and fluid along the GI tract, and the extreme sensitivity of the horse to the deleterious effects of the structural components of the bacteria that reside within the lumen of the intestine.

GI Anatomy

The horse is a monogastric animal, with a relatively small stomach (capacity 8–10 L)

that is located on the left side of the abdomen beneath the rib cage. The junction of the distal esophagus and the cardia is a functional 1-way valve, permitting gas and fluid to move into the stomach but not out. Consequently, conditions that impede the normal aboral movement of gas and fluid through the small intestine may result in severe dilation and rupture of the stomach. Because of its position, the stomach is difficult to visualize with radiography or ultrasonography in large adult horses. The smaller size of the foal, however, permits assessment of gastric emptying by contrast radiography.

The small intestine comprises the duodenum, jejunum, and ileum, with the latter joining the cecum at a distinct ileocecal junction. The duodenum is positioned primarily dorsally on the horse's right side, where it is suspended from the dorsal body wall by a short mesentery of 3–5 cm.

Consequently, the duodenum is not involved in small-intestinal displacements involving the mesentery (volvulus). At the base of the cecum in the right paralumbar fossa region, the duodenum turns toward the midline. It is at this point that the duodenum, if distended with gas or fluid (eg, in horses with proximal enteritis), can be felt on rectal examination.

As the small intestine reaches the dorsal midline, it turns anteriorly, its mesentery lengthens, and it becomes known as the jejunum. The characteristic long mesentery allows loops of the jejunum to rest on the contents of the ventral portion of the abdomen. The jejunum is ~65 ft (19.5 m) long; its length, coupled with its long mesentery, allow it to be involved in small-intestinal volvulus and incarcerations. At the end of the jejunum, the wall of the intestine becomes more muscular, the lumen is narrowed, and an additional mesenteric attachment becomes apparent. The last 18 in. (45 cm) of the small intestine, the ileum, joins the cecum at its dorsal medial aspect. This junction is identified by the attachment of the ileocecal fold from the ileum to the dorsal band of the cecum. This ileocecal fold is used as a landmark to locate the ileum during abdominal surgery.

From the ileum, the ingesta enters the cecum, a large, blind-ended fermentation vat situated primarily on the horse's right side, extending from the region of the paralumbar fossa to the xiphoid cartilage on ventral midline. The cecum is 4–5 ft (1.2–1.5 m) long and can hold 27–30 L of feed and fluid. Under the influence of the cecal musculature, the ingesta in the cecum is massaged, mixed with microorganisms capable of digesting cellulose, and eventually passed through the cecocolic opening into the right ventral colon. The attachment of the cecum to the dorsal body wall is wide, thus minimizing the likelihood the cecum can become displaced or twisted on its own.

The right ventral colon is divided into sacculations that help mix and retain plant fibers until they are digested. It is positioned on the ventral aspect of the abdomen, extending from the flank region to the rib cage. The ventral colon then turns toward the left, becoming the sternal flexure and then the left ventral colon. The left ventral colon, which also is large and sacculated, passes caudally to the left flank area. Near the pelvic region, the diameter of the colon decreases markedly, and the colon folds back on itself. This region, called the pelvic flexure, is the initial portion of the unsacculated left dorsal colon. Presumably because of the abrupt decrease in diameter,

the junction between the left ventral colon and pelvic flexure is the most common location for impactions.

The diameter of the dorsal colon is largest either at its diaphragmatic flexure or in the right dorsal colon. There are no sacculations in either the left or right portion of the dorsal colon. The right dorsal colon is closely attached to the right ventral colon by a short intercolic fold and to the body wall by a tough, common mesenteric attachment with the base of the cecum. In contrast, neither the left ventral nor left dorsal colons are attached directly to the body wall, allowing these portions of the colon to become displaced or twisted.

Ingesta moves from the large right dorsal colon into the short transverse colon, which has a diameter of ~10 cm and is fixed firmly to the most dorsal aspect of the abdominal cavity by a strong, short, fibrous mesentery. The transverse colon is located cranial to the cranial mesenteric artery. Finally, the ingesta enters the sacculated descending colon, which is 10–12 ft (3–3.6 m) long.

Blood Supply to the GI Tract

The celiac and cranial mesenteric arteries (branches of the abdominal aorta) supply blood to the GI tract. The celiac artery supplies arterial blood to the stomach, pancreas, liver, spleen, and the first portion of the duodenum. The cranial mesenteric artery supplies arterial blood to the remaining portion of the duodenum; to all of the jejunum, ileum, cecum, large colon, and transverse colon; and to the first portion of the descending colon. Because the large colon is attached to the body wall only in the region near the cranial mesenteric artery, the blood supplying all portions of the colon must traverse the entire length of the colon. The pelvic flexure receives its blood supply from two branches of the cranial mesenteric artery; one branch supplies the right and left dorsal colons before reaching the pelvic flexure, and the other branch supplies the right and left ventral colons before reaching the pelvic flexure. Thus, volvulus of the large colon near the junction of the colon and cecum may impede the flow of blood to the entire left colon.

The major branches of the cranial mesenteric artery can be damaged by the migrating forms of *Strongylus vulgaris* (see p 316).

Natural Openings in the Abdomen

There are several natural openings or spaces within the abdominal cavity that can be important in conditions causing colic.

Left medial view of cecum and right colon, horse. Illustration by Dr. Gheorghe Constantinescu.

The inguinal canal provides an opening through which intestine might pass and become trapped. Although inguinal hernias are common in young foals, they rarely cause clinical problems; the situation is considerably different in stallions. Similarly, if the ventral abdominal wall fails to form properly around the umbilicus, an opening remains and the potential exists for intestinal problems to develop secondary to an umbilical hernia. The epiploic foramen, a natural opening between the portal vein, the caudal vena cava, and the caudate lobe of the liver, can be the site of intestinal incarcerations. Finally, there is a natural space between the dorsal aspect of the spleen and the left kidney. This space is bounded by the renosplenic ligament, a strong band of tissue that connects the dorsomedial aspect of the spleen with the fibrous capsule of the left kidney. This ligament provides a "shelf" over which large colon can be displaced.

Colonic Motility Patterns

Normograde peristalsis in the left ventral colon moves ingesta toward the left dorsal colon, and the muscles in the wall of the left dorsal colon contract to move the ingesta toward the diaphragmatic flexure. There is evidence, however, that the muscles in the left ventral colon contract in a retrograde fashion, from the pelvic flexure region toward the sternal flexure. Furthermore, these contractions appear to originate from a pacemaker region in the pelvic flexure. It has been hypothesized that this pacemaker senses either the size or the consistency of

the feed particles in the ingesta and then initiates the appropriate motility pattern. If the ingesta has been digested sufficiently, it is moved in a normograde direction; if additional digestion is necessary, the ingesta is moved in a retrograde direction to retain it in the ventral colon. This theory has been proposed to help account for the common clinical occurrence of obstruction at or near the pelvic flexure.

Clinical Findings

Numerous clinical signs are associated with colic. The most common include pawing repeatedly with a front foot, looking back at the flank region, curling the upper lip and arching the neck, repeatedly raising a rear leg or kicking at the abdomen, lying down, rolling from side to side, sweating, stretching out as if to urinate, straining to defecate, distention of the abdomen, loss of appetite, depression, and decreased number of bowel movements. It is uncommon for a horse with colic to exhibit all of these signs. Although they are reliable indicators of abdominal pain, the particular signs do not indicate which portion of the GI tract is involved or whether surgery will be needed.

Diagnosis

A diagnosis can be made and appropriate treatment begun only after thoroughly examining the horse, considering the history of any previous problems or treatments, determining which part of the intestinal tract is involved, and identifying the cause of the particular episode of colic.

The large intestine of the horse. Illustration by Dr. Gheorghe Constantinescu.

In most instances, colic develops for one of four reasons: 1) The wall of the intestine is stretched excessively by either gas, fluid, or ingesta. This stimulates the stretch-sensitive nerve endings located within the intestinal wall, and pain impulses are transmitted to the brain. 2) Pain develops due to excessive tension on the mesentery, as might occur with an intestinal displacement. 3) Ischemia develops, most often as a result of incarceration or severe twisting of the intestine. 4) Inflammation develops and may involve either the entire intestinal wall (enteritis) or the covering of the intestine (peritonitis). Under such circumstances, proinflammatory mediators in the wall of the intestine decrease the threshold for painful stimuli.

The list of possible conditions that cause colic is long, and it is reasonable first to determine the most likely type of disease and begin appropriate treatments and then to make a more specific diagnosis, if possible. The general types of disease that cause colic include excessive gas in the intestinal lumen (flatulent colic), simple obstruction of the intestinal lumen, obstruction of both the intestinal lumen and the blood supply to the intestine (strangulating obstruction), interruption of the blood supply to the intestine alone (nonstrangulating infarction), inflammation of the intestine (enteritis), inflammation of the lining of the abdominal cavity (peritonitis), erosion of

the intestinal lining (ulceration), and "unexplained colic." In general, horses with strangulating obstructions and complete obstructions require emergency abdominal surgery, whereas horses with the other types of disease can be treated medically.

The history of the present colic episode and previous episodes, if any, must be considered to determine whether the horse has had repeated or similar problems or whether this episode is an isolated event. The duration of the present episode, the rate of deterioration of the horse's cardiovascular status, the severity of pain, whether feces have been passed, and the response to any treatments are important pieces of information. It is also critical to determine the horse's deworming history (schedule, treatment dates, drugs used), when the teeth were floated last, if any changes in feed or water supply or amount have occurred, whether or not the horse is a "cribber," and whether the horse was at rest or exercising when the colic episode started.

The physical examination should include assessment of the cardiopulmonary and GI systems. The oral mucous membranes should be evaluated for color, moistness, and capillary refill time. The mucous membranes may become cyanotic or pale in horses with acute cardiovascular compromise and eventually hyperemic or muddy as peripheral vasodilation develops later in shock. The capillary refill time (normal ~1.5

sec) may be shortened early but usually becomes prolonged as vascular stasis (venous pooling) develops. The membranes become dry as the horse becomes dehydrated. The heart rate increases due to pain, hemoconcentration, and hypotension; therefore, higher heart rates have been associated with more severe intestinal problems (strangling obstruction). However, it is important to note that not all conditions requiring surgery are accompanied by a high heart rate.

An important aspect of the physical examination is the response to passing a nasogastric tube. Because horses can neither regurgitate nor vomit, adynamic ileus, obstructions involving the small intestine, or distention of the stomach with gas or fluid may result in gastric rupture. Passing a stomach tube may, therefore, save the horse's life and assist in diagnosis of these conditions. If fluid reflux occurs, the volume and color of the fluid should be noted. In healthy horses, it is common to retrieve <1 L of fluid from the stomach.

The abdomen and thorax should be auscultated and the abdomen percussed. The abdomen should be auscultated over several areas (cecum on the right, small intestine high on the left, colon lower on both the right and left). Intestinal sounds associated with episodes of pain may indicate an intraluminal obstruction (eg, impaction, enterolith). Gas sounds may indicate ileus or distention of a viscus. Fluid sounds may indicate impending diarrhea associated with colitis. A complete lack of sounds is usually associated with adynamic ileus or ischemia. Percussion helps identify a grossly distended segment of intestine (cecum on right, colon on left) that may need to be trocarized. The respiratory rate may be increased due to fever, pain, acidosis, or an underlying respiratory problem. Diaphragmatic hernia is also a possible cause of colic.

The most definitive part of the examination is the rectal examination. The veterinarian should develop a consistent method of palpating for the following: aorta, cranial mesenteric artery, cecal base and ventral cecal band, bladder, peritoneal surface, inguinal rings in stallions and geldings or the ovaries and uterus in mares, pelvic flexure, spleen, and left kidney. The intestine should be palpated for size, consistency of contents (gas, fluid, or impacted ingesta), distention, edematous walls, and pain on palpation. In healthy horses, the small intestine cannot be palpated; with small-intestinal obstruction, strangulating obstruction, or enteritis, the distended duodenum can be palpated

dorsal to the base of the cecum on the right side of the abdomen, and distended loops of jejunum can be identified in the middle of the abdomen.

A sample of peritoneal fluid (obtained via paracentesis performed aseptically on midline) often reflects the degree of intestinal damage. The color, cell count and differential, and total protein concentration should be evaluated. Normal peritoneal fluid is clear to yellow, contains <5,000 WBCs/ μ L (most of which are mononuclear cells), and <2.5 g of protein/dL.

The age of the horse is important, because a number of age-related conditions cause colic. The more common of these include the following: in foals—atresia coli, meconium retention, uroperitoneum, and gastroduodenal ulcers; in yearlings—ascarid impaction; in the young—small-intestinal intussusception, nonstrangulating infarction, and foreign body obstruction; in the middle-aged—cecal impaction, enteroliths, and large-colon volvulus; and in the aged—pedunculated lipoma and mesocolic rupture.

Ultrasonographic evaluation of the abdomen may help differentiate between diseases that can be treated medically and those that require surgery. The technique also can be applied transrectally to clarify findings noted on rectal palpation. In foals, echoes from the large colon and small intestine are commonly identified from the ventral abdominal wall, whereas only large-colon echoes are usually seen in adult horses. The large colon can be identified by its sacculated appearance. The duodenum can be identified in the tenth intercostal space and traced around the caudal aspect of the right kidney. The jejunum is rarely identified during transabdominal ultrasonographic examination of normal adult horses, whereas the thick-walled ileum can be identified by transrectal examination.

The most common abnormalities identified by ultrasonography include inguinal hernia, renosplenic entrapment of the large colon, sand colic, intussusception, enterocolitis, right dorsal colitis, and peritonitis. Stallions with inguinal hernia have incarcerated intestine on the affected side; it is possible to identify the intestine and to obtain information concerning the thickness of its wall as well as the presence or lack of peristalsis. In horses with renosplenic entrapment of the large colon, the tail of the spleen or the left kidney cannot be imaged, or the gas-filled large colon is present in the caudodorsal aspect of the abdomen in the region of the renosplenic space. Horses with sand colic have granular

hyperechoic echoes originating from the affected portion of the colon. The characteristic finding in horses with intussusception is the "bull's eye" appearance of the affected portion of the small intestine. Very often the intestine proximal to the intussusception is distended, and the strangulated portion is thickened. Horses with enterocolitis frequently have evidence of hyperperistalsis, thickened areas of the bowel wall, and fluid distention of the intestine. In contrast, horses with right dorsal colitis commonly have marked thickening of the wall of the right dorsal colon. In horses with peritonitis, the peritoneal fluid may be anechoic, or there may be evidence of flocculent material and fibrin between serosal surfaces of the viscera.

Treatment

Horses with colic may need either medical or surgical treatments. Almost all require some form of medical treatment, but only those with certain mechanical obstructions of the intestine need surgery. The type of medical treatment is determined by the cause of colic and the severity of the disease. In some instances, the horse may be treated medically first and the response evaluated; this is particularly appropriate if the horse is mildly painful and the cardiovascular system is functioning normally. Ultrasonography can be used to evaluate the effectiveness of nonsurgical treatment. If necessary, surgery can be used for diagnosis as well as treatment.

If evidence of intestinal obstruction with dry ingesta is found on rectal examination, a primary aim of treatment is to rehydrate and evacuate the intestinal contents. If the horse is severely painful and has clinical signs indicating loss of fluid from the bloodstream (high heart rate, prolonged capillary refill time, and discoloration of the mucous membranes), the initial aims of treatment are to relieve pain, restore tissue perfusion, and correct any abnormalities in the composition of the blood and body fluids (see TABLE 5). If damage to the intestinal wall (as a result of either severe inflammation or a displacement or strangulating obstruction) is suspected, steps should be taken to prevent or counteract the ill effects of bacterial endotoxins that cross the damaged intestinal wall and enter the bloodstream. Finally, if there is evidence the colic episode is caused by parasites, one aim of treatment is to eliminate the parasites.

Pain Relief: In most cases of colic, pain is mild, and analgesia is all that is needed.

In these instances, the cause of colic is presumed to be spasm of intestinal muscle or excessive gas in a portion of the intestine. If, however, the pain is due to an intestinal twist or displacement, some of the stronger analgesics may mask the clinical signs that would be useful in making a diagnosis. For these reasons, a thorough physical examination should be completed before any medications are given. However, because horses with severe colic or pain may hurt themselves and become dangerous to people nearby, analgesics often must be given first. Additionally, many horses with less severe problems may need pain relief until the other treatments have time to be effective. An analgesic that has the fewest adverse effects and causes the least alteration in the horse's attitude should be selected.

Medications used commonly for abdominal pain are NSAIDs that reduce the production of prostaglandins. When these drugs are used as recommended, their toxic effects on the kidneys and GI tract occur infrequently. Clinical experience suggests that flunixin meglumine may mask the early signs of conditions that require surgery and, therefore, must be used carefully in horses with colic.

The most commonly used sedative for colic is xylazine, an α_2 -agonist. Within a few minutes after administration, the horse stands quietly and is less responsive to pain. Unfortunately, the effects of xylazine are short-lived, and it inhibits intestinal muscular activity; it also decreases cardiac output and thus reduces blood flow to the tissues. Detomidine, a more potent α_2 -agonist that is much longer acting, is used successfully in similar circumstances.

Of the narcotic analgesics, butorphanol is used most often in horses with colic. Butorphanol has few adverse effects on the GI tract or heart. However, when given in large doses, narcotics can cause excitement, and the horse may become unstable. Butorphanol is frequently combined with an α_2 -agonist to produce a more prolonged period of analgesia.

Although pain relief usually is provided by analgesics, there are other important ways to reduce the degree of pain. For example, passing a nasogastric tube (also an important part of the diagnostic evaluation) may remove any fluid that has accumulated in the stomach because of an obstruction of the small intestine. The removal of this fluid not only relieves pain from gastric distention but also prevents rupture of the stomach.

Horses with displacement of the colon over the renosplenic ligament (ie, left dorsal

displacement of the colon) may benefit from administration of phenylephrine. This drug is given to contract the spleen and often is followed by light exercise on a lunge line in an effort to dislodge the entrapped colon. It is important to note that this treatment may cause fatal hemorrhage due to hypertension in horses >15 yr old.

Fluid Therapy: Many horses with colic benefit from fluid therapy to prevent dehydration and maintain blood supply to the kidneys and other vital organs. The fluids may be given either through the nasogastric tube or IV, depending on the particular intestinal problem (see TABLE 5). Horses with strangulating obstruction or enteritis must be given fluids IV, because absorption of fluids from the diseased intestine is impaired and fluid may be secreted into the lumen of the intestine. The latter mechanism causes a buildup of fluid in the intestine, which must be removed from the stomach through a nasogastric tube. This abnormal movement of body fluids into the intestine contributes to the development of circulatory shock, which is often the ultimate cause of death.

In healthy horses, most of the fluid in the intestinal tract is reabsorbed in the cecum and colons. In fact, ~95% of the fluid that normally enters the lumen of the large intestine is returned to the bloodstream. Therefore, horses with intestinal obstructions near the pelvic flexure usually require relatively small amounts of IV fluids, whereas horses with small-intestinal obstructions need extremely large amounts.

The volume and type of fluid to be given are determined by the severity and cause of the problem. Laboratory tests to determine

the degree of hemoconcentration and whether concentrations of electrolytes are abnormal are critical for accurate treatment of horses with severe colic. The balance of body fluids can be reestablished by administering IV fluids formulated to replenish the deficient electrolyte(s). In most instances, however, fluid therapy must be started before laboratory results are available, particularly when the horse is showing clinical signs of circulatory shock.

When IV fluids are needed but the clinical signs are mild to moderate, the horse is usually given 8–10 L of a sterile replacement fluid that contains electrolytes in concentrations similar to those that normally exist in the blood. This volume is administered throughout 1–2 hr, and the horse is reevaluated to determine whether additional fluids are needed. Horses in circulatory shock require much larger volumes of IV fluids, given as rapidly as possible; as much as 20 L in 1 hr may be needed to reestablish tissue perfusion. In severe cases, hypertonic saline (7% NaCl) may be given to rapidly increase plasma volume. Depending on the cause of colic, IV fluids may be needed for several days until intestinal function has returned, electrolyte concentrations are balanced, and the horse can maintain its fluid needs by drinking. Under such circumstances, the daily IV fluid requirements may range from 30 to 100 L.

Fluids are sometimes given through the nasogastric tube as part of the treatment of impactions of the colon. Many clinicians believe the same result can be accomplished by giving large volumes of fluids IV. If the horse will not drink voluntarily and there is no obstruction in the small intestine, hydration may be maintained

TABLE 5

GENERAL CONCEPTS REGARDING FLUID NEEDS IN DEHYDRATED HORSES

Determining Factor	Formula Used	Amount for a 500-kg Horse
Fluid deficit	% dehydration $\times$ body weight (kg)	4%–10% $\times$ 500 = 20–50 L
Maintenance	50 mL/kg/24 hr	50 $\times$ 500 = 25 L/24 hr
Fluid losses	Estimate reflux or diarrhea volume	
Rate of administration	50% in 1–2 hr; 50% throughout rest of day	20–35 L in first 1–2 hr; remainder distributed throughout next 23 hr

Adapted, with permission, from Zimmel DN, Management of pain and dehydration in horses with colic. In *Current Therapy in Equine Medicine*, 5, 2003, Robinson, NE, (ed), Elsevier.

by administering fluids through the tube. Fluids or medications should not be given through the nasogastric tube if fluid reflux is being removed from the stomach, because this indicates either the stomach or the small intestine is not emptying properly.

Protection Against Components of Enteric Bacteria:

In healthy horses, the mucosal lining of the GI tract restricts enteric bacteria and their structural components (eg, endotoxins, lipoproteins, nucleic acids, flagellin) to the intestinal lumen. These bacterial components exist in high concentrations in the intestinal lumen, because they are released when the bacteria die or, in some cases, when bacteria multiply rapidly. However, when this mucosal barrier is disrupted, as occurs with intestinal ischemia or inflammation, the bacterial components can move into the peritoneal cavity and then be absorbed into the systemic circulation. Based on recent research studies, equine leukocytes are most sensitive to endotoxins but also respond strongly to other components, most notably flagellin. Most studies performed to date have focused on endotoxins, because they are assumed to be the primary triggers for the systemic inflammatory responses that occur in many horses with GI disease. These responses can include fever, depression, hypotension, reduced tissue perfusion, and coagulation abnormalities. In fact, many equine practitioners refer to these physiologic responses as "endotoxemia." Thus, minimizing the inflammatory responses to endotoxemia is a vital part of colic therapy.

Prostaglandins are involved in causing many of endotoxin's early ill effects. Flunixin meglumine reduces the cellular production of prostaglandins and can help prevent some of their effects. Because flunixin can help prevent some of the early effects of endotoxemia at dosages less than the recommended dosage (1.1 mg/kg), smaller dosages (0.25 mg/kg) can be administered without masking clinical signs associated with conditions that require surgery.

There is considerable controversy regarding the efficacy of plasma or serum that contains antibodies designed to neutralize endotoxin. These antibodies are directed against the components of endotoxins that are consistent among different gram-negative bacteria. The results of clinical studies using such antibodies have been conflicting, with evidence of protection being seen in some studies and no positive effects identified in

others. This apparent lack of efficacy of anti-endotoxin antibodies also may indicate that some of the systemic inflammatory responses encountered are triggered by other bacterial components. Because endotoxin itself stimulates the generation of a wide array of inflammatory substances that ultimately produce the pathophysiologic effects, neutralizing antibodies should be used as early as possible in the course of the disease.

As an alternative approach, polymyxin B has been used to prevent endotoxin from interacting with the horse's inflammatory cells. Polymyxin B has well-documented nephrotoxicity; however, concentrations of polymyxin B that bind endotoxin are far less than those that cause toxic effects. Polymyxin B has been evaluated in several experimental studies of endotoxemia and is being used in clinical cases at 1,000–5,000 U/kg, bid-tid. This form of therapy should be started as early as possible in the clinical course of the disease. In addition, fluid replacement therapy should be maintained in hypovolemic horses, and serum creatinine concentration should be closely monitored. This latter concern is especially relevant for azotemic neonatal foals, because they appear to be more susceptible to the nephrotoxic adverse effects of polymyxin B.

Intestinal Lubricants and Laxatives:

A common cause of colic in horses is simple obstruction of the large colon by dehydrated ingesta, sometimes mixed with sand. These impactions generally develop near the pelvic flexure or in the right dorsal colon but may involve any portion of the large colon, descending colon, or cecum. In most instances, lubricants or fecal-softening agents given through a nasogastric tube soften the impacted ingesta, allowing it to be passed. This form of therapy can be aided by the simultaneous administration of IV fluids. Keeping the horse muzzled is advised to prevent further impaction of feed material while the obstruction is softening.

Mineral oil is the most commonly used medication in the treatment of a large-colon impaction. It coats the inside of the intestine and aids the normal movement of ingesta along the GI tract. It is administered through a nasogastric tube, as much as 4 L, once or twice daily, until the impaction is resolved. Although mineral oil is safe, it is not highly effective in treating severe impactions or sand impactions, because it may simply pass by the obstruction without softening it.

Dioctyl sodium sulfosuccinate (DSS) is a soap-like compound that acts by drawing

water into the dry ingesta. It is more effective than mineral oil in softening impactions; however, it may interfere with the normal fluid absorptive functions of the colon and can be toxic. Thus, DSS can be given safely only in small quantities two times 48 hr apart.

A safe and useful compound to treat impactions, especially those containing sand, is psyllium hydrophilic mucilloid. When mixed with water, it forms a gelatinous mass that carries ingesta along the GI tract. Although usually given through a nasogastric tube to horses with impactions, psyllium also may be used as a preventive by mixing the dry powder into the feed. Horses that live in a sandy environment or that persistently develop impactions may be given psyllium powder, 400 g/500 kg/day, in their feed for 7 days. This treatment is repeated 2–3 times each year in an effort to prevent development of sand impactions.

Strong laxatives that stimulate intestinal contractions are not commonly used to treat impactions and, in fact, may worsen the problem. Occasionally, horses with extremely hard impactions are treated with magnesium sulfate, which draws body fluids into the GI tract. Adverse effects include dehydration and an increased risk of diarrhea.

Fluid therapy, whether the fluids are administered through a nasogastric tube or IV, is an important and effective part of treating horses with colonic or cecal impactions. If an impaction does not start to break down within 3–5 days, surgery may be necessary to evacuate the intestine and help restore normal motility.

Larvicidal Deworming: The normal migratory routes of the larvae of large bloodworms, particularly *Strongylus vulgaris*, have been implicated in many cases of colic. In response to the migratory and maturation processes of the larvae in the cranial mesenteric artery, the wall of the artery becomes thickened and forms loose plaques of inflammatory tissue. It has been hypothesized that these plaques activate coagulation, resulting in thromboembolism. The blood supply to the intestine may be reduced, resulting in altered intestinal motility, a change in the absorption of nutrients from the intestine, or death of the intestine. Thus, thromboembolism has been presumed to be a cause of recurrent episodes of colic and weight loss.

Modern deworming medications, such as ivermectin and moxidectin, have activity against migrating *S. vulgaris* larvae.

Fenbendazole kills migrating strongyles if given at twice the recommended dosage daily for 5 days or at 10 times the recommended dosage daily for 3 days. As a result of common use of these anthelmintics, chronic intermittent colic once thought to be caused by thromboembolism or parasite larval migration has largely been eliminated from equine practice.

There is considerable evidence that damage caused by cyathostomins causes colic, diarrhea, and loss of condition, particularly in young horses. These signs are seen on a seasonal basis and are synchronous with the emergence of large numbers of encysted larvae into the lumen of the large colon. In temperate areas of the Northern hemisphere, the larvae encyst during the winter months and emerge in the late winter and spring, causing ulceration, edema, and inflammation of the mucosa of the large colon. This may result in diarrhea, protein loss, weight loss, and mild intermittent colic and fever. Horses with cyathostomiasis require treatment with larvacidal dosages of anthelmintics such as ivermectin, moxidectin, and fenbendazole. Some horses require analgesics, supportive care, and proper nutritional support.

See also p 316 for a detailed discussion of treatment for large and small strongyles.

Surgery: Surgery usually is necessary if there is a mechanical obstruction to the normal flow of ingesta that cannot be corrected medically or if the obstruction also interferes with the intestinal blood supply. The latter conditions result in death of the horse unless surgery is performed quickly. Occasionally, surgery is indicated as an exploratory diagnostic procedure for horses with chronic colic that have not responded to routine medical therapy.

Under most circumstances, horses exhibiting signs of severe abdominal pain nonresponsive to analgesic therapy require emergency abdominal surgery. Generally, the lumen of the intestine is completely obstructed, such as occurs with a strangulating obstruction, enterolithiasis, or severe displacement. Similarly, horses with an abnormally distended intestine on rectal examination and peritoneal fluid with an increased total protein concentration and number of erythrocytes probably have a strangulating lesion that requires surgical correction. However, these classic findings that characterize horses requiring emergency surgery do not always exist. Some horses with mild or moderate pain may also require surgery, and a judgment must be based on a thorough physical

examination and other methods of evaluation, including abdominal ultrasonography. Some of the more commonly used indications for surgery in horses with colic include uncontrollable pain; >4 L of fluid reflux from the stomach; no borborygmi on auscultation; peritoneal fluid with increased protein, erythrocytes, and toxic neutrophils; and a tightly distended intestine, displaced colon, or enterolith or foreign body identified on rectal examination.

Performing surgery (if indicated) early is critical to success and improves the prognosis for survival. Therefore, it is more important to decide whether the horse should be referred to a clinic where surgery could be performed if needed than to determine whether emergency surgery is definitively required. It is generally prudent to refer the following types of cases: 1) a horse that responds initially to an analgesic but requires additional analgesic therapy a few hours later, 2) a horse that continues to exhibit signs of pain despite administration of analgesics, 3) a horse that remains painful but has normal peritoneal fluid, 4) a horse with distended loops of small intestine on rectal examination, or 5) a horse with large quantities of fluid removed from the stomach but no distended small intestine palpable on rectal examination.

When surgery is required, in most instances, the horse is anesthetized and positioned in dorsal recumbency, and the surgical incision is made on the ventral midline. Once the peritoneal cavity is entered, portions of the intestine should be examined to determine the definitive cause of the colic. Correction may involve repositioning a displaced portion of intestine, removing an obstruction, or resecting devitalized intestine. When devitalized segments of intestine must be removed or an enterotomy performed, postoperative care may include antibiotics, IV fluids, polymyxin B, antibodies directed against endotoxin, and NSAIDs to combat endotoxemia. When a displaced segment of intestine is simply returned to its normal location, the postoperative care is much less intense. Each horse must be handled individually, and its treatment needs are based on the response to surgery and development of complications.

Prognosis

A large retrospective study in the USA documented an overall survival rate of 60% for horses with colic and a survival rate of 50% for those horses undergoing abdominal surgery, including those euthanized during

surgery for inoperative conditions. Survival rates for horses with strangulating obstruction and inflammatory diseases were only 24% and 42%, respectively. In contrast, horses with an undefined cause for the colic episode had a survival rate of 94%. When the segment of the GI tract was considered, the survival rates for conditions affecting the small intestine and stomach were poorer than for those affecting the large colon. In addition, conditions that interfered with both the passage of ingesta and the intestinal blood supply dramatically decreased the chances of survival. The results of more recent studies are far more promising, with survival rates for horses undergoing emergency abdominal surgery often >80%. Furthermore, there have been reports documenting survival rates of 70% for horses requiring resection of strangulated small intestine or correction of large-colon volvulus. In earlier retrospective studies, these conditions were associated with survival rates $\leq$ 30%. Although data on longterm survival (ie, the horse returning to its intended use) are more difficult to obtain, recent findings indicate that most horses that die or are euthanized because of serious problems do so within 3 mo after surgery.

Values obtained from several variables are often combined to predict survival in horses with colic. Prognostic indicators include pain assessment, intestinal distention, mucous membrane color, and cardiovascular system function. Survival rates are highest for horses with mild abdominal pain and are lowest for horses with severe pain. Horses with palpable intestinal distention have lower survival rates than horses lacking evidence of intestinal distention, and survival rates are even lower if no intestinal sounds are audible on auscultation of the abdomen. Red mucous membranes are frequently associated with endotoxemia, which decreases the survival rate. Cardiovascular system function reflects the degree of shock and, therefore, correlates with the prognosis for survival. For instance, horses with low systolic blood pressure or a high heart rate have a decreased chance of survival.

Of the laboratory analyses used to predict survival, blood lactate concentration and the anion gap are used most often. Measurement of blood lactate has been used as an indicator of tissue perfusion, with increasing concentrations of lactic acid corresponding with poor tissue perfusion. In recent studies, changes in blood lactate concentration over time have been

particularly useful to determine the prognosis for survival, with increasing concentrations being associated with a poor prognosis. Furthermore, changes in peritoneal fluid lactate concentrations over time have been used to help identify horses that require emergency abdominal surgery. Similarly, the anion gap (the calculated difference between the measured cations and the measured anions) reflects the generation of organic anions, most notably lactic acid, due to reduced tissue perfusion. The concentration of protein in the peritoneal fluid also has been used to predict survival, with higher concentrations associated with a poorer prognosis.

DISEASES ASSOCIATED WITH COLIC BY ANATOMIC LOCATION

Stomach

Gastric Dilatation and Gastric Rupture:

The most common cause of gastric dilatation in horses is excessive gas or intestinal obstruction. Gastric dilatation may be associated with overeating fermentable feedstuffs such as grains, lush grass, and beet pulp. Presumably, the large increase in production of volatile fatty acids inhibits gastric emptying. If untreated, gastric dilatation associated with overeating can rapidly lead to gastric rupture. If intestinal obstruction is the cause, the obstruction most often involves the small intestine. The fluid from the obstructed small intestine accumulates in the lumen of the stomach, causing dilatation of the stomach and retrieval of gastric reflux on passage of the nasogastric tube. Gastric dilatation also may develop in some horses with certain colonic displacements, most notably right dorsal displacement of the colon around the cecum (see p 265). It is presumed that the displaced colon obstructs duodenal outflow. Gastric dilatation with fluid and gastric reflux also are characteristic findings in horses with proximal enteritis-jejunitis.

Rupture of the stomach is a fatal complication of gastric dilatation. The stomach generally tears along its greater curvature. Approximately two-thirds of all gastric ruptures occur secondary to mechanical obstruction, ileus, and trauma; the remaining cases are due to overload or to idiopathic causes.

Clinical signs associated with gastric dilatation include severe abdominal pain, tachycardia, and retching. The mucous membranes may be pale. Classically, these acute signs are replaced by relief, depres-

sion, and toxemia after the stomach has ruptured. The prognosis for survival may be excellent in most cases of gastric dilatation, but gastric rupture is fatal.

Gastric Impaction: Impaction of the stomach is an uncommon cause of colic. Although it may be associated with ingestion of certain feedstuffs (eg, beet pulp, pelleted feeds, persimmon seeds, straw, barley), contributing factors (eg, diseased teeth, inadequate intake of water, and rapid eating) should also be considered. Because the incidence of this condition is low, it is difficult to determine which factors may be most important. The most striking clinical sign associated with gastric impaction is severe abdominal pain. Because of the lack of other characteristic findings, the diagnosis most often is made at surgery, and the decision for surgery is based on unrelenting pain. Use of a 3-m endoscope has made it possible to identify this problem without surgery.

Treatment usually involves repeated intragastric administration of saline carbonated drinks ("soft drinks") if the condition has been identified without surgery. If the gastric impaction has been identified at surgery, saline or water can be infused into the mass through a needle passed through the wall of the stomach. After the fluid has been injected into the mass, the stomach then is massaged and the obstruction is broken down. If a nasogastric tube is in place at the time of surgery, water may be pumped into the stomach and the mass massaged. Gavage is continued after surgery with the hopes of removing some of the impacted material, and this can be followed by feeding slurries and pasture grazing once the impaction begins to resolve. The prognosis is favorable if the diagnosis has been made without surgery or if decision to perform exploratory surgery is made early and the impaction can be broken down manually at surgery.

Small Intestine

Clinical signs of colic may arise due to obstruction, inflammation, or strangulating obstruction of the small intestine. The prognosis for conditions affecting the small intestine is often guarded. Hence, rapid diagnosis and appropriate treatment are critical.

Ileal Impaction: The most common condition producing simple obstruction of the lumen of the small intestine is ileal impaction. It is most common in the

southeastern USA, Germany, and the Netherlands. The results of clinical studies in the UK indicate that infection with the intestinal tapeworm *Anoplocephala perfoliata* and ileal impaction are strongly associated. In a similar study performed in the USA, two risk factors for ileal impaction were identified: 1) the feeding of Coastal Bermuda hay, and 2) the lack of administration of pyrantel pamoate, an anthelmintic with some efficacy against *A. perfoliata*, within the 3 mo preceding development of the impaction. Further, it has been suggested that the impaction develops secondary to spastic contractions of the ileal musculature against ingesta.

Clinical signs include the onset of mild to severe abdominal pain followed by reduced intestinal sounds, gastric reflux, and tachycardia. Although early rectal examination may permit identification of the impaction in the ileum low in the right caudal abdominal quadrant, subsequent distention of the jejunum may make this identification difficult or impossible. The most common differential diagnosis is proximal enteritis-jejunitis, and distinguishing the two conditions can often be difficult. Because the horse's condition initially may remain stable and the degree of abdominal pain may be mild, many horses with this condition are not referred for intensive care or surgery for >18 hr. The protein concentration of the peritoneal fluid may increase if the impaction has persisted for this long.

Horses with ileal impaction respond to treatment with fluids and mineral oil if the impaction has been identified early (ie, before gastric reflux has developed). If surgery is indicated, the impacted mass may be mixed with saline or carboxymethylcellulose and massaged into the cecum, or an enterotomy may be performed in the distal jejunum and the ingesta removed through the incision. Ileus may develop after surgery. Depending on the degree of damage to the serosal surface of the small intestine at the time of surgery, complications may develop several weeks after surgery due to intra-abdominal adhesions (see below).

Adhesions: Intra-abdominal adhesions generally affect the small intestine and usually cause obstruction of the intestinal lumen, although they may cause strangulating obstruction. These adhesions develop in response to peritoneal injury and, most often, are the result of previous small-intestinal surgery, chronic small-

intestinal distention, peritonitis, or larval parasite migration. The tissue response to ischemia, traumatic tissue handling, foreign material, hemorrhage, or dehydration results in the formation of fibrous (and subsequently fibrous) adhesions. Clinical signs are seen if the adhesion causes kinking, compression, or stricture of the intestine.

Adhesions should be considered if the horse has had prior abdominal surgery and a more recent history of recurrent abdominal pain. Clinical signs associated with intra-abdominal adhesions range from mild, recurrent colic to severe unrelenting pain. Most commonly, intra-abdominal adhesions cause clinical signs within 60 days of the initial surgery if they are going to be a significant problem for the horse.

Surgical treatment involves transection of the adhesion, resection of the affected intestine, and anastomosis to achieve normal flow of ingesta. Therapeutic agents purported to reduce the subsequent formation of additional adhesions then are used. These include the systemic administration of antimicrobials, NSAIDs, and instillation of sterile carboxymethylcellulose into the abdomen at the time of closure. The owner should be informed that adhesions are likely to recur and that the longterm prognosis for horses with extensive adhesions is poor.

Ascarid Impaction: Young horses, particularly those on farms with inadequate parasite control programs, may develop ascarid impactions of the small intestine. These impactions are seen after administration of an anthelmintic with high efficacy against *Parascaris equorum*. The anthelmintics most commonly associated with this condition are ivermectin, piperazine, and organophosphates. These drugs paralyze the ascarids, resulting in accumulation of masses of the worms in the small-intestinal lumen. It has been suggested that disruption of the surface of the ascarid releases antigenic fluids that inhibit intestinal muscular activity, thereby increasing the likelihood of intestinal obstruction.

Clinical signs range from mild to severe abdominal pain, evidence of toxemia, and gastric reflux that may contain ascarids. Ascarid impaction should be suspected if the affected horse is a weanling or yearling, in poor condition, and has a recent history of deworming. Medical treatment with fluids and intestinal lubricants may be successful in some cases. Other horses may

require surgical intervention and removal of the ascarids through multiple enterotomies. The prognosis is guarded if surgery has to be performed. The owner should be advised that other young horses on the premises should be treated with anthelmintics that have lower efficacy against ascarids, such as fenbendazole. These initial treatments can then be followed with more efficacious compounds.

Proximal Enteritis–Jejunitis: This poorly understood disease affects the proximal portion of the small intestine and has various names, including proximal enteritis–jejunitis, anterior enteritis, and duodenitis–jejunitis. The condition has been recognized in the southeastern and northeastern USA, England, and on the European continent. The cause is unknown. The affected intestine contains lesions varying from hyperemia to necrosis and infiltration of the submucosa with inflammatory cells. Often, there is edema and hemorrhage in the various layers of the intestinal wall.

Varying degrees of abdominal pain, ranging from mild to severe, are characteristic. When the prevalence of the condition peaked in the 1980s, it was characterized by voluminous amounts of gastric reflux, progression from pain to depression, and moderate to severe distention of the small intestine on rectal examination. In addition, the distended duodenum often was palpated as it coursed around the base of the cecum. The peritoneal fluid often contained an increased concentration of protein (>3 g/dL) with a normal number of WBCs, but this finding did not consistently distinguish the condition from other causes of small-intestinal disease. Based on anecdotal reports, the prevalence and clinical severity of the condition have decreased, at least in regions of the USA where the condition characteristically had a more severe course and was accompanied by a high incidence of laminitis.

Treatment may be either medical or surgical. Medical treatment includes continued gastric decompression until the gastric reflux abates, IV fluids, and analgesics, as required. Many clinicians administer penicillin and low doses of flunixin meglumine; some also administer neostigmine, lidocaine, or metoclopramide to stimulate small-intestinal motility. Some surgeons, particularly in the UK, believe exploratory laparotomy and intestinal decompression result in a more rapid recovery. The survival rate associated with proximal enteritis–jejunitis is reported to

be 44%. The horse's feet should receive particular attention because acute laminitis has been reported as a common complication, with a prevalence of ~25%.

Intussusception: Most intussusceptions that develop in horses are jejuno-jejunal, ileal-ileal, or ileocecal. The length of intestine that has become invaginated (the intussusceptum) into the more distal segment of intestine (the intussusciens) may range from a few centimeters to as much as a meter. Although the precise cause of most intussusceptions remains speculative, alterations in peristalsis due to enteritis, surgical trauma, parasite damage, anthelmintics, and *Anoplocephala perfoliata* infection have been suggested. Horses <3 yr old are affected most commonly.

Abdominal pain may be either acute due to complete obstruction of the intestinal lumen or chronic due to partial occlusion of the lumen. If the occlusion of the intestinal lumen is complete, the horse is acutely painful and has gastric reflux, and distended loops of small intestine are palpable per rectum. It may be possible to palpate the turgid intussusception, especially if the ileum is involved. Because the strangulated intussusceptum is contained within the intussusciens, the WBC count in the peritoneal fluid may not reflect the degree of intestinal damage.

Treatment requires surgery to reduce the intussusception, if possible, followed by resection and anastomosis. Because of the edema and hemorrhage in the wall of the affected intestine, it may be difficult to assess the viability of the bowel. Additionally, the damage to the intussusceptum may result in the development of adhesions. If the jejunum is involved, a jejuno-jejunal anastomosis must be performed. If the intussusception involves only the ileum, the affected intestine must be resected and a jejuno-cecal anastomosis performed. If the ileum has invaginated into the cecum, the terminal portion of the ileum should be transected close to the cecum and a jejuno-cecal anastomosis performed. The prognosis for survival is good if surgery is performed before the intussusception has become irreducible. The prognosis is fair to poor in the latter case because of the development of peritonitis, ileus, adhesions, and abscess formation.

Volvulus: A small-intestinal volvulus is seen when the intestine rotates on its mesenteric axis $>180^\circ$. As the degree of the rotation increases, the vascular supply to

the intestine is lost. Presumably because of its attachment to the cecum, the distal aspect of the volvulus is the ileum in most cases.

Horses with small-intestinal volvulus have acute pain and an increased heart rate, a prolonged capillary refill time, and gastric reflux. Because of the loss of fluid into the intestine and stomach, these horses rapidly become dehydrated and have increased PCV and plasma protein concentrations. The horse's status may deteriorate rapidly because of hypovolemia and endotoxemia. Rectal examination generally reveals turgid distended loops of small intestine, and the peritoneal fluid contains increased numbers of WBCs and protein.

Treatment involves surgical correction of the volvulus via a ventral midline celiotomy. If the intestine is nonviable, it must be resected and an anastomosis performed. The prognosis for survival depends on the duration of illness and amount of intestine that must be resected. Prognosis is good with early detection and surgery. Horses with a longer period of illness preoperatively, or those that develop postoperative ileus and peritonitis, are at increased risk of adhesion formation. It has been suggested that euthanasia is warranted if >50% of the length of the small intestine must be removed. However, results of an experimental study in ponies indicated that removal of 70% of the small intestine did not result in malabsorption provided the ponies were fed several (8) small pelleted meals each day.

Pedunculated Lipomas: Colic due to pedunculated lipomas is seen in horses >10 yr old. Pedunculated lipomas are suspended from the mesentery by a stalk or pedicle, which wraps around a segment of intestine, occluding the lumen of the intestine and interfering with its blood supply. The lipoma frequently forms a knot with the pedicle.

Clinical signs range from depression to severe abdominal pain, gastric reflux, and rapid deterioration in metabolic status. Distended loops of small intestine are palpable on rectal examination and can be identified with abdominal ultrasonography; the lipoma can be felt per rectum in rare cases. The peritoneal fluid contains an increased number of WBCs and RBCs and an increased protein content.

Treatment requires transection of the pedicle and, if necessary, resection of the devitalized intestine. The prognosis depends on the time between onset of clinical signs and surgery. If surgery is performed early, the prognosis is good; however, if surgery is not performed until

signs of cardiovascular deterioration are present, the prognosis for survival is fair to poor.

Internal Incarceration: The most common sites for internal incarcerations are mesenteric rents and the epiploic foramen. **Mesenteric rents** are defects in the small-intestinal mesentery. Problems develop when a segment of small intestine passes through the mesenteric defect, and the intestine becomes incarcerated. Because the intestine distends with fluid and blood, volvulus of the affected segment frequently occurs. Mesenteric rents causing intestinal incarceration occur in horses of all ages.

The **epiploic foramen** is a natural opening bounded by the caudate lobe of the liver, the portal vein, and the caudal vena cava. The distal jejunum and ileum are the most common portions of the intestine that become incarcerated through the epiploic foramen. Although generally the intestine passes through the epiploic foramen from left to right, tearing the omentum in the process, it also may pass in the opposite direction to enter the omental bursa. It has been reported that horses >7 yr old are affected most frequently by epiploic foramen entrapment. However, the condition also often develops in horses <7 yr old.

Clinical signs may be vague and similar to those of horses with proximal enteritis or pedunculated lipomas. The diagnosis may have to be made at surgery. Furthermore, in some cases, because of the position of the affected intestine within the omental bursa, the peritoneal fluid available for analysis may be normal.

Treatment of horses with either mesenteric rents or epiploic foramen entrapments is surgical. The affected segment of intestine must be exteriorized, its viability evaluated, and, if necessary, a

resection and anastomosis performed. The prognosis for survival depends on the time between onset and surgery. If surgery is performed early in the course of the disease, the prognosis is good. However, because the clinical signs may be vague, the decision to perform surgery may be delayed, worsening the prognosis.

Inguinal Hernia: Inguinal hernias generally develop in stallions after breeding a mare, trauma, or a hard workout. Hernias appear to be most common in Tennessee Walking Horses, American Saddlebreds, and Standardbreds. In most cases, the hernia results in acute colic. The intestine descends through the vaginal ring in most cases and lies next to the testis and epididymis. Physical examination reveals a swollen testis that is firm and cool to the touch. If the hernia has occurred within hours, the intestine may be palpated in the inguinal canal. In this situation, an attempt may be made to reduce the hernia by pulling down on the testis to tighten the boundaries of the inguinal canal and then forcing the intestine up toward the vaginal ring. Once the incarcerated intestine, which frequently includes the ileum, has become edematous, it is not possible to reduce the hernia manually. Rectal examination will reveal distended loops of small intestine, with one of the loops tracing to the vaginal ring on the affected side. There will be gastric reflux, and the horse's condition will deteriorate rapidly. Peritoneal fluid generally reflects the degree of ischemia.

Surgery involves a ventral midline celiotomy and inguinal approach to reduce

the hernia. Often, the testicle on the affected side must be removed, and the affected intestine resected. The prognosis for survival seems to be breed-dependent, with Standardbred horses having a good prognosis and Tennessee Walking Horses having a fair to poor prognosis. Presumably, this reflects the fact that many Tennessee Walking Horse stallions with inguinal hernias show little evidence of pain, which delays the decision for surgery.

Cecum and Large Intestine

Impaction: The most common sites of impaction are the pelvic flexure region of the left colon, the junction of the right dorsal colon with the transverse colon, and the base and body of the cecum. The pelvic flexure and transverse colon regions are anatomically predisposed to obstruction because of the dramatic changes in size. The underlying reason for impaction of the cecum is unknown, although it has been speculated that cecal muscular activity is abnormal in affected horses. Other predisposing factors include feed that is too coarse, diseased or poorly managed teeth, and insufficient water intake. In one clinical study, Morgan, Arabian, and Appaloosa breeds were overrepresented among horses with cecal impaction, and it has been proposed that the condition may develop secondary to infection with the tapeworm *Anoplocephala perfoliata*. Impactions also may develop secondary to other intestinal diseases and may be associated with prolonged hospitalization. Consequently, the fecal output of horses being treated for

Most common sites of impaction, cecum and large intestine, in a horse (larger dots indicate more frequent impaction at that site). Illustration by Dr. Gheorghe Constantinescu.

other abnormalities should be assessed on a routine basis. This is especially important in horses receiving NSAIDs on a daily basis.

Horses with simple impactions of the cecum or large colon exhibit mild intermittent signs of colic, and there is minimal evidence of systemic deterioration unless the impaction has a prolonged course. Generally, the heart rate is only slightly increased. Intestinal sounds are usually heard on auscultation of the abdomen and may be associated with the onset of pain as the affected portion of the intestine contracts against the obstruction. Diagnosis is made on rectal examination. Although the most common site of obstruction is considered to be the pelvic flexure region of the large colon, the impacted ingesta actually fills much or all of the left ventral colon. The impacted mass may be felt extending cranially in the abdomen, and the affected segment of bowel is identified by palpating the longitudinal bands on the surface of the ventral colon. Impaction of the cecum is relatively easy to identify, because the mass is situated in the right paralumbar region. The cecum can be definitively identified by palpating the taut ventral cecal band and the fat and blood vessels overlying the medial cecal band. Peritoneal fluid analysis may be normal, or the total protein concentration may be increased as the course becomes more prolonged.

Cecal impactions tend to cause colic in horses >8 yr old. Alternatively, impactions may be seen in horses hospitalized for other reasons and are often associated with abrupt rupture of the cecum in these cases. Consequently, there is some controversy regarding the best method of treatment. Because medical therapy in some clinical studies has been unsuccessful in 50% of the cases, surgical removal of the impacting mass followed by an ileocolostomy has been strongly recommended. Other veterinarians report good results with aggressive medical therapy, particularly if abdominal pain associated with the cecal impaction was the primary reason the horse required veterinary attention.

Medical treatment of horses with cecal or large-colon impaction involves the administration of analgesics as necessary, large volumes of balanced IV fluids, and intragastric administration of either mineral oil or dioctyl sodium sulfosuccinate and water. Feed should be restricted until the impaction is relieved. Many veterinarians consider aggressive fluid therapy to be the mainstay of treatment. Balanced electrolyte

solutions are administered to induce movement of fluid from the plasma into the lumen of the intestine. This form of treatment may require administration of >50 L of fluid/day to a 450-kg horse until the impaction is resolved. Interest has increased in using enteral fluid therapy to treat horses with impactions, primarily because enteral fluid therapy is significantly less expensive than IV fluid therapy. The clinical results with enteral fluid therapy have been rewarding, and the results of experimental work in healthy horses have shown that enteral fluid therapy is more effective than IV fluid therapy in promoting hydration of colonic contents.

If the large-colon impaction does not resolve with medical management, surgery can be performed. Generally, the impaction is approached via a ventral midline celiotomy, with the affected portion of the colon gently exteriorized and positioned on a sterile colon tray. An enterotomy then is made in the pelvic flexure and the contents of the colon removed.

Surgery for treatment of cecal impactions requires general anesthesia, a ventral midline celiotomy, isolation of the cecum from the celiotomy site, and removal of the contents of the cecum via an enterotomy. Because impactions have recurred after simple evacuation, some surgeons prefer to bypass the cecum with an ileocolostomy.

The prognosis associated with impactions involving the large colon is excellent, with a survival rate of >95%. The survival rate associated with cecal impactions is ~80% for those horses that can be treated medically and 60%–70% for those horses requiring surgical intervention.

In some geographic areas, the offending material may be sand, especially if the amount of pasture grass is insufficient and the horses are fed on the ground. The sand accumulates in the right dorsal colon and transverse colon. Intermittent signs of abdominal pain may occur because of the weight of the sand in the intestine. More severe signs of pain occur when the impaction occludes the lumen of the transverse colon. Under such circumstances, the colon proximal to the obstruction distends with gas, resulting in extreme pain. It may not be possible to distinguish this condition from an intestinal displacement or volvulus. Sand also may be identified in the feces by mixing fecal material with water in a plastic rectal examination sleeve.

Treatment of sand impaction may be either medical or surgical. Medical

treatment generally involves intragastric administration of psyllium (400 g/500 kg body wt, daily for 7 days) to purge the sand from the lumen. The psyllium flakes are added to 7.5 L of warm water and rapidly pumped into the stomach. These treatments are accompanied by analgesics as needed and IV fluids to promote movement of fluid into the intestinal lumen.

Surgery via a ventral midline celiotomy is necessary if the sand completely obstructs the lumen of the transverse colon. The left colon is exteriorized on a sterile colon tray, and the sand is removed via an enterotomy. The prognosis is usually good. Problems sometimes develop during surgery if the colon was damaged due to the extensive weight of the sand or while the sand is being removed from the intestine (*see p 287*).

Enterolithiasis: Enteroliths are concretions composed of magnesium ammonium phosphate crystals around a nidus (eg, wire, stone, nail). Enteroliths may be seen singly or in groups and are commonly found in horses in certain parts of the USA, including California, the southwest, Indiana, and Florida. Enterolithiasis commonly affects Arabian horses, but the fact that these horses are extremely popular in the aforementioned areas confounds the question regarding breed association. Most horses with enteroliths are ~10 yr old; enterolithiasis rarely is seen in horses <4 yr old. Although not all factors that contribute to the formation of enteroliths have been identified, results of clinical studies indicate that large-colon contents from horses with enteroliths have higher mineral (magnesium, calcium, and phosphorus) concentrations and pH than contents from horses with colic not due to enteroliths. A common factor associated with enterolithiasis is the consumption of alfalfa hay, which results in a higher pH and increased concentrations of calcium, magnesium, and sulfur in the large colon.

Many horses with enterolithiasis have a history of recurring colic, presumably indicating that the enterolith(s) had caused partial or temporary obstruction of the colonic lumen. If the enterolith becomes lodged at the origin of the transverse colon, the colon proximal to the obstruction distends with gas and the pain is severe. Distention of the abdomen may be marked. Heart and respiratory rates are increased, and the mucous membranes may be pale or pink. Generally, colonic

and cecal distention is evident on rectal examination, but the mass rarely is palpable because the transverse colon is cranial to the cranial mesenteric artery. Analysis of the peritoneal fluid is usually within normal limits unless ischemia of the colonic wall has developed over the enterolith. In areas where the problem is endemic, radiography may be used to identify the enteroliths.

Treatment involves surgery via a ventral midline celiotomy to decompress the colon and cecum and then to remove the stone(s). The left portion of the large colon is exteriorized and positioned on a sterile colon tray, the ingesta removed via an enterotomy, and then the enterolith(s) removed. If the stone has a flat side or a polyhedral shape, this is indicative of the presence of one or more additional enteroliths. Consequently, the rest of the large and small colons must be thoroughly checked for other stones. The prognosis is excellent, with practices in endemic areas reporting survival rates of 95%.

Left Dorsal Displacement: Left dorsal displacement of the colon is seen when either the pelvic flexure or the entire left colon becomes displaced over the renosplenic ligament. Because the renosplenic ligament is not attached to the most dorsal aspect of the spleen, a natural cleft exists between the spleen and left kidney. Although all ages and sexes of horses are affected equally, results of a clinical study indicate that the displacement is common in young horses.

Because left dorsal displacement results in simple obstruction of the colon at the point where it hangs across the ligament, the condition usually is associated with moderate abdominal pain or a prolonged course of intermittent painful episodes. The mucous membranes remain normal, and the heart rate is increased only slightly. The diagnosis usually is made on rectal examination (palpating the pelvic flexure over the ligament, palpating the bands of the left ventral colon running dorsocranially to the left kidney, and detecting that the spleen is displaced toward the middle of the abdomen). The condition also may be identified using ultrasonography. A paracentesis may yield blood if the spleen is displaced toward the midline.

Four forms of treatment have been used: 1) withholding feed to determine whether evacuation of the intestinal contents will allow the colon to return to its normal position, 2) rolling the horse to dislodge the

colon from the ligament, 3) administering phenylephrine and/or jogging the horse to cause splenic contraction and correction of the displacement, or 4) performing surgery to return the colon to its correct position. The rolling procedure involves short-term anesthesia (generally xylazine or detomidine and ketamine), elevation of the horse's hindlimbs, and rolling the horse 360°. Surgery is performed via a ventral midline celiotomy. The advantage of surgery is that the viability of the colon can be assessed. Phenylephrine should not be administered to horses >15 yr old because of the increased risk of fatal hemorrhage in aged horses given this drug. If left dorsal displacement of the colon recurs, the renosplenic space may be sutured closed laparoscopically. Overall, the prognosis is good, with most studies reporting survival rates >80%.

Right Dorsal Displacement: The left colons move laterally around the base of the cecum to lie between the cecum and the right body wall. With the most common form of this displacement, the pelvic flexure ends up positioned near the diaphragm. In many instances, the displacement may be complicated by twisting of the colon near the base of the cecum. Although there may be some interference with venous drainage from the affected colon, usually the arterial supply remains intact.

Most horses with right dorsal displacements exhibit moderate degrees of pain, and there is slow development of systemic deterioration. In some cases, however, the pain may be severe. Rectal examination may reveal the taenia of the colon running transversely across the pelvic inlet. It may not be possible to palpate the ventral cecal band on rectal examination. Some horses with this condition have gastric reflux, presumably due to occlusion of the lumen of the duodenum.

Some horses with this condition appear to be stable and may show intermittent signs consistent with mild abdominal pain. Treatment may be conservative, involving attention to fluid needs and administration of mild analgesics. For painful horses, however, surgery must be performed to locate the pelvic flexure, to exteriorize and decompress the left portion of the colon, if possible, and then to relocate the colon to its normal position by rotating it around the cecal base. The twisting of the colon must be identified and corrected. The prognosis for survival is good, provided that the colonic wall is not damaged during surgery.

Right Dorsal Colitis: Right dorsal colitis has been recognized with increasing regularity in recent years, particularly in, but not limited to, horses receiving excessive amounts of NSAIDs. Because the condition has been identified in horses receiving recommended doses of these drugs, it appears that some horses are particularly sensitive to their toxic effects. The drug most commonly associated with right dorsal colitis is phenylbutazone, but this may reflect the common and often chronic use of this drug. The most common lesions reported in horses with right dorsal colitis are ulceration and thickening and/or fibrosis of the wall of the right dorsal colon.

Horses commonly present with abdominal pain, anorexia, and lethargy. In many cases, the signs are consistent with severe abdominal pain, fever, endotoxemia, and diarrhea. Horses with the more chronic form of the disease present with intermittent abdominal pain, weight loss, lethargy, and anorexia. In most cases, hypoproteinaemia is a common finding on hematology and may account for ventral edema in some horses with the chronic form of the disease. The diagnosis is usually based on the history, clinical signs, and hematologic findings. In some cases, ultrasonographic evaluation of the colon via the twelfth to fifteenth intercostal spaces may provide evidence of marked thickening of the colonic wall.

Treatment of affected horses includes discontinuation of NSAIDs, rest, and a change in diet to a complete pelleted feed that contains ≥30% dietary fiber. Some clinicians recommend the feeding of many small meals daily, many recommend the inclusion of psyllium to promote mucosal healing, and some administer sucralfate or metronidazole. Horses with uncontrollable pain may require surgery to resect or bypass the affected portion of the right dorsal colon. The prognosis for horses with right dorsal colitis is guarded.

Volvulus of the Large Colon: Although the term "torsion" has been used for years to indicate that the colon has twisted on itself, the involvement of the mesentery between the ventral and dorsal colons indicates that the condition is a volvulus. When viewed from the most common site of the volvulus (the junction between the right ventral colon and the cecum), the volvulus most often occurs in a clockwise direction; the cecum may or may not be involved. If the volvulus is <270°, there may be obstruction of the bowel lumen without ischemia. If the volvulus is >360°, there is

strangulating obstruction of the entire left colon.

The onset of colic is sudden, and the degree of pain may be mild to moderate if the volvulus results only in obstruction of the intestinal lumen. When the twist is more extensive, the pain is severe and the horse may not respond to analgesics. The colon is extremely enlarged, and the mesentery between the dorsal and ventral colons is edematous on rectal examination. The heart rate is rapid, the horse's condition deteriorates rapidly, and there is poor peripheral perfusion. Distention of the abdomen usually is marked. Generally, results of peritoneal fluid analysis and the degree of colonic involvement are poorly correlated.

Although the cause of colonic volvulus remains unknown, it is presumed to be associated with a disproportionate amount of gas in the colon. On broodmare farms, the condition frequently is associated with recent (within 90 days) or impending parturition, a grass diet, or highly fermentable feeds. The presence of a foal at the mare's side (recent history of parturition) is an additional risk factor.

Treatment of colonic volvulus requires surgery to correct the volvulus and remove affected bowel, if necessary. Although the technique for removal of 90% of the colon has been perfected in healthy horses, extreme difficulty can be encountered if the colon is edematous. Because the recurrence rate has been estimated to be as high as 20% in some clinical studies, colopexy procedures have been devised to reduce the recurrence of the condition in broodmares. Although the results of a study involving several university hospitals reported a 27% survival rate, survival rates >85% are common for practices situated near broodmare farms.

Impaction and Foreign Body Obstruction of the Descending Colon:

Abnormalities involving the descending (small) colon are infrequent, accounting for <5% of conditions characterized by colic in one study. The more common causes include meconium retention, impaction, and foreign body obstruction. Meconium retention is seen in newborn male foals within the first 24 hr of life. Affected foals swish their tails from side to side, strain to defecate, and roll. The diagnosis is made by careful digital examination. Treatment involves gentle administration of a warm, soapy water enema. The prognosis is excellent.

Impaction of the descending colon is seen in ponies, miniature horses, and adult horses with limited access to drinking water or with other causes of intestinal stasis. Most recently, the condition has been associated with salmonellosis, although a cause and effect relationship has not been proved. Pain may be severe if the obstruction is complete. In such cases, tympany of the colon occurs secondarily, and ileus results. The diagnosis is made in adult horses by palpating the obstructing mass in the ventral portion of the abdomen on rectal examination. Foreign body obstruction of the descending colon must be considered if the horse is <3 yr old; the offending material may be rubber fencing, nylon fibers from halters or lead shanks, hay net, or feed sacks. Horses with impactions may be treated medically with analgesics, IV fluids, and gentle enemas. Often, however, surgery is required to evacuate the colon due to severity of pain and gas distention. The prognosis associated with impaction of the descending colon is fair, unless it is complicated by severe colitis after the obstruction has been removed. The prognosis associated with foreign body obstruction is good.

INTESTINAL DISEASES IN RUMINANTS

INTESTINAL DISEASES IN CATTLE

Determination of the cause of intestinal disease in cattle is based on clinical, epidemiologic, and laboratory findings. Nonspecific therapy includes oral and parenteral fluid therapy to restore

the fluid, electrolyte, and acid-base homeostasis. Specific therapy and prevention are detailed under the individual disease headings. Intestinal diseases of neonates are discussed separately, although some of the causes also affect older animals.

Bovine Viral Diarrhea and Mucosal Disease Complex

Bovine viral diarrhea (BVD) is most common in young cattle (6–24 mo old). The clinical presentation can range from inapparent or subclinical infection to acute and severe enteric disease to the highly fatal mucosal disease complex characterized by profuse enteritis in association with typical mucosal lesions. BVD must be distinguished from other viral diseases that produce diarrhea and mucosal lesions. These include malignant catarrhal fever (see p 758), which usually is a sporadic disease in more mature cattle, bluetongue (see p 738), and rinderpest (see p 771), which is currently considered to be eradicated worldwide.

Bovine viral diarrhea virus (BVDV), the causal agent of BVD and mucosal disease complex, is classified in the genus *Pestivirus* in the family *Flaviviridae*. Although cattle are the primary host for BVDV, several reports suggest most even-toed ungulates are also susceptible. Classically, isolates of BVDV are separated into noncytopathic and cytopathic biotypes based on their ability or lack of ability to cause overt cytopathic change and cell death in cell cultures. Noncytopathic BVDV is the predominant viral biotype in nature, whereas cytopathic BVDV is relatively rare and of little epidemiologic relevance. The cytopathic biotype arises in cattle that are persistently infected with noncytopathic biotype of the same or a genetically similar BVDV strain. The switch in biotype is the result of mutations that often involve recombination of noncytopathic viral RNA with itself, with heterologous viral RNA, or with host cell RNA.

Based on comparisons of nucleotide sequence in the viral RNA, there are at least two viral genotypes (distinct genetic groups) of BVDV that can be further divided into subgenotypes or genogroups. The viral genotypes are termed BVDV type 1 and BVDV type 2, and both cytopathic and noncytopathic BVDV are represented in each viral genotype. In recent years, a new group of atypical pestiviruses, apparently forming a separate species, of which cattle are the most likely host species, have been recognized. Virus of this third *Pestivirus* genotype are designated as “HoBi”-like pestiviruses. The subgenotypes are clusters of viruses within a viral genotype that are highly similar in nucleotide sequence of the viral RNA. (Subgenotypes are designated by lower case letters; thus, subgenotypes of BVDV

genotype 1 are represented as 1a, 1b, 1c, etc.). Currently, at least 12 subgenotypes for BVDV-1 (BVDV-1a to BVDV-1l) and two subgenotypes for BVDV-2 (BVDV-2a and BVDV-2b) are recognized.

BVDV type 1 and type 2 appear to be distributed worldwide; however, the prevalence of each type of virus varies considerably among regions. The distribution of viral subgenotypes is more restricted, with many viral subgenotypes being found only in certain regions of the world and, in some cases, only certain regions of a country. All BVDV, regardless of genotype or subgenotype, are antigenically related. However, serologic assays that use serum obtained from convalescent cattle can distinguish BVDV type 1 from type 2. The extent of antigenic variation among BVDV of different genotypes and subgenotypes remains unknown, but there is concern that the antigenic differences among BVDV may be sufficient to affect protection conferred by vaccination.

Etiology and Epidemiology: Serologic surveys conducted throughout the world suggest that BVDV is endemic in the cattle population of most cattle-producing countries. In some countries, BVD is considered the single most important viral infection of cattle. The prevalence of antiviral antibody in cattle varies greatly among countries and geographic regions because of differing cattle housing practices, population densities, vaccination practices, and implementation of different control or eradication programs. Prevalence of antiviral antibody may be >90% if vaccination is practiced commonly in a geographic region. Although cattle of all ages are susceptible, most cases of overt clinical disease are seen in cattle between 6 mo and 2 yr old.

Cattle persistently infected with noncytopathic BVDV serve as a natural reservoir for virus. Persistent infection develops when noncytopathic BVDV is transmitted transplacentally during the first 4 mo of fetal development. The calf is born infected with virus, remains infected for life, and usually is immunotolerant to the resident noncytopathic virus. Transplacental infection that occurs later in gestation can result in abortion, congenital malformations, or birth of healthy calves that have antibody against BVDV. The prevalence of persistent infection varies among countries and between regions within a country. The estimated mean animal prevalence of persistent infection with BVDV is

~1%–2% but may approach 4% on dairy farms with endemic BVDV infection. On a given farm, persistently infected cattle are often found in cohorts of animals that are approximately the same age. Persistently infected cattle can shed large amounts of BVDV in their secretions and excretions and readily transmit virus to susceptible herdmates. Clinical disease and reproductive failure often are seen after healthy cattle come in contact with a persistently infected animal. Although persistently infected cattle are important in transmission of BVDV, the virus also may be spread by biting insects, fomites, semen, biologic products, and other animals, including swine, sheep, goats, camelids, and possibly wild ruminants.

Clinical Findings and Lesions: Disease induced by BVDV varies in severity, duration, and organ systems involved. Infection of immunocompetent susceptible animals with either noncytopathic or cytopathic BVDV is termed acute or transient BVD. Inapparent or subclinical infection without any clinical signs that is followed by seroconversion is the most common form of infection in the field. Acute clinical disease may range from mild disease of high morbidity and low mortality to severe enteric disease with considerable mortality. Biphasic fever (~104°F [40°C]), depression, decreased milk production, transient inappetence, rapid respiration, excessive nasal secretion, excessive lacrimation, and diarrhea are typical signs of acute clinical BVD. Clinical signs of disease usually are seen 6–12 days after infection and last 1–3 days. Transient leukopenia may be seen with onset of signs of disease. Recovery is rapid and coincides with production of viral neutralizing antibody. Gross lesions seldom are seen in cases of mild disease. Lymphoid tissue is a primary target for replication of BVDV, which may lead to immunosuppression and enhanced severity of intercurrent infections.

Some isolates of BVDV (BVD type 2) have been associated with severe clinical disease that manifests as high fever (~107°F [41°–42°C]), oral ulcerations, eruptive lesions of the coronary band and interdigital cleft, diarrhea, dehydration, leukopenia, and thrombocytopenia. In thrombocytopenic cattle, petechial hemorrhages may be seen in the conjunctiva, sclera, nictitating membrane of the eyes, and on mucosal surfaces of the mouth and vulva. Prolonged bleeding from injection sites also occurs. Swollen lymph nodes, erosions and

ulcerations of the GI tract, petechial and ecchymotic hemorrhages on the serosal surfaces of the viscera, and extensive lymphoid depletion are associated with severe forms of acute BVD. The duration of overt disease may be 3–7 days. High morbidity with a mortality of ≥25% is common. Severity of acute BVD is related to the virulence of the viral strain infecting the animal and does not depend on viral biotype.

In pregnant cattle, BVDV may cross the placental barrier and infect the fetus. The consequences of fetal infection usually are seen several weeks to months after infection of the dam and depend on the stage of fetal development and on the strain of BVDV. Infection of the dam near the time of fertilization may result in reduced conception rates. Infection during the first 4 mo of fetal development may lead to embryonic resorption, abortion, growth retardation, or persistent infection. Congenital malformations of the eye and CNS result from fetal infections that occur between months 4–6 of development. Fetal mummification, premature birth, stillbirth, and birth of weak calves also are seen after fetal infection.

Persistent infection is an important sequela of fetal infection with noncytopathic BVDV. Persistently infected calves may appear healthy and normal in size, or they may show stunted growth and be prone to respiratory or enteric ailments. They often have a short life span, and death before 2 yr of age is common. Persistently infected cows always give birth to persistently infected calves, but most calves sired by a persistently infected bull will not be infected with virus in utero. Lesions attributable to BVDV often are not seen in persistently infected cattle at necropsy. Antibody against BVDV seldom is detected in persistently infected cattle in the absence of vaccination or superinfection with an antigenically heterologous BVDV. Persistently infected cattle exposed to BVDV that is antigenically different from their resident noncytopathic virus can produce antiviral antibody. Therefore, screening for persistent infection using serologic tests to identify animals that lack antiviral antibody may not detect some persistently infected cattle.

Mucosal disease is an uncommon but highly fatal form of BVD occurring in persistently infected cattle and can have an acute or chronic presentation. Mucosal disease is induced when persistently infected cattle become superinfected with cytopathic BVDV. The origin of the

cytopathic BVDV is usually internal, resulting from a mutation of the resident persistent, noncytopathic BVDV. In those cases, the cytopathic virus is antigenically similar to the resident noncytopathic virus. External origins for cytopathic BVDV include other cattle and modified-live virus vaccines. Cattle that develop mucosal disease due to exposure to a cytopathic virus of external origin often produce antiviral antibody. Prevalence of persistent infection usually is low, and many persistently infected cattle do not develop mucosal disease, regardless of exposure. Acute mucosal disease is characterized by fever, leukopenia, dysenteric diarrhea, inappetence, dehydration, erosive lesions of the nares and mouth, and death within a few days of onset. At necropsy, erosions and ulcerations may be found throughout the GI tract. The mucosa over Peyer's patches may be hemorrhagic and necrotic. Extensive necrosis of lymphoid tissues, especially gut-associated lymphoid tissue, is seen on microscopic examination.

Clinical signs of chronic mucosal disease may last several weeks to months and are less severe than those of acute mucosal disease. Intermittent diarrhea and gradual wasting are common. Coronitis and eruptive lesions on the skin of the interdigital cleft cause lameness in some cattle. Lesions found at necropsy are less pronounced than, but similar to, those seen in acute mucosal disease. Often, the only gross lesions seen are focal ulcerations in the mucosa of the cecum, proximal colon, or rectum, and the mucosa over Peyer's patches of the small intestine may appear sunken.

Diagnosis: BVD is diagnosed tentatively from disease history, clinical signs, and gross and microscopic lesions. Diagnostic laboratory support is required when clinical signs and gross lesions are minimal. Laboratory support also is required in some outbreaks of mucosal disease or clinically severe acute BVD, because either disease may appear similar to rinderpest (*see* p 771) or malignant catarrhal fever (*see* p 758).

Laboratory tests for BVDV include isolation of virus or viral antigen in clinical specimens and tissues, and assays that detect anti-BVDV antibody in serum or milk. Because antibody against BVDV can be highly prevalent in regions with high infection prevalence and/or common use of BVD vaccines, a single serologic test is seldom sufficient for diagnosis of recent infection. A >4-fold increase in antibody titer in paired serum samples obtained ≥ 2 wk

apart is necessary to verify recent infection. Isolation of BVDV from blood, nasal swab specimens, or tissues confirms active infection. Identification of persistent infection requires detection of virus in clinical specimens obtained at least 3 wk apart. Colostral antibody can impair the sensitivity of virus isolation in blood during the first weeks of life. At necropsy, tissues of choice for viral isolation include spleen, lymph node, and ulcerated segments of the GI tract.

Alternatives to viral isolation include antigen-capture ELISA to detect virus in blood, serum, or tissue biopsies; immunohistochemistry to detect viral protein in frozen or fixed tissues; PCR to detect viral RNA in clinical specimens; and PCR or *in situ* hybridization to detect viral RNA in fresh or fixed tissues. Differentiation of viral genotypes and subgenotypes may be accomplished by PCR assays alone, or by PCR assays followed by analysis of nucleotide sequence, restriction fragment analysis, or palindromic nucleotide substitution analysis. Monoclonal antibody binding assays and viral neutralization assays also differentiate viral genotypes.

Treatment and Control: Treatment of BVD remains limited primarily to supportive therapy. Control is based on sound management practices that include use of biosecurity measures, elimination of persistently infected cattle, and vaccination. Replacement cattle should be tested for persistent infection before entry into the herd. Quarantine or physical separation of replacement cattle from the resident herd for 2–4 wk should be considered, and vaccination of replacement cattle for BVD should be done before commingling with the resident herd. Embryo donors and recipients also should be tested for persistent infection. If vaccination of embryo donors or recipients is warranted, it should be done at least one estrous cycle before embryo transfer is performed. Because BVDV is shed into semen, breeding bulls should be tested for persistent infection before use. Artificial insemination should be done only with semen obtained from bulls free of persistent infection.

Screening cattle herds for persistent infection can be done by PCR assays using skin biopsies, blood, or milk; by classical virus isolation methods using serum or buffy coat cells; by antigen-capture ELISA using serum, buffy coat, milk, or skin biopsies; or by antigen detection using

immunochemical methods on tissue or skin biopsies. Several strategies, based on herd size, type of herd being screened, financial limitations of the herd owner, and testing ability of the diagnostic laboratory being used, are available to screen herds for persistent infection. When identified, persistently infected cattle should be removed from the herd as soon as possible, and direct or indirect contact with pregnant cattle should be prevented.

Inactivated and modified-live virus vaccines are available. They contain a variety of strains of BVDV representing both viral biotypes and viral genotypes 1 and 2. Antigenic diversity among BVDV may affect the efficacy of a given vaccine if the vaccine virus or viruses differ significantly from the challenge virus. Proper and safe immunization of cattle with either inactivated or modified-live virus vaccines requires adherence to the manufacturer's instructions. Because BVDV is fetotropic and immunosuppressive, use of modified-live virus vaccines is not recommended in cattle that are pregnant or showing signs of disease. Inactivated viral vaccines may be used in pregnant cattle. Protection conferred by inactivated vaccines may be of short duration, and frequent vaccination may be necessary to prevent disease or reproductive failure. Colostral antibody confers partial to complete protection against disease in most calves for 3–6 mo after birth. Vaccination of neonatal cattle that have acquired colostral antibody may not stimulate a protective immune response, and revaccination at 5–9 mo of age may be necessary. A booster dose of vaccine is often administered before first breeding, and additional booster doses of vaccine may be administered in subsequent years before breeding.

Jejunal Hemorrhage Syndrome

(Hemorrhagic bowel syndrome of cattle)

Jejunal hemorrhage syndrome is a sporadic disease of uncertain etiology that is observed with increasing frequency in cattle. It is manifest by sudden onset of abdominal pain, progressing to sternal recumbency, shock, and death.

Etiology and Pathogenesis: The etiology of jejunal hemorrhage syndrome is uncertain but is believed to be multifactorial. *Clostridium perfringens* type A, a normal inhabitant of the bovine digestive tract, has been incriminated as an important

causative agent, because this organism is isolated from the intestines of naturally occurring cases at a higher frequency and in higher numbers than from cattle with other intestinal diseases. Another proposed potential causative agent is *Aspergillus fumigatus*, a common fungus in feed and forages. The primary lesion is similar to that caused by *C. perfringens* in young, rapidly growing animals and consists of an acute, localized, necrotizing, hemorrhagic enteritis of the small intestine that leads to development of an intraluminal blood clot. The clot causes a physical obstruction, with proximal accumulation of intestinal fluid and gas and development of hypochloremia, hypokalemia, dehydration, and varying degrees of anemia. The hemorrhagic enteritis is progressive. Ischemia and necrosis extends through the intestinal wall, and within 24–48 hr, there is a fibrinous peritonitis, continued electrolyte imbalance, profound toxemia, and death.

Epidemiology: Jejunal hemorrhage syndrome occurs sporadically, primarily in mature lactating dairy cows in North America and Europe, but it has also been recorded in beef cattle. Most cases occur in mature dairy cattle in the first 3 mo of lactation, with highest incidence rates during the cold months of the year. Possible risk factors for disease are those associated with management practices aimed at achieving high milk production, such as high fermentable carbohydrate content of the diet and feeding a total mixed ration. The animal-level disease incidence rate is estimated to be 1%–2%, but outbreaks in a herd can be associated with morbidity rates of ≥10%. Mortality in general is high, with 80%–100% of affected animals dying within 48 hr.

Clinical Findings: Cattle affected by jejunal hemorrhage syndrome have a history of sudden anorexia and depression, a pronounced reduction in milk production, abdominal distention and pain with kicking at the abdomen, and weakness progressing to recumbency. Clinical findings include depression, dehydration, increased heart and respiratory rates, and pale mucous membranes. The abdomen may be moderately distended on the right side, the rumen is atonic, and fluid sounds may be elicited by succussion over the right abdomen. Dark red blood clots may be found in the feces and rectum. Distended and firm loops of intestine may be palpable on deep rectal examination. On laparotomy, a segment of the small intestine is dark red and distended, with a serosal

surface covered by tags of fibrin. The small intestine proximal to the affected segment and the abomasum are distended with gas and fluid. Ultrasonography may aid in diagnosis.

Most affected cattle die within 2–4 days despite intensive fluid and electrolyte therapy. Sudden death without prior clinical findings may occur. The hemogram is variable; serum biochemistry reflects obstruction of the upper small intestine and sequestration of abomasal secretions with resultant hypokalemia and hypochloremia.

Lesions: Necrohemorrhagic jejunitis with intraluminal hemorrhage is severe. The affected segment of intestine is dark red and dilated, with tags of fibrin on the serosal surface. The lumen contains a firm blood clot adherent to the mucosa, and the affected segment of intestine is necrotic.

Diagnosis: Diagnosis of jejunal hemorrhage syndrome can be made either during an exploratory laparotomy or at necropsy and is based on the presence of a characteristic focal necrohemorrhagic enteritis of the distal small intestine. Differential diagnoses include other causes of physical or functional obstruction of the small intestine such as intussusception (see p 245), cecal dilatation and volvulus, and diffuse peritonitis (see p 670), from right-sided torsion of the abomasum (see p 238) and torsion at the root of the mesentery, and from diseases with melena such as abomasal ulcer (see p 241).

Treatment and Control: Fluid and electrolyte therapy and laparotomy with massage of affected bowel loops to break down obstructing blood clots and, in advanced stages, resection of the affected segment of the intestine are treatment options for jejunal hemorrhage syndrome. Even with such treatment, the fatality rate is very high, and the prognosis is grave. No preventive strategies have been identified. A short-term protective effect of a *C. perfringens* type C and D vaccine against hemorrhagic bowel syndrome in some herds has been reported anecdotally, but there is currently no corroborating scientific evidence.

Winter Dysentery

Winter dysentery is an acute, highly contagious GI disorder that affects housed adult dairy cattle, primarily during winter. Clinical features include explosive diarrhea

(sometimes accompanied by dysentery), a profound drop in milk production, variable anorexia and depression, and mild respiratory signs such as coughing. The disease has a high morbidity but low mortality, and spontaneous recovery within a few days is typical.

Etiology: Although the precise etiology of winter dysentery has not been conclusively confirmed, an increasing body of evidence implicates a bovine coronavirus (BCoV), closely related to the virus that causes diarrhea in neonatal calves. Evidence for BCoV as the cause of winter dysentery includes the following: 1) clinical signs and pathologic findings are consistent with disease induced by BCoV, 2) seroconversion to BCoV has been demonstrated in affected cattle, 3) the virus is frequently isolated from diarrheic feces of cattle that exhibit clinical signs of winter dysentery, and 4) the disease has been reproduced by briefly exposing BCoV seronegative, lactating cows to a calf experimentally infected with feces from cows with winter dysentery. Notwithstanding, it has not been possible to consistently reproduce winter dysentery through oral inoculation of adult cattle with BCoV. Concurrent risk factors, such as changes in diet, cold temperatures, closed confinement with high animal density, poor ventilation, and presence of other microorganisms, may be required before BCoV causes clinical disease in adult cattle.

Transmission, Epidemiology, and Pathogenesis:

BCoV is transmitted via the fecal-oral route through ingestion of feed or water contaminated with feces from clinical cases or clinically healthy carrier animals. Viral particles present in respiratory secretions of affected animals may further enhance transmission. Transmission of disease is promoted by close confinement. Winter dysentery is highly contagious and easily introduced to barns by visitors, carrier animals, and fomites. Winter dysentery is common in northern climates where animals are housed indoors for extended periods during the winter months. It is seen frequently in the northern USA, Canada, the UK, Europe, Australia, New Zealand, Israel, and Japan. Coronaviruses survive best at low temperatures and at low ultraviolet light intensities, which can lead to a buildup of virus in the environment during the colder months. Adult lactating cows that have recently calved are most severely affected, but the disease can affect younger or older animals and males. Mortality rates associated with winter

dysentery are generally low (1%–2%), but morbidity in affected herds is high, with 20%–50% of the animals in a herd exhibiting clinical signs within a few days, and close to 100% of animals in the herd exhibiting signs within a week. Some degree of immunity to winter dysentery appears to develop, because recurrences, if seen in the same herd, are noted at 1- to 5-yr intervals.

Inflammatory mediators that cause hypersecretion in the small intestine and colon are thought to contribute to the voluminous diarrhea seen in cattle with winter dysentery. In addition, destruction of epithelial cells in the colonic crypts results in transudation of extracellular fluid and blood, explaining the hemorrhagic nature of the diarrhea in some cases.

Clinical Findings: Winter dysentery is characterized clinically by an acute onset of fluid diarrhea and a profound decrease in milk production (25%–95% production loss). Feces are liquid and homogenous with little odor, dark green to black, and may contain blood (typically in first-lactation heifers) or mucus. A sweet, musty, unpleasant odor is reported in barns with large numbers of affected cattle. Nasolacrimal discharge or cough may accompany or precede the diarrhea. Other signs include mild colic, dehydration, depression, a brief period of anorexia, and some decrease in body condition. Occasionally, animals exhibit more severe signs such as passage of feces with variable amounts of blood, severe dehydration, and weakness. Fatalities are rare. Diarrhea in individual animals has a short course, and feces return to normal in 2–3 days in most animals. Disease in the herd typically subsides in 1–2 wk, but milk production may take weeks to months to return to normal.

Lesions: The small intestine may be dilated and flaccid. Lesions are primarily seen in the large intestine and consist of cecal and colonic mucosal hyperemia, linear streaks or pinpoint-sized hemorrhages mostly along the colonic mucosal ridges, and blood in the lumen of the large intestine. Histologic findings may include widespread degeneration and necrosis of colonic glandular epithelium.

Diagnosis: A diagnosis of winter dysentery can be confirmed by demonstrating coronaviral particles in fecal samples via ELISA or electron microscopy. Seroconversion to coronavirus in acute and convalescent serum samples, taken 8 wk apart, also helps confirm the diagnosis.

Differential diagnoses for acute diarrhea in adult cattle include bovine viral diarrhea (BVD), enteric salmonellosis, and coccidiosis. These diseases can be excluded by absence of mucosal lesions (BVD), negative fecal cultures (*Salmonella* spp), and negative fecal flotation (coccidiosis), as well as by the characteristic clinical presentation of winter dysentery (rapid onset of diarrheal disease of short duration in a herd with high morbidity but low mortality).

Treatment and Control: Most cattle affected by winter dysentery recover spontaneously. Fresh water, palatable feed, and free-choice salt should be available at all times. The use of astringents, protectants, and adsorbents is controversial. IV fluid therapy or blood transfusions may be required in severely affected cattle.

There is no vaccine for winter dysentery. Isolation of newly introduced cattle for 2 wk and isolation of any adult cow with diarrhea is advised to decrease the likelihood of disease introduction into a herd. In an outbreak, access to the premises should be restricted, and all persons in contact with affected cattle should ensure that their footwear and clothing are clean before leaving an affected farm.

Other Intestinal Diseases of Cattle

Infection with *Salmonella* spp (see p 195) can produce diarrhea in animals of all ages, especially those that are stressed, closely stocked, or exposed to a heavily contaminated feed or water supply. In older animals, the disease is manifest by dysentery and toxemia, and mortality can be significant.

Rotavirus and coronavirus occasionally cause outbreaks of diarrhea in suckling calves up to 2–3 mo old. The feces are voluminous and may contain mucus. Toxemia is not evident and mortality is negligible, but growth is decreased. (See also DIARRHEA IN NEONATAL RUMINANTS, p 275.)

Necrotic enteritis of unknown etiology is seen in beef cattle 5–12 wk old, commonly affecting several calves within the herd. There is sudden onset of fever, depression, and profuse diarrhea. The feces are initially dark green, contain blood, and frequently stain the perineum. Circular erosions may be present in the oral mucosa. A proportion of calves recover after a clinical course of 3–5 days. The clinical course is longer in fatal cases; animals have scant mucohemorrhagic feces that are passed with tenesmus and develop a severe nonregenerative leukopenia. A secondary fibrinous broncho-

pneumonia may develop. Mortality is high despite intensive antibiotic treatment. At necropsy, there is ulcerative necrosis of the terminal small intestine and the large intestine.

Coccidiosis (see p 205) usually is seen in calves >2 mo old but <1 yr old, especially in situations of heavy stocking density and overgrazing. It is characterized by dysentery and tenesmus and may be accompanied by nervous signs. Intestinal helminthiasis, particularly ostertagiosis (see p 308), is seen in cattle of the same age group. Type I ostertagiosis is seen in cattle on pasture, but Type II ostertagiosis may be seen in housed animals.

Explosive outbreaks of diarrhea in mature cattle are associated most commonly with winter dysentery (see p 271) but also with salmonellosis when there is heavy contamination of feed or water.

Chronic diarrhea and wasting often in combination with good appetite, occurring as a sporadic disease in adult cattle is typical for paratuberculosis (see p 762). Chronic diarrhea and wasting also occurring in younger animals may be caused by chronic salmonellosis and chronic BVD infection. Other possible causes of chronic diarrhea include congestive heart failure, uremia, and chronic peritonitis. Persistent diarrhea with unthriftiness, and occasionally wasting in yearling and mature cattle, can be associated with a secondary copper deficiency due to excess molybdenum in the pastures. Diarrhea may also accompany selenium-responsive ill-thrift syndromes in growing cattle.

Individual cases or outbreaks of diarrhea may be associated with dietary indiscretions. Diarrhea may follow cases of simple indigestion and is common in grain overload (see p 222). It also follows ingestion of toxic amounts of chemicals (eg, arsenic, copper, zinc, and molybdenum) or certain poisonous plants and mycotoxicoses; dipyrldyl and organophosphate poisoning can also cause diarrhea.

Cattle may also harbor organisms such as *Escherichia coli* O157:H7, *Yersinia enterocolitica*, and *Campylobacter jejuni* in the intestine; although these are rarely associated with clinical disease in cows, fecal contamination of milk may lead to outbreaks of gastroenteritis in people who consume unpasteurized milk or cheese products. Retail meat products can also be infected if there has been fecal contamination of the carcass at slaughter.

Intestinal adenocarcinoma, commonly seen in association with bovine enzootic hematuria, is believed to result from the

interaction of a carcinogen (ptaquiloside) in bracken fern (*Pteridium* spp, see p 3089) and papilloma virus.

Intestinal obstructions are seen sporadically (see p 245). Cecal dilatation and volvulus are seen predominantly in adult cattle in the postparturient period. Intussusception occurring at the distal jejunum or proximal ileum is the most common cause of complete obstruction in both adult cattle and calves. Ileoceccocolic, cecocolic, and colonic intussusceptions are seen less frequently in calves and not at all in adult cattle because of the greater strength of the ileocecal ligament and the presence of mesenteric fat, which stabilize this region of the bowel in older cattle. Intestinal volvulus and volvulus around the mesenteric root are seen sporadically at all ages. Rarely, intestinal obstruction is caused by incarceration and entrapment of the small intestine by persistent urachal or umbilical remnants, by obstruction of the small intestine or descending colon by phytoezoars and enteroliths, or by compression from fat necrosis or lipoma. Intestinal obstruction can also be caused by congenital disease (see p 168), most commonly by atresia coli (which is seen both sporadically and in clusters on a farm and may be caused by rectal palpation of the amniotic vesicle at 35 and 41 days of pregnancy) but also by atresia ani (which may be accompanied by urogenital defects and defects of the tail).

INTESTINAL DISEASES IN SHEEP AND GOATS

The causes and circumstances of diarrhea in neonatal lambs and kids are similar to those in newborn calves. Intensive lambing practices and shed-lambing increase the potential for disease and buildup of infectious agents and can be associated with serious outbreaks of diarrhea. The serotypes of enteropathogenic *Escherichia coli* that cause secretory diarrhea in calves also do so in lambs, and the approach to diagnosis, treatment, and control is similar. Similarly, rotavirus, coronavirus, and cryptosporidia (see p 209) also cause outbreaks of diarrhea in lambs. (See also DIARRHEA IN NEONATAL RUMINANTS, p 275.) Lamb dysentery caused by *Clostridium perfringens* type B (see p 609) is a distinct intestinal disease of lambs in the first week of life. It is seen principally in hill breeds of sheep in the UK and is characterized by sudden death or diarrhea, dysentery, and toxemia. In the USA, *C. perfringens* type C causes a similar

syndrome. Watery mouth or rattle belly (see below), a disease of uncertain etiology associated with failure of transfer of passive immunity, is seen predominantly in the UK. Coccidiosis (see p 206) and GI helminthiasis (see p 312), except for haemonchosis, are important causes of diarrhea in older nursing and weaned sheep. Terminal ileitis and villous atrophy, both of unknown etiology, are often present in the intestine of lambs culled because of poor growth.

GI helminthiasis is the most common cause of diarrhea in pastured sheep. Coccidiosis develops in association with overstocking or intensive indoor housing and poor sanitation. Salmonellosis (see p 195) can cause diarrhea in all ages; the circumstances in young lambs are similar to those in calves. It also can cause outbreaks of diarrhea late in pregnancy and is frequently accompanied by abortion. Salmonellosis is more common when sheep or goats are congregated intensively or stressed, particularly by shipping. *Yersinia pseudotuberculosis* and *Y enterocolitica* have both been associated with enterocolitis and diarrhea in young sheep at pasture that are debilitated from factors such as starvation and cold weather. Diarrhea may be present in bluetongue in sheep (see p 738) and is accompanied by typical mucosal lesions. In goats, diarrhea is often prominent in enterotoxemia associated with *C perfringens* type D (see p 610). This is not a feature of the clinical disease in sheep but may be present in flockmates of affected sheep. In feedlot sheep, diarrhea most commonly is associated with grain overload, salmonellosis, or coccidiosis.

Other intestinal diseases of adult sheep may manifest with diarrhea. Infection with *C perfringens* type C (struck, see p 609) manifests with abdominal pain, tenesmus, and rapid death. Intestinal obstruction due to intestinal accidents occurs sporadically but is usually not seen clinically. Sheep with paratuberculosis (see p 762) usually show progressive emaciation without diarrhea. Progressive emaciation also is the primary sign in adult sheep with intestinal adenocarcinoma, which can be prevalent in certain areas, associated with ingestion of bracken fern (see p 3089).

Watery Mouth Disease in Lambs

(Slavery mouth, Slavers, Rattle belly)

Watery mouth disease is a condition of intensively reared lambs occurring during the first days of life. Morbidity in a flock can be as high as 30%, and the mortality rate may exceed 80%.

Etiology and Pathogenesis: Watery mouth disease has been associated with ingestion of gram-negative bacteria, particularly *E coli*, that survive in the neonatal GI tract and translocate from the gut to the bloodstream. The strains involved are K99 antigen negative and regarded normally as nonenteropathogenic and nonenterotoxigenic. The resultant bacteremia may be tolerated by the lamb, but $>10^4$ colony-forming units/mL are associated with release of free endotoxin, and endotoxic shock develops rapidly.

Lambs 12–72 hr old with inadequate or delayed access to colostrum are at greatest risk. Other risk factors that have a negative effect on colostrum intake include being born in larger litters, being born to a dam with poor body condition, and stressors such as early castration.

Clinical Findings: Lambs affected with watery mouth disease are hypothermic, dull, stop feeding, and, classically, have long strings of saliva drooling from the mouth. Less obvious cases may have a wet muzzle; others may show no external signs of excess salivation, but the mouth may be cold to the touch and contain frothy saliva. Lacrimation may also be seen. The abomasum may become distended with gas and liquid, giving the deceptive appearance of a well-fed lamb, but if these lambs are lifted and shaken gently, a noise associated with the alternative name of “rattle belly” may be heard. Although scours occasionally occur, this is not a characteristic feature of the condition.

Lesions: Necropsy may reveal a bloated and inflamed GI tract, retained meconium, pale kidneys and muscle, dehydration, and enlarged and reactive mesenteric lymph nodes.

Diagnosis: Biochemical and hematologic changes and necropsy findings in lambs affected with watery mouth disease are consistent with endotoxemia and the clinical diagnosis of endotoxic shock. Terminally, lambs develop endotoxemia, leukopenia, severe hypoglycemia, lactic acidemia, and metabolic acidosis. Differential diagnoses include joint ill or navel ill, hypothermia, primary starvation, and infectious enteritis.

Treatment: There is no specific treatment for watery mouth disease. Parenteral antimicrobial and anti-inflammatory therapy combined with oral rehydration are essential; 50–200 mL of an

electrolyte and 5%–10% glucose solution containing a water-soluble antibiotic (neomycin and/or streptomycin) given tid by stomach tube will help maintain hydration and provide energy. Systemic antimicrobial therapy with a gram-negative spectrum and anti-inflammatory therapy with NSAIDs or corticosteroids to counteract the effects of endotoxemia should also be administered. Purgatives or enemas may help overcome gut stasis and expel the infecting bacteria. Treatment should be continued until signs resolve and the lamb is sucking again. Boosting body temperature by external warming may also be required. However, such care is time-consuming and expensive and carries no guarantee of success.

Prevention: Ewes should be well nourished to ensure a plentiful supply of colostrum. Yards, pens, ewes, and equipment should be kept as clean as possible throughout lambing to help control the buildup of *E. coli* and keep the incidence of disease low. Supplementary feeding of lambs using stored colostrum (ewe, cow, or goat) or commercial colostrum substitute should provide a minimum of 50 mL/kg within 6 hr of birth. Lambs should not be castrated in the first 24 hr because this depresses colostrum intake.

In controlled experiments, a single dose of oral antibiotic given within 2 hr of birth to colostrum-deprived lambs delivered into a contaminated indoor environment was as effective as ewe colostrum in preventing neonatal disease and death in all lambs up to 3 days old, despite the absence of maternal antibodies. Thus, antibiotic treatment can provide simple, quick, and inexpensive protection against watery mouth disease and is an attractive option for the busy sheep farmer. However, it is important that such treatment be targeted to lambs in the high-risk categories specified above, because indiscriminate dosing may encourage antibiotic resistance.

DIARRHEA IN NEONATAL RUMINANTS

(Scours)

Diarrhea is common in newborn calves, lambs, and kids. The clinical presentation can range from mild diarrhea without systemic disease to profuse, acute diarrhea associated with rapid dehydration, severe disturbance of acid-base and electrolyte balance, and death, sometimes in as few as

12 hr. This discussion emphasizes the disease in calves, but the principles of pathophysiology and treatment apply to lambs and kids as well.

Etiology: Several enteropathogens are associated with diarrhea in neonates. Their relative prevalence varies geographically, but the most prevalent infections in most areas are *Escherichia coli*, rotavirus, coronavirus, and *Cryptosporidium parvum*. Cases of neonatal diarrhea are commonly associated with more than one of these agents, and the cause of most outbreaks is multifactorial. Determining the particular agents associated with an outbreak of diarrhea can be important, because specific therapy and prophylaxis are available for some. Also, some agents have zoonotic risk. Diarrhea is also present in septicemic colibacillosis.

Bacteria: *E. coli* is the most important bacterial cause of diarrhea in calves during the first week of life; at least two distinct types of diarrheal disease are produced by different strains of this organism. One type is associated with enterotoxigenic *E. coli*, which has two virulence factors associated with production of diarrhea. Fimbrial antigens enable them to attach to and colonize the villi of the small intestine of neonatal calves in the first days of life. Strains in calves most commonly possess K99 (F5) or F41 fimbrial antigens, or both. These antigens are the focus of immunologic protection. Enterotoxigenic *E. coli* also elaborate a thermostable, nonantigenic enterotoxin (Stx) that influences intestinal ion and fluid secretion to produce a noninflammatory secretory diarrhea. Diarrhea in calves and lambs also has been associated with enteropathogenic *E. coli* that adhere to the intestine to produce so-called attaching and effacing lesions, with dissolution of the brush border and loss of microvillous structure at the site of attachment, a decrease in enzyme activity, and changes in ion transport in the intestine. These enteropathogens are also called “attaching and effacing *E. coli*.” Some produce verotoxin, which may be associated with a more severe hemorrhagic diarrhea. The infection most frequently is in the cecum and colon, but the distal small intestine can also be affected. The damage in severe infections can result in edema and mucosal erosions and ulceration, leading to hemorrhage into the intestinal lumen.

Salmonella spp., especially *S. Typhimurium* and *S. Dublin*, but occasionally other serovars, cause diarrhea in calves 2–12 wk

Enterotoxigenic *Escherichia coli* adhering to the intestine of a 2-day-old calf. Courtesy of Dr. J. J. Hadad and Dr. Carlton Gyles.

old. *Salmonellae* produce enterotoxins but are also invasive and produce inflammatory change within the intestine. In calves, infection commonly progresses to a bacteremia. (See also SALMONELLOSIS, p 195.)

Clostridium perfringens types A, B, C, and E produce a variety of necrotizing toxins and cause a rapidly fatal hemorrhagic enteritis in calves. The disease in calves is rare and usually sporadic. Infection with type B or C is a common cause of enteritis and dysentery in lambs (see p 609).

Campylobacter jejuni and *Yersinia enterocolitica* may be present in the feces of calves and lambs with diarrhea but also may be found in the feces of healthy animals.

Viruses: Rotavirus is the most common viral cause of diarrhea in calves and lambs. Groups A and B rotavirus are involved, but group A is most prevalent and clinically important and contains several serotypes of differing virulence. Rotavirus replicates in the mature absorptive and enzyme-producing enterocytes on the villi of the small intestine, leading to rupture and sloughing of the enterocytes with release of virus to infect adjacent cells. Rotavirus does not infect the immature cells of the crypts. With virulent strains of rotavirus, the loss of enterocytes exceeds the ability of the intestinal crypts to replace them; hence, villous height is reduced, with a consequent decrease in intestinal absorptive surface area and intestinal digestive enzyme activity.

Coronavirus is also commonly associated with diarrhea in calves. It replicates in the epithelium of the upper respiratory tract and in the enterocytes of the intestine, where it produces similar lesions to rotavirus but also infects the epithelial cells of the large intestine to produce atrophy of the colonic ridges.

Other viruses, including Breda virus (torovirus), a calici-like virus, astrovirus, and parvovirus, have been demonstrated in the feces of calves with diarrhea and can produce diarrhea in calves experimentally. However, these agents have also been found in the feces of healthy calves. The importance of these agents in the syndrome of diarrhea in neonates has yet to be determined. The viruses of bovine virus diarrhea and infectious bovine rhinotracheitis are reported to cause calf diarrhea, but this is not a common manifestation of these infections.

Protozoa: *Cryptosporidium parvum* (see p 209) is a common cause of diarrhea in calves and lambs. The parasite does not invade but adheres to the apical surface of enterocytes in the distal small intestine and the colon. This results in loss of microvilli, decreased mucosal enzyme activity with villous blunting and fusion (leading to a reduced villous surface absorptive area), and inflammatory changes in the submucosa. Mammalian cryptosporidia lack host specificity.

Giardia duodenalis is a common asymptomatic infection in the intestine of young calves and lambs. It has been found in the feces of poorly growing calves that have a chronic mucoid diarrhea, but there is little evidence for a causative association of this organism with diarrhea in calves or lambs.

Other Causes: Calves fed large amounts of milk or inappropriately formulated milk replacers produce a large volume of feces with a greater than normal fluid content but do not have a fluid diarrhea with weight loss. Similarly, calves sucking high-producing beef cows grazing lush pasture may have loose feces. Milk replacers with poor quality, heat-denatured proteins or with excessive amounts of soybean or fish protein or carbohydrates of nonmilk origin have a higher risk of producing diarrhea.

There is some evidence that oral administration of chloramphenicol, neomycin, or tetracycline to young calves for 3–5 days can result in villous change with resultant malabsorption and mild diarrhea. Prolonged and high-dose antibiotic

treatment of calves can lead to diarrhea associated with bacterial superinfection of the intestine. Colisepticemia (see p 749) and ruminal drinking (see p 236) can also be accompanied by diarrhea.

Epidemiology and Transmission:

Enteropathogens associated with diarrhea are commonly found in the feces of healthy calves; whether intestinal infection leads to diarrhea depends on a number of determinants, including differences in virulence of different strains of a pathogen and the presence of more than one pathogen. The resistance of the calf is of major importance and is largely determined by successful passive transfer of colostral immunoglobulins. Colostrum-deprived calves are highly susceptible to infection with enteropathogens and develop severe and often fatal disease.

The progression of infection, the severity of lesions produced, and the severity of the diarrhea can be modulated by immunoglobulins received via colostrum. Immunoglobulins act directly on pathogens in the intestinal lumen during the period of colostrum ingestion as well as after, because significant amounts of circulating immunoglobulins are re-secreted into the intestine, especially when the concentration of circulating immunoglobulin is high. The lack of specific antibodies in dams that have not been exposed to specific pathogens, and the use of specific vaccines, further modulate this influence. Stress caused by a poor environment, inadequate protection from the weather, or an insufficient or inappropriate diet also increases the risk of disease.

With all of the enteropathogens, healthy adult cattle may be carriers and periodically excrete the organism in feces. Excretion may increase around parturition and be more frequent in primiparous cows. This can lead to contaminated calving areas and infection of the udder and perineum of the dam. Other sources of infection include the feces of healthy calves and the feces of diarrheic calves, which contain large numbers of organisms early in the course of infection. A few scouring calves can result in severe contamination of the calf-rearing area. Transmission is by fecal-oral contact, fecal aerosol, and, in the case of coronavirus, by respiratory aerosol.

Pathogenesis: Diarrhea in neonatal ruminants is usually associated with disease of the small intestine and can be caused by hypersecretion or malabsorption. Hypersecretory diarrhea develops when an

abnormal amount of fluid is secreted into the gut, exceeding the resorptive capacity of the mucosa. In malabsorptive diarrhea, the capacity of the mucosa to absorb fluid and nutrients is impaired to the extent that it cannot keep up with the normal influx of ingested and secreted fluids. This is usually the result of villous atrophy, in which the loss of mature enterocytes at the tips of the villi results both in a decrease in villous height (with a consequent decrease in the surface area for absorption) and in loss of the brush border digestive enzymes. The extent and distribution of villous atrophy varies with different pathogens and can explain variation in the severity of clinical disease. Malabsorptive diarrhea may be aggravated by the colonic fermentation of nutrients that normally would have been absorbed in the small intestine. Fermentation products, especially lactic acid, appear to draw water into the colon osmotically, which contributes to the severity of diarrhea.

Inflammation contributes to the pathophysiology of diarrhea in most intestinal infections, and mediators of inflammation can affect ion flux within the intestine. Inflammation also leads to vascular and lymphatic damage and to structural damage of the crypt-villus unit. Most infectious forms of diarrhea have hypersecretory, inflammatory, and malabsorptive components, although one usually predominates. These lead to a net loss of water, sodium, potassium, and bicarbonate; if severe, the calf develops hypovolemia, hyponatremia, acidemia, and prerenal azotemia.

Enterotoxigenic *E. coli* produce the enterotoxin *Stx*, which stimulates marked hypersecretion by activating guanylate cyclase and by inducing a net secretion of sodium and chlorine. The membrane-bound sodium-glucose cotransport system remains functional but cannot compensate for the increased secretory activity. Salmonellae also elaborate enterotoxins. Inflammation, leading to necrosis of the enterocyte, submucosal inflammatory infiltration, and villous atrophy, is also a major component of the pathophysiology of diarrhea produced by salmonellae, as well as of diarrhea produced by enteropathogenic *E. coli* and by toxigenic *C. perfringens*. Infections with verotoxin-producing enteropathogenic *E. coli* result in accumulation of fluid within the large intestine and extensive damage to the large intestinal mucosa, with edema, hemorrhage, and erosion and ulceration of the mucosa, which results in blood and mucus in the lumen.

Viruses usually produce a malabsorptive diarrhea by destroying the absorptive cells of the mucosa, thus shortening the intestinal villi. The mechanism by which cryptosporidia produce diarrhea is not completely understood, but it appears to have both malabsorptive and inflammatory components.

Inappropriately formulated milk replacers produce diarrhea by two mechanisms, both associated with malabsorption. Vegetable (especially soybean) products are commonly used as protein sources in the manufacture of milk replacers. Depending on the degree of refinement, these products may contain carbohydrates that are indigestible in young calves. Such carbohydrates are not absorbed in the small intestine and may contribute to diarrhea via colonic fermentation. In addition, most calves <3 wk old appear to have an allergic reaction to soy proteins that results in villous atrophy, leading to diarrhea that is probably malabsorptive.

Clinical Findings: The major signs are diarrhea, dehydration, profound weakness, and death within one to several days of onset.

Diarrhea due to enterotoxigenic (K99-bearing) *E coli* is seen in calves <3–5 days old, rarely later. However, the age of susceptibility may be extended in the presence of other pathogens. Onset is sudden. Profuse amounts of liquid feces are passed, and the calves rapidly become depressed and recumbent. Calves may lose >12% of body weight in fluid, and hypovolemic shock and death may occur in 12–24 hr. Body temperature may be increased but is commonly normal or subnormal. If fluid and electrolyte therapy is administered early, response is usually good. Disease produced by attaching and effacing *E coli* is seen predominantly in calves from 4 days to 2 mo old and may manifest with diarrhea or primarily as dysentery with blood and mucus in the feces. The clinical course is short.

Diarrhea due to *Salmonella* spp usually is not seen in calves <14 days old. It is characterized by feces that are foul smelling and contain blood, fibrin, and copious amounts of mucus. Septicemia, with high fever and depression progressing to prostration and coma, is the salient manifestation of salmonellosis in calves and, although diarrhea is present, death is usually from septicemic rather than from hypovolemic shock. Calves with salmonellosis usually lose weight rapidly and often die despite vigorous therapy.

Hemorrhagic enterotoxemia due to *C perfringens* type B or C is characterized by acute onset of depression, weakness, bloody diarrhea, abdominal pain, and death within a few hours. It usually develops in vigorous calves just a few days old that have large appetites and a ready source of milk. Calves affected with *C perfringens* usually die before treatment can be instituted.

Diarrhea due to rotavirus, coronavirus, and other viruses usually is seen in calves 5–15 days old but can affect calves up to several months of age. Affected calves are only moderately depressed and often continue to suck or drink milk. The feces are voluminous, soft to liquid, and often contain large amounts of mucus. Diarrhea commonly persists for 3 to several days, with some cases of coronaviral diarrhea becoming chronic. Cases of viral diarrhea that are uncomplicated by other pathogens commonly respond within a few days to fluid and electrolyte therapy and adequate nutritional support.

Cryptosporidiosis (see p 209) is seen in calves 5–35 days old but most commonly in the second week of life. It is characterized by persistent diarrhea that does not respond to therapy. Diarrhea due solely to *Cryptosporidium* spp is often mild and self-limiting, although the severity may be related to the general strength of the calf and to the intensity of challenge with the organism. Combination infections with cryptosporidia, rotavirus, and coronavirus are common and result in persistent diarrhea often characterized by emaciation and death. Death from hypoglycemia also occurs as a sequela of cryptosporidiosis in calves 3–4 wk of age that have recovered from diarrhea but are still emaciated. Death often occurs during a bout of cold weather and is more likely to occur on farms where there is a policy of reducing the amount of milk fed to calves during periods of diarrhea.

Dietary diarrheas are seen in calves <3 wk old and are characterized by voluminous feces of pasty to gelatinous consistency. Initially, the calves are bright and alert and have good appetites. Eventually, however, they become weak and emaciated if the diet is not corrected. Infectious forms of diarrhea are often complicated by poor-quality diets or insufficient nutritional intake.

Diagnosis: It is difficult to make a definite etiologic diagnosis for diarrhea based solely on clinical findings. However, the history, age of the animal(s) affected, and clinical signs may permit a presumptive diagnosis.

Fecal samples can be submitted for isolation and characterization of the common enteropathogens. Samples should be taken from several untreated calves in the early stages of diarrhea. Special techniques are necessary for the demonstration of viruses, cryptosporidia, and K99-bearing *E. coli*. The interpretation of fecal microbiology can be difficult because of mixed infections and because enteropathogens are commonly present in the feces of healthy calves.

The best diagnostic information is usually obtained by submitting untreated, acutely affected animals for necropsy. This allows examination of intestinal mucosa for evidence of diagnostic lesions and for the presence of enteropathogens such as cryptosporidia. It may be the only way that disease such as that associated with attaching and effacing strains of *E. coli* can be diagnosed. The diagnostic value of a necropsy diminishes quickly with time after death; important lesions can disappear within minutes due to autolysis.

Complete laboratory examination can be expensive, and it has also been argued that there is little value in expending large amounts of money on diagnosis unless there are specific control procedures that can be implemented based on the information gained. In all cases, information on total milk or milk replacer consumption should be obtained. When milk replacer is being fed, the composition of the diet should be evaluated. Nonspecific immunity should be assessed by determining immunoglobulin and vitamin A concentrations in serum.

Treatment: Many of the factors involved in disease resistance are nonspecific; thus, important preventive measures can be taken and therapy can be started before an etiologic diagnosis has been established. Treatment includes fluid therapy for water and electrolyte replacement and correction of acid-base disturbances, alteration of the diet, and antimicrobial and anti-inflammatory therapy.

Fluid and electrolyte therapy is most important and should be started as soon as possible regardless of whether clinical evidence of dehydration has developed (clinical signs of dehydration are not apparent until the calf has lost at least 6% of its body weight in fluid). Calves still able to stand and willing and able to suck can often be treated with oral electrolyte solutions alone. Fluids for oral rehydration should promote the cotransport of sodium with

glucose and amino acids and should contain sodium, glucose, glycine or alanine, potassium, and either bicarbonate or citrate or acetate as alkalizing agents. Several commercial preparations are available. These can be administered by nipple bottle or, if necessary, by stomach tube. The solutions should be used liberally until the animal is rehydrated.

Whether milk should be fed during the rehydration period remains controversial. Feeding milk may increase fecal volume, but it provides energy to the calf and may promote gut healing. Calves have large energy requirements and little reserve. Electrolyte solutions do not meet calf energy requirements, and milk should not be withheld for >24 hr, if at all.

Calves that are recumbent, weak, and show evidence of water loss of ≥8% of their body weight require IV fluid therapy. These calves are usually acidotic, and the fluid and base deficits can be corrected initially by rapidly administering a hypertonic solution of sodium bicarbonate (either 500 mL of a 4.2% solution, or 250 mL of an 8.4% solution), followed by a physiologically balanced electrolyte solution administered at up to 40 mL/kg/hr until the volume deficit is corrected. Because diarrheic calves are frequently hypoglycemic, adding 25–50 g of dextrose to the electrolyte solution is often beneficial in the initial treatment phase. Oral electrolyte solutions should be used concurrently with and after IV fluid therapy to compensate for ongoing fluid and electrolyte losses.

Although mild diarrhea without systemic disease is not an indication for antimicrobial therapy, use of parenteral antibiotics should be considered whenever calves are systemically ill or recumbent. Field studies revealed that at least 30% of diarrheic calves with systemic disease are bacteremic—a clear indication for parenteral antimicrobial therapy. Because the large majority of cases of bacteremia and septicemia in neonatal calves are associated with *E. coli*, the chosen antibiotic should be effective against gram-negative bacteria.

In several studies, severely affected diarrheic calves treated with NSAIDs in conjunction with fluid therapy showed fewer signs of pain, made a faster recovery, and had better weight gains in the convalescent period. These effects reported for several NSAIDs have been attributed to their analgesic, anti-inflammatory, antipyretic, and antisecretory properties.

The use of drugs to reduce intestinal motility such as hyoscine-N-butylbromide

or atropine is sometimes advocated, because they decrease fecal output. Although reducing fecal production may be interpreted as a positive treatment outcome, it can also be seen as sequestration of gut fluid containing bacteria, toxins, and undigested nutrients in the intestinal tract. The literature does not provide any strong supportive evidence for or against the use of antimotility drugs.

Intestinal gels and adsorbents, such as kaolin and pectin, are in general use, but their only established effect is to increase fecal consistency; they do not reduce the loss of water and ions.

Prevention and Control: Because of the complex nature of diarrhea in neonates, it is unrealistic to expect total prevention—economical control is the major objective. The incidence of clinical disease and the case fatality rate depend on the balance between the levels of exposure to infectious agents and the resistance in the calf. Differences in herd size; availability of facilities, land, and labor; and general management objectives make it impossible to recommend specific management procedures applicable to all situations. However, three broad principles apply in all herds: 1) the degree of exposure of neonates should be reduced by isolating diseased animals or by moving calving and calf rearing to a separate area, and by practicing good general hygiene; 2) nonspecific resistance should be maximized by providing good nutrition to the dam and neonate and assuring that newborn calves consume $\geq 5\%$ of their body wt of high-quality colostrum, preferably within 2 hr and certainly within 6 hr of birth, followed by equivalent amounts at 12-hr intervals for the next 48 hr; and 3) the specific resistance of the newborn should be increased by vaccinating the dam or the newborn. A significant portion of both naturally sucking dairy calves and calves handfed colostrum do not acquire adequate amounts of immunoglobulin because of delayed sucking or feeding, ingestion of an inadequate volume of colostrum, or ingestion of colostrum of inferior immunoglobulin concentration. When time constraints on labor preclude an ensured intake of colostrum by nipple-bottle feeding, administration of 4 L of colostrum by esophageal feeder within the first 2 hr of life can be the best colostrum feeding policy. (See also MANAGEMENT OF REPRODUCTION: CATTLE, p 2171.)

Immunization of calves against colibacillosis by vaccination of pregnant dams can

control enterotoxigenic colibacillosis. The pregnant dam is vaccinated 6 and 2 wk before parturition to stimulate antibodies to strains of enterotoxigenic *E. coli*; these antibodies are then passed on to the newborn through the colostrum (provided the calf ingests it). A single booster is given in subsequent years. Monoclonal K99 *E. coli* antibody is commercially available for oral administration to calves immediately after birth. It is an effective substitute for the K99-specific antibody in the colostrum of vaccinated cows, although calves that receive this product should also receive colostrum for its nonspecific protection.

Vaccination of pregnant cows with rotavirus and coronavirus vaccines increase the amount of specific antibody in colostrum and milk, but the concentration of antibodies in milk may be insufficient to provide local antibody in the intestinal lumen during the period of peak prevalence of infection, which, in calves, is 5–15 days of age. Controlled trials of commercial vaccines have shown variable results. The addition of small amounts of immune colostrum to milk fed during the period of susceptibility can provide some protection against disease.

Zoonotic Risk: Several of the agents that produce diarrhea in calves can also produce diarrheal disease in people. *Cryptosporidium parvum* and *S. Typhimurium* can produce serious disease, particularly in immunocompromised individuals. These organisms are commonly present as subclinical infections in the gut of calves and lambs; immunocompromised people should avoid contact with young ruminants and possibly all farm animals.

Cattle, including calves, are one of the reservoirs for the verotoxic *E. coli* serotype O157:H7 associated with human hemorrhagic colitis and the hemolytic uremic syndrome. Infection in people is usually acquired by consumption of contaminated food, but the infective dose is low and the possibility of infection by direct contact exists. Other verotoxic *E. coli* associated with human disease can also be isolated from the feces of healthy cattle. Human disease from infection with enteric livestock pathogens has occurred after seemingly trivial contact associated with visits to livestock fairs, petting zoos, and farm educational tours. Hand cleansing and disinfection should be a component of these visits.

INTESTINAL DISEASES IN HORSES AND FOALS

Intestinal disease in horses and foals is suggested by diarrhea, weight loss, hypoproteinemia, and abdominal pain. (See also COLIC IN HORSES, p 248.)

DIARRHEAL DISEASE IN HORSES

A definitive cause of diarrhea can be determined in <50% of cases. Yet, treatment of most horses and foals with diarrhea is similar and thus allows supportive therapeutic management despite the lack of a definitive diagnosis.

Diarrhea in adult horses can be acute or chronic. Infectious agents that have been cited as potential causes of acute diarrhea in adult horses include numerous *Salmonella* serovars, *Neorickettsia risticii*, *Clostridium difficile*, *C perfringens*, *Aeromonas* spp, coronavirus, and cyathostomiasis. Other differential diagnoses for acute diarrhea in horses include ingestion of a toxicant(s), antimicrobial-induced colitis, NSAID toxicity, and sand enterocolopathy. An acute, fatal diarrheal disease of unknown etiology is known as colitis-X. Diarrhea that persists >1 mo is considered chronic and is often a diagnostic challenge. Chronic diarrhea can be caused by inflammatory or neoplastic conditions involving the intestine or by disruption of the normal physiologic process in the bowel. Differential diagnoses include sand enterocolopathy and infiltrative lesions, such as those associated with inflammatory bowel disease or intestinal lymphosarcoma. The body's response to certain components of feed may play a role in chronic diarrhea of horses due to bowel inflammation but has not frequently been established as a cause.

Noninflammatory conditions of the colon can also result in diarrhea. These include altered fermentation in the large colon, which is potentially the result of altered intestinal flora or milieu secondary to antimicrobial treatment, alteration in diet, or unknown etiologies. Nonintestinal causes of chronic diarrhea include congestive heart failure and chronic liver disease. The diagnostic approach to these cases is aimed at differentiation of infiltrative diseases of the intestine from physiologic causes of diarrhea.

Because of the large volume of the colon and cecum of horses, massive fluid losses can occur in a short time. Thus, diarrhea in adult horses can be an explosive event with morbidity and mortality exceeding that associated with diarrheal diseases in other animals and people.

SALMONELLOSIS

Salmonellosis (see p 195) is one of the most commonly diagnosed infectious causes of diarrhea in adult horses. Clinical manifestations range from no abnormal clinical signs (subclinical carrier) to acute, severe diarrhea and even death. The disease is seen sporadically but may become an epidemic, depending on the virulence of the organism, level of exposure, and host factors. Infection can occur via contamination of the environment, feed, or water or by contact with animals actively shedding the bacteria. Stress appears to play an important role in the pathogenesis—a history of surgery, transportation, or change in feed; concurrent disease, particularly GI disorders (colic); or treatment with broad-spectrum antimicrobial drugs often precedes the diarrhea.

Salmonella enterica of the serogroup B includes *S enterica* serovar Typhimurium and *S enterica* Agona, two of the most frequently isolated serovars from horses with clinical disease. Knowing the serovar and antibiogram can help track or monitor the type of serovar of salmonellae affecting any given group or population of horses (eg, tracking nosocomial spread within a veterinary hospital). The emergence of multidrug-resistant *S enterica* isolates is concerning both in dealing with nosocomial infections and zoonosis.

Clinical Findings: Three forms of salmonellosis have been recognized in adult horses. One is the subclinical carrier, which may or may not be actively shedding the organism but has the potential to transmit the bacteria to susceptible animals either by direct contact or by contamination of the environment, water, or feed sources. Multiple fecal cultures may be necessary to identify carriers, because the organism is shed in the feces intermittently and in small numbers. If stressed, the carrier may

develop clinical disease. The national prevalence of fecal shedding of *S enterica* by normal horses in the USA is estimated to be <2%; however, the proportion of hospitalized horses shedding is much higher (~8%). The most common serovars identified among the general population of horses were *S enterica* Muenchen and *S enterica* Newport (both serogroup C2).

The second form of the disease is characterized by a mild clinical course, with signs of depression, fever, anorexia, and soft but not watery feces. Affected horses may have an absolute neutropenia. Clinical disease may last 4–5 days and usually is self-limiting, and *S enterica* can be isolated from the feces. Recovered horses may continue to excrete the organism in their feces for days to months; therefore, isolation of the shedding horse and thorough cleaning and subsequent disinfection of the contaminated area are recommended.

The third form of salmonellosis is characterized by an acute onset of severe depression, anorexia, profound neutropenia, and frequently abdominal pain. Diarrhea develops 6–24 hr after the onset of fever; feces are fluid and foul smelling. Affected horses dehydrate rapidly, and metabolic acidosis and electrolyte losses occur as the horse deteriorates. Clinical signs of sepsis and hypovolemic shock can progress rapidly. There may be signs of abdominal discomfort, straining, or severe colic secondary to ileus, gas distension, and colonic inflammation and possible infarction. Protein-losing enterocolopathy can occur with plasma protein concentrations becoming dangerously low (albumin <2 g/dL) after a few days of diarrhea. These horses can become bacteremic because of bacterial translocation of enteric organisms, and coagulation abnormalities resulting in disseminated intravascular coagulation can occur. If untreated, this form of salmonellosis is often fatal.

Salmonella bacteremia can occur in neonatal foals, especially from farms with endemic salmonellosis (see p 289).

Diagnosis: Diagnosis is based on clinical signs, severe neutropenia, and isolation of salmonellae from feces, blood, or tissues. Submission of 10–30 g of feces for culture has been more successful in identifying salmonellae than has culturing fecal swabs. It is important to collect and submit feces based on the recommendations of the laboratory performing the culture. Working with a diagnostic laboratory that uses

enrichment techniques along with agars specifically selected to optimize recovery of *S enterica* is advisable. Because salmonellae cannot be consistently cultured from feces, multiple daily samples (generally 3–5) should be collected from each horse. Culturing of rectal mucosal biopsies increases the probability of isolating the organism; however, the technique is not without risk to the horse. Fecal samples that must be mailed should be placed in transport media suitable for enteric pathogens at the time of collection and shipped on ice. A PCR test is available and, depending on the primers used, appears to be more sensitive than routine bacterial culture for detection of salmonellae.

Treatment: Treatment of the severe form of salmonellosis is based on IV fluid and electrolyte replacement and efforts to control the host's responses initiated by the systemic inflammatory response. A polyionic isotonic fluid is used for volume replacement. Because of active secretion of fluid and electrolytes into the lumen of the intestine, IV fluid volumes of 40–80 L/day may be necessary. Electrolyte and acid-base deficiencies are common and are corrected by use of oral and/or IV fluids supplemented with electrolytes. It is difficult to predict the electrolyte status of affected horses. Deficits should be determined by serum biochemical analysis; supplementation with sodium chloride, potassium chloride, calcium gluconate, magnesium sulfate, and occasionally sodium bicarbonate may be indicated.

Antimicrobial treatment in adult horses with salmonellosis is controversial and does not appear to alter the course of the colitis or decrease shedding of salmonellae; however, it may reduce the likelihood of bacteremia. Selection of an antimicrobial is not easy and should ideally be based on the sensitivity of the organism isolated. Resistance patterns vary among *Salmonella* isolates and can change over the course of an outbreak. There is potential nephrotoxicosis from aminoglycoside antibiotics in volume-depleted horses; therefore, the hydration status of the horse should be considered when selecting an antimicrobial. The ideal antibiotic should also be lipid soluble.

The use of GI protectants (eg, biosponge, bismuth subsalicylate, activated charcoal) may be beneficial. These substances may bind bacterial toxins. NSAIDs, such as flunixin meglumine, help counteract the effect of endotoxin, control pain, and possibly help prevent laminitis. The dosage

of NSAID used has been quite variable. Serious adverse effects, such as gastric and colonic ulceration and renal nephrotoxicosis, can result from NSAID treatment, so the minimum effective dosage should be used. Equine plasma may be administered to correct hypoproteinemia and to supply coagulation factors and, depending on the source of the plasma, specific antibodies to endotoxin and *Salmonella*. Colloidal plasma substitutes such as hetastarch may be necessary to maintain oncotic pressure in horses with substantial protein loss into the GI tract. These colloidal plasma substitutes may be less expensive and better tolerated than equine plasma in some horses. Often, equine plasma and colloidal plasma substitutes are both used in horses with hypoproteinemia due to colitis.

Low-dose polymyxin B (6,000 units/kg, bid) has also been advocated to bind circulating endotoxin. In controlled trials, polymyxin B ameliorated some of the known effects of endotoxemia in horses. Antimicrobial doses of polymyxin B are substantially higher than the dose used to bind endotoxin and may be nephrotoxic. Low-dose polymyxin B therapy is unlikely to be nephrotoxic in adequately hydrated horses receiving IV fluids.

Prevention: Prevention of salmonellosis is difficult, because the organism is present in the environment as well as in the feces of some healthy animals. In a hospital environment where horses are stressed, may be off feed, and are often receiving antimicrobial treatment, aggressive identification and strict isolation of salmonellae-infected horses is indicated. Biosecurity practices to minimize cross-contamination between hospitalized horses are also advisable. Serotyping, antimicrobial susceptibility profiles and genotyping by pulse field electrophoresis, plasmid profile analysis, and phage typing can be used to determine whether isolates are genetically related and help determine whether infection is nosocomial.

Owners should be made aware of the zoonotic risk of *S enterica* infection. People working with infected animals should practice strict hygiene.

POTOMAC HORSE FEVER

(Equine monocytic ehrlichiosis, Ditch fever, Shasta River crud, Equine ehrlichial colitis)

Potomac horse fever (PHF) is an acute enterocolitis syndrome producing mild

colic, fever, and diarrhea in horses of all ages, as well as abortion in pregnant mares. The causative agent is *Neorickettsia risticii*. The infection of enterocytes of the small and large intestine results in acute colitis, which is one of the principal clinical signs of PHF. The disease is seen in spring, summer, and early fall and is associated with pastures bordering creeks or rivers. The epidemiology of PHF has been shown to involve a trematode vector. Sporadic disease caused by *N risticii* has been reported in dogs and cats; cattle appear to be resistant to infection. PHF has been reported in many areas of the USA and Canada using an indirect fluorescent antibody test as evidence of exposure; however, recent studies indicate a high rate of false-positive titers with this test, and the true geographic range of distribution is not known. Isolation or detection of the causative agent from clinical cases of PHF using conventional cell culture or PCR assay has been reported only from California, Illinois, Indiana, Kentucky, Maryland, Michigan, New York, New Jersey, Ohio, Oregon, Pennsylvania, Texas, and Virginia.

Etiology and Pathogenesis: *N risticii* is a gram-negative obligate intracellular bacterium with a trophism for monocytes. Initial morphologic studies of this organism isolated from cell culture, as well as the serologic responses of *N risticii*, caused this bacterium to be assigned to the genus *Ehrlichia*. However, DNA analyses have shown *N risticii* is most closely related to *N helminthoeca*, the agent of salmon poisoning in dogs, and *Ehrlichia sennetsu*, a disease of people in Japan. The organism is not visible in monocytes in blood films from clinical cases, in contrast to *Anaplasma phagocytophilum*, which is readily identifiable in granulocytes of infected horses.

N risticii has been identified in freshwater snails and isolated from trematodes released from the snails. *N risticii* DNA was detected in 13 species of immature and adult caddisflies (Trichoptera), mayflies (Ephemeroptera), damselflies (Odonata, Zygoptera), dragonflies (Odonata, Anisoptera), and stoneflies (Plecoptera). Transmission studies using *N risticii*-infected caddisflies have reproduced the clinical disease. One route of exposure is believed to be inadvertent ingestion of hatched aquatic insects that carry *N risticii* in the metacercarial stage of a trematode. The

incubation period is ~10–18 days. The causative organism is present in the feces of experimentally infected horses, but the biologic significance of this is unknown. Clinically ill horses are not contagious and can be housed with susceptible horses. Additional studies are needed to determine the exact role of the vector and helminth hosts in the complex maintenance cycle of *N risticii*.

Clinical Findings and Lesions: The clinical features of PHF are typified initially by mild depression and anorexia, followed by a fever of 102°–107°F (38.9°–41.7°C). At this stage, intestinal sounds may be decreased. Within 24–48 hr, a moderate to severe diarrhea, with feces ranging in consistency from that usually seen in cows to watery, develops in ~60% of affected horses. The onset of diarrhea is often accompanied by mild abdominal discomfort. Some horses develop severe signs of sepsis and dehydration. Clinical signs can be indistinguishable from those of *Salmonella* and other infectious causes of enterocolitis. Laminitis can supervene as a severe complication of PHF in 20%–30% of affected horses. Hematologic findings vary in the early stage of PHF from leukopenia (characterized by neutropenia and lymphopenia) and thrombocytopenia to a normal hemogram, despite evidence of systemic illness. A common finding in cases of PHF is a marked leukocytosis, which is normally seen within a few days of onset. PHF may present with all or any combination of these clinical signs.

Several months after clinical disease in pregnant mares, abortion due to fetal infection with *N risticii* may occur. Experimentally, pregnant mares infected at 100–160 days of gestation abort at 190–250 days of gestation. The abortion is accompanied by placentitis and retained placenta. Fetal lesions include colitis, periportal hepatitis, and lymphoid hyperplasia of mesenteric lymph nodes and spleen. Necropsy findings in nonpregnant horses with enterocolitis are nonspecific and reveal diffuse inflammation, mainly in the large intestines.

Diagnosis: A provisional diagnosis of PHF often is based on the presence of typical clinical signs and on the seasonal and geographic occurrence of the disease. A definitive diagnosis should be based on isolation or identification of *N risticii* from the blood or feces of infected horses by cell culture or PCR. Serologic testing

is of limited value as a diagnostic tool, although many infected horses have high antibody titers at the time of infection. Because of the high prevalence of false-positive titers, interpretation of the indirect fluorescent antibody test in individual horses is difficult. Rising paired titers can be helpful. Isolation of the agent in cell culture, although possible, is time-consuming and not routinely available in many diagnostic laboratories. A real-time PCR assay that allows detection of *N risticii* DNA within 2 hr is a much more feasible test for routine diagnostic examination. To enhance the chances of detection of *N risticii*, the assay should be performed both on blood and fecal samples, because the presence of the organism in blood and feces may not necessarily coincide.

Treatment: Horses with PHF can be treated successfully with oxytetracycline (6.6 mg/kg, IV, bid), if given early in the clinical course of the disease. A response to treatment is usually seen within 12 hr. This is associated with a drop in rectal temperature, followed by an improvement in demeanor, appetite, and borborygmal sounds. If therapy is begun early, clinical signs frequently resolve by the third day of treatment. Generally, antimicrobial therapy is for no more than 5 days. In animals that exhibit signs of enterocolitis, fluids and NSAIDs should be administered. Laminitis is more common than in other causes of enterocolitis, and if it develops, is usually severe and often refractory to treatment. The overall case fatality rate is 5%–30%.

Prevention: Several inactivated, whole-cell vaccines based on the same strain of *N risticii* are commercially available. Although vaccination has been reported to protect 78% of experimentally infected ponies, it has been marginally protective in the field. Vaccine failure has been attributed to antigenic and genomic heterogeneity among the >14 different strains of *N risticii* isolated from naturally occurring cases. Furthermore, vaccine failure may also be due to lack of antibody protection at the site of exposure, because the natural route of transmission has been determined to be oral ingestion of the agent. Minimizing insect ingestion in stabled horses by turning off barn lights at night, which normally attract the insects, has been suggested.

No zoonotic risk is known.

CLOSTRIDIA-ASSOCIATED ENTEROCOLITIS

Clostridium difficile and *C perfringens* are common causes of enterocolitis in horses and foals. Antimicrobial administration has been associated with *C difficile* diarrhea. Some reports attribute 50% of cases of foal diarrhea to *C perfringens*. *C difficile* produces toxin A and/or toxin B, which cause fluid secretion and lead to intestinal inflammation. It is common for the GI tract of newborn foals to be rapidly colonized by *C difficile*, which can be cultured from feces using sensitive anaerobic techniques. Nontoxin-producing strains are considered commensals. *C difficile* can be isolated from various segments of the small and large intestine and rectum of a large proportion of healthy horses, and from fecal samples of as many as 8% of healthy horses. Approximately one-third of healthy broodmares and >90% of foals in the general population shed *C perfringens* in their feces; therefore, it is important to determine the presence of a toxin-producing strain.

Strains of *C perfringens* are classified by the toxins they produce. However, toxins and toxin-producing strains of *C perfringens* and *C difficile* can be detected in healthy as well as in diarrheic horses and foals. The most common type of *C perfringens* identified is type A, which can be detected in the feces of as many as 8% of healthy horses. Type C is rarely identified in the feces or environment of healthy broodmares and their foals but is associated with the highest mortality. Antimicrobial use, food deprivation, and other stressors have been suggested to predispose horses to the overgrowth of either or both *C perfringens* and *C difficile*, leading to GI disease. In one report, mares whose foals were being treated with erythromycin developed fatal enterocolitis associated with *C difficile*. Clostridial spores can persist in the environment and can be resistant to many disinfectants; therefore, nosocomial infection can occur in contaminated environments.

Clinical Findings: Clinical signs include sudden death, diarrhea with or without blood, colic, fever, reduced feed intake, and lethargy. Disease can range from subclinical to severe enterocolitis to peracute death before the development of diarrhea. With advanced diagnostic techniques, clostridial infections account for a large proportion of the previously undiagnosed cases known as

“colitis-X.” Because of the loss of mucosal integrity, bacterial translocation across the GI tract can occur, resulting in bacteremia due to clostridial or other enteric bacterial species. Clinical signs of sepsis or systemic inflammatory response are often present and consistent with other causes of enterocolitis. Clostridiosis cannot be clinically distinguished from salmonellosis. Foals affected at <3 days of age with *C perfringens*-associated enterocolitis often have bloody diarrhea and colic. Fluid and gas-filled intestine is often identified on ultrasound or radiography. In severe cases, necrotizing enterocolitis occurs with thickening and even intramural gas evident within the wall of the intestine. Several foals on a particular farm may be affected, but the disease is typically sporadic.

The role of *C perfringens* type A in enterocolitis in neonatal foals is less clear; it has been reported that >90% of foals at 3 days of age shed this organism in their feces and that *C perfringens* type A is likely one of the first bacteria to colonize the intestinal tract of newborn foals, irrespective of hygiene protocols.

C difficile has been associated with enterocolitis in newborn foals as well as in adult horses. It has been identified as a nosocomial infection in people, and this may also be seen in horses.

The mortality rate associated with *C difficile* and *C perfringens* enterocolitis, especially type C, can be high, even with intensive medical treatment.

Diagnosis: Diagnosis is based on identification of toxigenic clostridia from fresh fecal samples, reflux, intestinal contents, or tissue. Blood culture is indicated in foals and adults with severe enterocolitis. Fecal samples for culture and detection of toxins or toxin-producing genes should be delivered directly to the laboratory, or shipped overnight, chilled (not frozen) on ice. Samples for culture must be maintained in an anaerobic environment. Isolation of clostridial organisms requires anaerobic conditions and, depending on the organism, special growth media. *C difficile* is inherently difficult to culture, hence its name. Communicating to the laboratory that clostridial enterocolitis is a differential diagnosis is critical, because many veterinary laboratories do not routinely culture fecal samples anaerobically unless specifically requested to do so.

Because nonpathogenic serovars are common, a positive culture for *C difficile* or *C perfringens* must be confirmed by

identification of toxins or their genes. A PCR test, available at selected laboratories, allows differentiation of *C perfringens* types A, B, C, D, and E based on combinations of α , β , ϵ , or ι toxins, as well as on identification of the gene coding for the $\beta 2$ toxin. Commercially available tests for clostridial toxins include an ELISA for *C difficile* toxin A and *C perfringens* enterotoxin, and a latex agglutination test for *C perfringens* enterotoxin. Toxin tests can be performed in-house, are rapid, and for *C difficile* are both sensitive and specific. Diagnosis of clostridial enterocolitis is often made at necropsy and is based primarily on identification of intestinal necrosis associated with large gram-positive rods in intestinal smears. Tissue and fecal specimens must be taken immediately after death to avoid degradation of toxins or an overgrowth of clostridial organisms.

Treatment: Treatment with metronidazole (15–20 mg/kg, PO, tid-qid) appears to be beneficial in treating enteric clostridial infections. Pharmacokinetic studies have not been performed in foals, but oral and even IV metronidazole appears generally safe. In some geographic regions, metronidazole-resistant *C difficile* strains have emerged that appear sensitive to vancomycin; however, metronidazole should be used whenever possible.

Supportive care is similar to that for other causes of equine enterocolitis, often requiring large volumes of IV polyionic fluids, with supplemental electrolytes (potassium, magnesium, and calcium), plasma or synthetic colloids for low oncotic pressure, anti-inflammatories such as flunixin meglumine, and broad-spectrum antibiotics if the horse is leukopenic and at risk of bacterial translocation across the compromised GI tract. Polymyxin B may aid in binding systemic endotoxin. Total or partial parenteral nutrition to provide nutritional support can be useful in foals if milk is withheld or decreased to allow gut rest. Foals with colic or profuse diarrhea often benefit from milk withdrawal. Continuous infusion of IV fluids and parenteral nutritional support is optimal but labor intensive and requires separation of the foal and mare. However, the course of diarrhea appears to be dramatically shortened, thus justifying the more intensive approach in some severe cases.

The yeast *Saccharomyces boulardii* has been shown to be protective in clostridial diarrhea in other species, and there is some evidence of beneficial effects in the treatment of horses with colitis. It produces a

protease that specifically degrades *C difficile* toxins A and B. Orally administered DTO smectite powder also binds clostridial toxins and may be useful in horses with diarrhea.

Specific antitoxin for *C perfringens* type C and D has also been used in foals; however, it is not approved for this use. The benefit of type C and D antitoxin in disease associated with type A or $\beta 2$ toxin is unknown, but based on production methods, the α and $\beta 2$ toxins are unlikely to be present in high levels in this toxoid.

Prevention: No proven effective biologic products are available to immunize horses or foals against clostridial enterocolitis. When the disease is a problem in multiple foals on a farm, preventive measures have been implemented, but the efficacy and safety of these interventions have yet to be critically evaluated. These measures include vaccinating pregnant mares twice at 2- to 4-wk intervals at least 1 mo before foaling with *C perfringens* type C and D toxoid (bacterin products and those with oil adjuvants should be avoided); using *C perfringens* type C and D antitoxin prophylactically, PO, in newborn foals; and administering antimicrobials (eg, metronidazole) prophylactically to foals for the first 3–5 days of life. The *C perfringens* type C and D toxoid and antitoxin are not approved for use in horses; however, these products have been used by some owners because of the high mortality rate in foals with clostridial enterocolitis on problem farms. Adverse reactions to the *C perfringens* type C and D toxoid have been reported in broodmares.

The most important strategy for prevention is good farm hygiene. Clostridial spores are extremely resilient in the environment and resistant to many disinfectants. Keeping the foaling area and mare as clean as possible during the perinatal period and ensuring rapid ingestion (by stomach tube if necessary) of colostrum within 1 hr of birth have reduced incidence of disease on some contaminated farms. The mare's hindlegs, tail, and udder can also be washed in soapy water immediately after foaling to decrease ingestion of fecal material by newborn foals. Affected animals should be isolated to limit cross-infection and contamination of pastures and stalls.

COLITIS-X

Colitis-X is not actually a disease but a historic term used to describe undiagnosed causes of peracute, fatal enterocolitis in horses characterized by sudden onset of

profuse, watery diarrhea and development of hypovolemic shock. Many affected horses have a history of stress. Differential diagnoses include peracute salmonellosis, clostridial enterocolitis, *Aeromonas* spp colitis, and coronavirus. *Salmonella* spp and *Clostridia difficile* can be difficult to culture from fluid fecal material, and a diagnosis of salmonellosis or clostridial enterocolitis can easily be missed. Culture of GI tissue samples and mesenteric lymph nodes is recommended in addition to intestinal contents from necropsy cases. Negative cultures and toxin tests for clostridia do not necessarily exclude these conditions; therefore, thorough disinfection of the premises, hospital facilities, and trailers is recommended in all cases.

Clinically, there may be a short febrile period, but body temperature soon returns to normal or subnormal. Tachypnea, tachycardia, and marked depression are present. An explosive diarrhea develops, followed by extreme dehydration. Sometimes death occurs before diarrhea becomes evident, with severe enterocolitis observed at necropsy. Hypovolemic and endotoxic shock are manifest by poor capillary refill time, purplish mucous membranes, and cold extremities. Death may occur within 3 hr of onset of clinical signs. In less acute cases, death occurs within 24–48 hr. At necropsy, edema and hemorrhage in the wall of the large colon and cecum are pronounced, and the intestinal contents are fluid and often blood-stained.

Typically, the PCV is >65% even shortly after the onset of clinical signs. The leukogram ranges from normal to neutropenia with a degenerative left shift. Metabolic acidosis and electrolyte disorders are also present.

Disease onset is often closely associated with stress, eg, surgery or transport. Signs are similar to those of other diarrheal diseases, including peracute salmonellosis, toxemia caused by *Clostridium* spp, Potomac horse fever, experimental endotoxic shock, and anaphylaxis. A similar condition may be seen after administration of lincomycin to horses. Colitis-X is the term reserved for those cases in which no definitive diagnosis can be made and the horse dies.

Treatment for colitis-X usually is not effective (by definition) but would be similar to that for salmonellosis (see p 281). Large volumes of IV fluids are needed to counter the severe dehydration, and electrolyte replacement is often necessary. Plasma or synthetic colloids

are required to maintain plasma oncotic pressure if hypoproteinemia occurs secondary to protein-losing enteropathy. Flunixin meglumine may decrease inflammation, and polymyxin B can help bind endotoxin. Broad-spectrum antibiotics are indicated to treat bacteremia that often occurs secondary to bacterial translocation across the damaged GI tract.

CORONAVIRUS

Coronavirus has been identified in the feces of normal foals and those with intestinal disease. However, there have been recent outbreaks of diarrhea and colic in adult horses attributed to coronavirus. Clinical signs include anorexia, lethargy, and fever. Colic and changes in fecal consistency are seen in some cases. Occasionally, rapid progression leads to death (or euthanasia), but most cases resolve with supportive care.

Diagnosis is by detection of the organism in feces by real-time PCR, electron microscopy, and virus isolation. Leukopenia due to neutropenia and lymphopenia are the most common hematologic abnormalities.

PARASITISM

Both large and small strongyles have been incriminated as a cause of chronic diarrhea in horses and foals. The condition associated with small strongyles in horses is termed cyathostomiasis and has been reported to result in recurrent colic, diarrhea, and weight loss. (See GASTROINTESTINAL PARASITES OF HORSES, p 315.)

Giardiasis (see p 211) has been reported in a limited number of cases as a cause of intermittent diarrhea in horses. However, *Giardia* can also be found in the feces of a small number of healthy horses and is rarely recognized as a cause of diarrhea in horses. Cryptosporidia (see p 209) have been identified in the feces of both healthy and diarrheic foals. There is evidence that *Cryptosporidium* spp can cause diarrhea and even death in immunocompetent foals; cryptosporidia have been described as a cause of outbreaks of foal diarrhea on some farms.

SAND ENTEROCOLOPATHY

Consumption of large amounts of sand, which then accumulates in the large intestine, can produce diarrhea, weight loss, or colic. Sand is ingested when horses or foals are kept on sandy pasture or are fed hay or grain in a sandy area (paddock, stall, or pasture). Some horses or foals preferen-

tially eat dirt and sand if it is in their environment. A diagnosis is based on history of a sandy environment, the presence of sand in the feces, "sand sounds" on auscultation of the ventral abdomen, and (if available) abdominal radiographs that reveal the presence of sand in the large colon. Treatment involves use of a hemicellulose product (psyllium seed hull) administered via nasogastric tube or added to the grain daily. Diarrhea generally resolves within 2–3 days of initiation of treatment. Generally, 3–4 wk of treatment is necessary to remove most of the sand and may need to be repeated if the horse or foal is not removed from the source of sand. Preventive psyllium treatment (daily for 1 wk each month) has been used where sand enterocolitis is common. Several psyllium products are on the market; many horses prefer the pelleted over the powdered form. (See also p 262.)

RECURRENT DIARRHEA

Some horses develop semiformal feces when first introduced to lush pastures, alfalfa hay, or a temporarily stressful situation (eg, trailer ride, racing, showing, visit to a veterinary hospital). This change in fecal consistency is not of medical significance as long as the horse is healthy in all other regards, but owners may be concerned. It is important that horses with diarrhea have a physical examination and appropriate laboratory tests to exclude infectious causes and to determine whether treatment is required. Usually, the fecal consistency returns to normal when the horse adapts to its new diet or the stressful situation resolves.

INFILTRATIVE COLONIC DISEASE

Any process that causes a thickening of the wall of the large colon may interfere with absorption of fluid and result in chronic diarrhea, weight loss, and sometimes hypoproteinemia. Thickening may be due to neoplasia, inflammatory cells (such as lymphocytes, plasma cells, macrophages, or eosinophils), or scar formation from previous acute colitis.

Rectal palpation may help detect bowel thickening and mesenteric lymphadenopathy. Abdominal fluid cytology may reveal neoplastic cells. Ultrasonography can be used to determine the degree of thickening of the bowel wall (if the affected area of bowel can be imaged) and may reveal masses in the liver or spleen or on the peritoneal surfaces; a percutaneous biopsy

could provide a histopathologic diagnosis of neoplasia or inflammatory cell infiltrate. A biopsy of the rectal mucosa and duodenal mucosa (via 3-m endoscope) may be beneficial in diagnosis of inflammatory bowel disease and should also be cultured for *Salmonella*. Full-thickness jejunal, cecal, and colonic biopsies are more reliable for diagnosis of inflammatory bowel disease (see p 291) and can be obtained surgically either by standing flank laparotomy or recumbent ventral midline celiotomy. Surgical exploratory laparotomy can provide valuable information but is expensive and involves substantial risks of poor postoperative healing because of hypoproteinemia.

Treatment of abdominal neoplasia or inflammatory bowel disease is often unrewarding, but sometimes remission of clinical signs can be obtained with dexamethasone, especially with inflammatory bowel disease. Improvement of clinical signs and laboratory parameters with high-dose dexamethasone (0.1 mg/kg/day) treatment has been reported in three horses with clinical signs of GI tract lymphoma of T-cell origin. In two horses, the high-dose dexamethasone was followed by a lower dose (0.01–0.95 mg/kg/day) once clinical improvement occurred. Favorable responses persisted for >9 mo. The third horse had to be maintained on the higher dose of dexamethasone throughout treatment, because signs recurred whenever the dose was lowered. Clinical signs recurred despite high doses of dexamethasone, and after 2 mo of treatment the horse was euthanized. The mechanism of action of the steroid is speculated to be control of inflammation associated with the condition, as opposed to glucocorticoid-induced apoptosis.

MISCELLANEOUS CAUSES OF DIARRHEA

Other causes of diarrhea or semiformal to watery feces in horses include grain overload, thromboembolic disease of the colon, peritonitis, antibiotic treatment, renal failure, numerous toxicoses (eg, blister beetles [cantharidin], salt poisoning, slaframine, amitraz, propylene glycol, phosphorus, selenium, nicotine, reserpine, arsenic, mercury, monensin, organophosphates, oleander, Japanese yew, castor bean, avocado, thorn apple, potatoes, heath, algae, acorn or oak, *Hypericum*, corn cockle, mycotoxins, horse tail [scouring rush]), hyperlipidosis, and

resolving impact of the large intestine after treatment with oral cathartics such as magnesium sulfate.

DIARRHEAL DISEASE IN FOALS

FOAL HEAT DIARRHEA

From 4–14 days after birth, foals often develop a mild, self-limiting diarrhea. During this time, the dam is usually undergoing her first estrous cycle, hence the name “foal heat diarrhea.” However, diarrhea can also occur at this time in orphan foals; therefore, hormonal activity in the mare is unlikely to be involved in the pathogenesis. Although the cause is unknown, it may be associated with alterations in the foal's intestinal microbial flora or alteration in diet as the foal begins to eat small amounts of hay and grain. Coprophagy may also have a role.

The foal remains active and alert and has a normal appetite. Vital signs remain normal. Feces are semiformal to watery and not malodorous. Monitoring is important to ensure the foal's condition does not deteriorate. Specific treatment is usually not necessary, but application of a protectant to the skin around the perineum helps prevent scalding of the buttocks.

BACTERIAL DIARRHEA IN FOALS

Bacterial enterocolitis in neonatal foals can be a component of neonatal septicemia, and diarrhea can be seen with bacteremia of any cause. Organisms commonly involved in neonatal bacteremia and subsequent diarrhea in neonatal foals include *Salmonella* spp, *Escherichia coli*, and *Actinobacillus* spp. Although *E. coli* is the most important mediator of systemic sepsis in newborn foals, it is not as common as a primary cause of diarrhea in foals as it is in calves and piglets.

Intensive antimicrobial treatment, correction of fluid loss and electrolyte abnormalities, and nursing care are needed. Foals should be evaluated to determine whether adequate passive transfer of colostral antibodies has occurred; if not, a plasma transfusion is indicated. (See also SEPSIS IN FOALS, p 1728.) Markedly hypoproteinemic foals will benefit from plasma transfusion and/or administration of a plasma substitute such as hetastarch to improve oncotic pressure. IV fluid treatment without correction of the severe hypoproteinemia may induce pulmonary or peripheral edema.

An acute, fulminant, hemorrhagic diarrhea syndrome with high mortality in young foals <10 days old and commonly <3 days old has been associated with *Clostridium perfringens* type C infection (see p 285). Enterocolitis has also been associated with *C. perfringens* type A with or without $\beta 2$ toxin gene. The significance of this association is less clear than with type C, because type A has been identified in the feces in >90% of healthy neonatal foals in a farm-based study. It is possible that the number of bacteria and the phase of growth predispose to disease from type A. Infections may be sporadic or seen as outbreaks in multiple foals on a farm. Severe lethargy and rapid deterioration of cardiovascular status is followed by death in 24–48 hr in many cases. Intraluminal hemorrhage and extensive mucosal necrosis of the small intestine and, in some cases, the colon are found on necropsy.

Other bacteria that have been associated with diarrhea in foals are *Bacteroides fragilis*, *C. difficile* (see p 285), *Aeromonas hydrophila*, and *Rhodococcus equi*. Although *R. equi* primarily causes respiratory disease (see p 1451), both acute and chronic enteritis can cause diarrhea in foals 1–4 mo old. The diagnosis is more straightforward if pneumonia is also present. When cultured from tracheal wash fluid, *R. equi* is considered a pathogen; however, a positive fecal culture is not as helpful because *R. equi* can be found in the feces of healthy foals. Clarithromycin combined with rifampin is the treatment of choice for *R. equi* infection in foals. Other macrolides such as azithromycin or erythromycin can be used, but erythromycin can predispose to diarrhea and hyperthermia.

Equine Proliferative Enteropathy

(*Lawsonia intracellularis* infection)

Enteric infection with *Lawsonia intracellularis* causes proliferative enteropathy, resulting in outbreaks of diarrhea, rapid weight loss, colic, lethargy, subcutaneous edema, and protein-losing enteropathy in weanling foals. *Lawsonia* has a worldwide distribution and can affect many other species, including pigs, rodents, and ratites; it can survive in the environment for 2 wk, and a fecal-oral route of infection is speculated. *L. intracellularis* enters the enterocytes, avoiding lysosomal destruction. Infected cells continue to divide, resulting in hyperplastic crypts of immature epithelial cells that have a poorly developed brush border, leading to decreased

enzymatic activity and absorptive function. Decreased disaccharide activity results in maldigestion with subsequent overload of carbohydrates to the large colon and osmotic diarrhea. Hypoproteinemia results from a combination of malabsorption of amino acids and increased small-intestinal permeability and leads to low plasma oncotic pressure and subsequent ventral edema. Maldigestion and absorption of nutrients and protein-losing enteropathy result in weight loss and failure to thrive.

Affected foals range from 3–12 mo old, but those 4–6 mo old are most commonly infected. Stress may be a predisposing factor. Because of their debilitated state, infected foals are predisposed to secondary GI, skin, and respiratory infections. Morbidity and mortality rates are low if animals are treated appropriately, although sudden death has been reported. Marked hypoproteinemia (<4 mg/dL) with hypoalbuminemia (<1.5 g/dL) are the most common laboratory findings. The WBC count and fibrinogen concentrations tend to be normal to moderately increased. Anemia, hyponatremia, hypochloremia, and hypocalcemia may be seen. CK concentration is often mildly increased.

Diagnosis can be confirmed at necropsy with characteristic intracellular bacteria observed in silver-stained tissues. *L. intracellularis* can be confirmed using PCR analysis and immunohistochemistry on tissues collected at necropsy. Because *Lawsonia* is an intracellular organism, it does not grow on standard microbiologic culture media, and permissive cell lines are required for isolation. PCR can be used to detect *L. intracellularis* DNA in feces, but false-negative results can occur. Serology to detect antibodies to *L. intracellularis* is more sensitive than fecal PCR, but discrimination between infected foals and exposed foals can be difficult. Indirect fluorescent antibody test and immunoperoxidase monolayer antibody tests are currently the best serologic tests available. An ELISA is also available. Both fecal PCR and serologic testing are recommended. If either test is positive in the presence of hypoproteinemia, then treatment is warranted. Foals can remain seropositive for 6 mo after clinical signs resolve. Frequently, transabdominal ultrasonography reveals a markedly thickened small-intestine wall.

Differential diagnoses for proliferative enteropathy include salmonellosis, clostridiosis, *Neorickettsia risticii*, *R. equi*, parasitic infections, and any cause of infiltrative/inflammatory bowel disease.

Response to treatment is considered confirmation of the diagnosis. Lack of response to therapy after 7–10 days should prompt reassessment of the diagnosis.

Lawsonia is an intracellular pathogen, so antimicrobials must be lipophilic or amphoteric to concentrate within the host cytoplasm. Treatment with oxytetracycline (6.6 mg/kg, IV, bid for 3–7 days) followed by doxycycline (10 mg/kg, bid for 14 days) has been successful. Mild cases respond to oral doxycycline alone. Alternatives include erythromycin (alone or in combination with rifampin) for 3–4 wk or chloramphenicol. Plasma transfusions are required only in the most severely affected foals. Glucocorticoids are not recommended. Response to therapy is indicated by improvement in attitude, appetite, and weight gain. Resolution of hypoproteinemia may take 4–5 wk and small-intestinal thickening 4–8 wk. With treatment, ~90% of foals usually survive.

VIRAL DIARRHEA IN FOALS

Viruses appear to cause diarrhea in foals but rarely affect adult horses. Rotavirus is the main cause of viral diarrhea in foals; however, other viruses (eg, coronavirus) have been implicated. Diarrhea induced by rotavirus is characterized by depression, anorexia, and profuse, watery, malodorous feces. It is usually seen in foals <2 mo old; younger foals typically have more severe clinical signs. The diarrhea usually lasts 4–7 days, although it can persist for weeks.

Rotavirus destroys the enterocytes on the tip of the villi in the small intestine, which results in malabsorption. Lactase becomes deficient, so lactose passing into the large intestine induces an osmotic diarrhea. Diagnosis is made by identification of virus in the feces by electron microscopy or commercial immunoassay kits designed for detection of human rotavirus. Requesting that the laboratory test specifically for rotavirus, collecting feces early in the course of disease, and sampling several foals improve the chances of virus detection.

Treatment is generally supportive. Certain farm management practices and disinfection techniques have effectively limited the spread of rotavirus during outbreaks. Sick foals are highly contagious and should be isolated in the stall in the barn in which the foal originally became ill or moved to a designated isolation facility. Personnel should wear disposable gloves and cleanable boots and wash their hands with soap before and after handling diarrheic foals. Foot dips

containing phenolic disinfectants outside the stalls of sick foals should also be used. Specific stall-cleaning equipment should be designated only for cleaning the stalls of diarrheic foals. Once the stall has been vacated, it should be cleaned of particulate material, washed with detergent, and then disinfected with phenolic compounds that meet EPA standards. Bleach, chlorhexidine, and quaternary compounds do not appear to be effective disinfectants for rotavirus. Fecal material of sick foals removed from stalls should not be spread on pastures used for horses and foals, and care should be taken to avoid fecal contamination of alleyways. All stall-cleaning equipment should be disinfected. Stalls with dirt floors are difficult to adequately clean and disinfect. Removal of the top layers of dirt may be required.

Arriving horses and foals, including those returning from veterinary hospitals, should be isolated for ≥ 7 days before being introduced to the resident population. A vaccine for pregnant mares to induce colostral antibodies directed at reducing the risk of rotavirus infection in their foals is available.

MISCELLANEOUS CAUSES OF DIARRHEA IN FOALS

Nutritional diarrhea can result from overfeeding (eg, when a foal is reunited with the mare after a period of separation) and improper nutrition (eg, orphan foals being fed calf milk replacer or sucrose). Lactose intolerance in foals is rare and can be determined by lactose tolerance challenge tests or clinical response to supplemental lactase. Diarrhea can also develop when foals consume indigestible substances such as roughage, sand, dirt, and rocks. Diarrhea in foals has been reported to be associated with infection by *Strongyloides westeri*, *Parascaris equorum*, and *Cryptosporidium* spp. (See also GASTROINTESTINAL PARASITES OF HORSES, p 315.)

WEIGHT LOSS AND HYPOPROTEINEMIA

The causes for weight loss in horses are numerous and can involve many body systems. This discussion is confined to diseases of the GI tract. Protein loss may or may not be associated with weight loss. The disorders commonly associated with either of these signs are neoplasia, inflammatory bowel disease, and toxicosis from treatment with NSAIDs.

GASTROINTESTINAL NEOPLASIA

Squamous cell carcinoma of the stomach and the alimentary form of lymphosarcoma are the most common forms of neoplasia involving the GI tract in horses. Chronic weight loss may be the primary clinical sign. Chronic diarrhea and hypoalbuminemia may develop when lymphosarcoma has infiltrated the wall of the intestine.

Because the incidence of GI neoplasia is low, other causes of weight loss should be investigated first. Diagnosis is usually made by exclusion of other causes of weight loss and by histopathologic examination of the tissue collected by duodenal or rectal mucosal biopsy during exploratory laparotomy or at necropsy. Squamous cell carcinoma of the stomach can be diagnosed by gastroscopy. An endoscope 2–3 m long is necessary to examine the gastric mucosa of adult horses. In horses with lymphosarcoma, enlarged mesenteric lymph nodes or thickened bowel may be detected by rectal palpation or by ultrasonographic examination. Occasionally, neoplastic cells are identified by cytologic examination of abdominal fluid. Ultrasonography may reveal masses in the liver or spleen, as well as facilitate percutaneous biopsy of the masses. An exploratory laparotomy with biopsy of intestinal or other masses can provide a definitive diagnosis.

Treatment of GI neoplasia in horses is generally not attempted, and the prognosis is grave. There have been a few reports of surgical removal of the affected segment of bowel. Chemotherapy may be an option for some horses, and corticosteroid therapy may prolong survival time in some cases.

INFLAMMATORY BOWEL DISEASE

This collection of diseases includes granulomatous enteritis (GE), lymphocytic-plasmacytic enterocolitis (LPE), multisystemic eosinophilic epitheliotropic disease (MEED), and idiopathic focal eosinophilic enterocolitis (IFEE). Disease is characterized by infiltration of the small and large intestine with inflammatory cells, including lymphocytes, plasma cells, macrophages, and eosinophils. The inflammatory condition may be limited to only a short segment of the bowel or be more diffuse. Malabsorption and a protein-losing enterocolopathy result. Diarrhea may or may not be a clinical feature. Inflammatory bowel disease should be considered in the differential diagnosis of horses with weight loss, recurrent colic, or hypoproteinemia, as well as in some horses with generalized skin disease.

Diagnosis is based on clinical signs, low serum protein concentration, possible thickened bowel (identified by ultrasonography or on rectal palpation), malabsorption, and intestinal or rectal biopsy. Malabsorption of carbohydrates occurs secondary to severe villous atrophy throughout the small intestine. Failure to absorb oral glucose or D-xylose verifies malabsorption from the small intestine.

Histologic diagnosis is subjective and should be performed by a pathologist experienced in reading equine intestinal biopsies. Rectal mucosal biopsy is useful in the diagnosis of ~50% of cases of GE and MEED but is rarely helpful in the diagnosis of LPE and IFEE. High numbers of eosinophils and lymphocytes can be identified in the intestinal wall of normal horses, but overinterpretation should be avoided. The presence of eosinophilic granulomas, vasculitis, and fibrinoid necrosis of intramural vessels is diagnostic of MEED. Horses with MEED may have severe dermatitis, eosinophilic infiltrations in the liver or pancreas, and sometimes marked eosinophilia. Horses with IFEE have eosinophilic infiltration restricted to the intestine and have a better prognosis for survival. Full-thickness intestinal biopsies can be obtained by using a laparoscopic procedure via a flank incision or by ventral midline celiotomy. Because most of the horses have severe hypoproteinemia at the time of diagnosis, incisional healing can be problematic.

The pathophysiology of the various syndromes is not well understood. An altered immune response to a common intestinal factor (eg, feed, parasites, bacteria) has been suggested. Histopathologic similarities exist between GE in horses, Johne's disease in cattle, and Crohn's disease in people. Standardbreds seemed to be predisposed to GE and MEED, which suggests possible genetic predisposition.

Various medical treatments have been tried with limited success. Corticosteroids, dietary alterations, metronidazole, and the antimetabolite azathioprine have been used. Hyper eosinophilic syndrome in people often responds to hydroxyurea or vincristine, and sometimes interferon- α and cyclosporine are used. Supportive nutritional care should involve frequent feeding of good-quality, high-energy feeds. The prognosis is grave. If only a limited and accessible section of the bowel is affected, surgical removal may be successful. This is more common in IFEE, in which horses commonly present with colic rather than weight loss. Focal thickening, sometimes restricted to circumferential

mural bands, is detected via exploratory laparotomy or necropsy; a diagnosis can be made by subsequent histopathology. Horses with IFEE respond to surgical resection of the diseased segment of intestine. Medical treatment with corticosteroids and feeding small frequent meals has also led to resolution of clinical signs after small-intestinal decompression without resection.

NSAID TOXICOSIS

The toxicity of NSAIDs is related to COX selectively, dosage, and duration (*see* p 2110). It is hypothesized that nonselective COX inhibitors have greater risk of toxicity than COX-selective drugs. COX inhibitors also cause delayed GI healing. The GI tract and kidneys are most commonly affected by NSAID toxicity. NSAID-induced injury can occur anywhere in the GI tract, but the large colon (especially the right dorsal colon) and gastric mucosa appear to be the most sensitive. The ulcerogenicity of phenylbutazone is greater than that of flunixin meglumine, which has greater ulcerogenicity than ketoprofen. The COX-2 selective inhibitor firocoxib appears to be safer. Ulcerative lesions in the large colon lead to a protein-losing enteropathy, often with clinical signs of ventral edema, anorexia, lethargy, weight loss, diarrhea, and colic. Scarring of the right dorsal colon can occur leading to large-colon impactions, sometimes requiring large-colon resection.

Phenylbutazone administered at high doses or for prolonged periods causes a protein-losing enterocolopathy in horses. However, some horses are inherently sensitive to NSAIDs, and right dorsal colitis can occur at lower than recommended dosages. Toxicosis can develop from oral or parenteral administration of NSAIDs. Hypoproteinemia (hypoalbuminemia and hypoglobulinemia) is seen due to loss of protein into the intestinal lumen, which can occur without visible ulceration. Renal papillary necrosis may also be seen. Administration of flunixin meglumine at high doses or for prolonged periods can result in a singular toxicosis.

Clinical signs of NSAID toxicity include difficulty in mastication due to oral and lingual ulceration, hypersalivation, and signs of pain when swallowing due to esophageal ulceration. Gastric ulceration can result in recumbency after eating, signs of colic, and anorexia. Horses with colonic ulceration can have soft feces, diarrhea, and ventral edema. Intestinal ulceration can be severe enough to allow endotoxin and

bacterial translocation and signs of systemic inflammation and septicemia. Dehydration, fever, and tachycardia can occur in severe cases. Clinical signs can occur days to weeks after NSAID therapy. More chronic cases present with recurring colic, weight loss, and soft feces.

A tentative diagnosis can be made based on history of NSAID administration, clinical signs, and presence of hypoproteinemia. Severe cases may have hyponatremia, hypochloremia, hypocalcemia, and acidemia in addition to hypovolemia. Ultrasonography may detect thickening of the colon. Gastric ulceration can be confirmed by gastroscopy but requires an endoscope 2–3 m long.

Treatment includes discontinuing use of phenylbutazone or any other NSAID. In acute toxicosis, administration of 1 gal. of mineral oil repeated after 2 hr may be beneficial to decrease drug absorption. To help prevent gastric ulceration, reducing production of gastric acid with an H_2 -receptor blocker (eg, ranitidine) or a proton pump inhibitor (eg, omeprazole) may be beneficial; sucralfate may be indicated as well. Administration of misoprostol (a synthetic prostaglandin analogue) may be beneficial but can cause additional signs of diarrhea and colic. IV fluid therapy is indicated in cases of hypovolemia, especially with concurrent azotemia. Plasma

transfusion or synthetic colloids can be used to increase plasma oncotic pressure.

Longterm dietary management consisting of a low-fiber complete pelleted ration fed several times throughout the day, and elimination of roughage is recommended. Corn oil can be given to provide supplemental calories and may help heal damaged intestinal mucosa. Psyllium mucilloid can also promote colonic healing by increasing the concentration of short-chain fatty acids. Surgery may be required if scarring of the bowel has resulted in partial obstruction of the intestine.

Prevention of NSAID toxicity involves limiting the dose and duration of NSAID treatment, using a COX-2 selective NSAID, or relying on alternative analgesic therapy. Monitoring for fecal consistency and serum albumin concentrations are easy methods to detect the development of right dorsal colitis in horses receiving NSAIDs.

SMALL-INTESTINAL FIBROSIS

Extensive fibrosis of the submucosa of the small intestine has been associated with weight loss and recurrent colic in adult horses on pasture in northern Colorado. All affected horses died or were euthanized because of their deteriorating condition. The cause is unknown.

INTESTINAL DISEASES IN PIGS

Pigs of all ages are susceptible to intestinal diseases, and diarrhea is the sign common to nearly all such disorders. Transmission of infectious agents that cause enteropathies is by the fecal-oral route. At least 16 different etiologic agents, including bacteria, viruses, and parasites, can cause primary intestinal disease. Porcine circovirus type 2 (PCV 2) virus may be isolated from the intestines of pigs with diarrhea. PCV 2 is the cause of several multisystemic diseases in pigs, including postweaning multisystemic wasting syndrome (see p 723). Diarrhea in a herd may be due to a single agent, but concurrent infections are common. Because some diseases are age-dependent, differential diagnosis is best considered by age group (see TABLE 6).

CLOSTRIDIUM DIFFICILE ENTERITIS

C difficile is an important emerging pathogen that causes diarrhea primarily in neonatal swine. The agent was first recognized as a cause of antibiotic-associated diarrhea in people. It most commonly causes disease in piglets 1–7 days old and in other domestic and laboratory animals.

Etiology and Pathogenesis: *C difficile* is an anaerobic, gram-positive, sporeforming rod that is more oxygen-sensitive than *C perfringens*. The organism can be demonstrated in the intestine by direct Gram stain of smears. Survival of *C difficile* in the environment and shedding by carrier sows is believed to be important in transmission.

TABLE 6 AGE DISTRIBUTION OF DIARRHEAL DISEASES IN PIGS

	Age Group		
	Nursing	Weaning	Growing-finishing or Breeding
BACTERIAL DISEASES			
<i>Clostridium difficile</i> enteritis	+++	+	+
<i>C perfringens</i> type A enteritis	++	+	—
<i>C perfringens</i> type C enteritis	++	—	—
Enteric colibacillosis	+++	+++	—
Intestinal spirochetosis	—	++	+++
Porcine proliferative enteritis	—	++	+++
<i>Salmonella</i> enteritis	+	++	+++
Swine dysentery	+	++	+++
PARASITISM			
<i>Cryptosporidium</i> sp	+	+	—
<i>Iso spor a suis</i>	+++	+	—
<i>Strongyloides ransomi</i>	+	+	+
<i>Trichuris suis</i>	—	—	++
VIRAL DISEASES			
Porcine circovirus diarrhea	+	++	+
Porcine epidemic diarrhea	+++	+++	++
Rotaviral enteritis	+++	+++	+
Transmissible gastroenteritis	+++	+++	++

— Rare or does not occur; + Uncommon; ++ Common; +++ Very common

C difficile produces “large clostridial toxins” A and B, which are thought to be involved in lesion production. Toxin A is an enterotoxin that causes fluid secretion into the gut lumen, and toxin B is a cytotoxin.

Clinical Findings: Affected piglets may have dyspnea, abdominal distention, and scrotal edema. Diarrhea may not be present in all pigs affected.

Lesions: Ascites, hydrothorax, and edema of the ascending colon have been reported. Urates are commonly present in the kidneys. Pasty to watery colonic contents may be seen. Microscopically, the colon is primarily affected with multifocal exudation of mucus and fibrin plus submucosal edema.

Diagnosis: Gross lesions are not pathognomonic, and diagnosis must be confirmed by culture or demonstration of either toxin A or B and histopathology. *C difficile* can be cultured on selective media containing cefoxitin, cycloserine, taurocholate, and fructose under anaerobic conditions. The genes of toxins A and B are identified readily by PCR. The toxins can also be detected directly in suspensions of intestinal contents by commercially available enzyme immunoassays.

Treatment and Control: Based on minimum inhibitory concentration determinations, it has been suggested that erythromycin, tetracycline, and tylosin may be useful for treatment of suckling piglets,

and tiamulin and virginiamycin may help to reduce levels of the organism in adult swine. No controlled studies on the effect of antibiotics on clinical disease have been reported.

CLOSTRIDIUM PERFRINGENS TYPE A ENTERITIS

Infection of the small intestine by type A strains of *C. perfringens* is a milder condition and rarer than disease caused by *C. perfringens* type C (see below). Suckling and sometimes weaned pigs are affected and exhibit yellow-colored feces with mucous and flecks of blood. Growth rates are suppressed but with low to no mortality. The lesions at necropsy are milder and bloodfree as compared with those of *C. perfringens* type C enteritis. Diagnosis, treatment, and control are as for *C. perfringens* type C enteritis.

CLOSTRIDIUM PERFRINGENS TYPE C ENTERITIS

Infection of the small intestine by type C strains of *C. perfringens* causes a highly fatal, necrohemorrhagic enteritis. It most commonly affects piglets 1–5 days old but may be seen in pigs up to 3 wk old (and in other species, see p 609).

Etiology and Pathogenesis: The organism penetrates between the absorptive cells of the upper jejunum and elaborates β toxin, a potent, heat-labile, trypsin-sensitive exotoxin that causes necrosis of all structural components of the villi. Necrotizing inflammation usually extends to the mucosal crypts. The infection may continue caudally and involve the ileum, but it rarely affects the colon. Necrosis of the mucosa is accompanied by blood loss into the intestinal wall and lumen.

Clinical Findings: Sudden onset of hemorrhagic diarrhea followed by collapse and death is characteristic in piglets 1–3 days old. In less acute cases, brownish liquid feces develop at 3–5 days. Infrequently, pigs develop a persistent, pasty, gray diarrhea and become progressively emaciated. In peracute cases, the perineal region is blood stained.

Lesions: The small intestines are dark red, hemorrhagic, and filled with hemorrhagic liquid. Less acute cases at 3–5 days may have gas bubbles in the wall of the jejunum and necrosis of the mucosa of the

jejunum and ileum. More chronic cases have a thickened small intestine lined by a pale yellow or gray necrotic membrane tightly adhered to the submucosa.

Diagnosis: Necropsy is usually sufficient to establish the diagnosis in the peracute hemorrhagic form and in the acute form with jejunal emphysema. A rapid presumptive diagnosis can be made by demonstrating large rod-shaped bacteria in gram-stained mucosal impression smears. Histologic demonstration of villous necrosis with mucosal colonization by numerous large gram-positive rods is adequate for confirmation. Subacute and chronic forms of the disease in piglets 6–14 days old are easily confused at necropsy with *Isospora suis* enteritis, but diagnosis is usually possible by histologic examination of the jejunum and ileum or by observation of clostridia in mucosal smears (Gram or Giemsa stain). Isolates of *C. perfringens* may be genotyped for the presence of genes that code for β toxin.

Treatment and Control: Treatment of pigs with clinical signs is of little benefit because lesions usually are irreversible at the onset of diarrhea. In an acute outbreak, prophylactic administration of type C antitoxin or antibiotic (or both) parenterally or PO is protective if given to piglets within 2 hr of birth. The disease tends to recur on infected premises. Vaccination of gestating sows at 6 and 3 wk before parturition with type C bacterin-toxoid confers some passive lactogenic immunity to subsequent litters, if piglets consume colostrum soon after birth. Once immunized with two doses of bacterin-toxoid, sows should receive one dose ~3 wk before each subsequent farrowing.

Clostridium perfringens enteritis in a piglet. Note the large numbers of gram-positive rods adhering to the necrotic jejunal epithelium. Courtesy of Dr. John Prescott.

EDEMA DISEASE

(*Escherichia coli* enterotoxemia)

Edema disease is an acute, highly fatal, neurologic disorder usually seen 5 days to 2 wk after weaning and possibly accompanied by diarrhea (see p 716).

ENTERIC COLIBACILLOSIS

Enteric colibacillosis is a common disease of nursing and weanling pigs caused by colonization of the small intestine by enterotoxigenic strains of *Escherichia coli*.

Etiology and Pathogenesis: Certain strains of *E coli* possess fimbria or pili that allow them to adhere to or colonize the absorptive epithelial cells of the jejunum and ileum. The common antigenic types of pili associated with pathogenicity are K88, K99, 987P, and F41. Pathogenic strains produce enterotoxins that cause fluid and electrolytes to be secreted into the intestinal lumen, which results in diarrhea, dehydration, and acidosis. Infection in neonates is commonly caused by K88 and 987P strains, whereas postweaning colibacillosis is nearly always due to the K88 strain.

Clinical Findings: Profuse watery diarrhea with rapid dehydration, acidosis, and death is common. Rarely, pigs may collapse and die before diarrhea begins.

Lesions: Dehydration and distention of the small intestine with yellowish, slightly mucoid fluid is characteristic. The colon contains similar fluid. The fundic portion of the gastric mucosa is often reddened. Pigs dying suddenly may have patchy cutaneous erythema. Histologically, the villi are usually of normal length and have many small bacterial rods adhered to the absorptive enterocytes.

Diagnosis: Confirmation is based on histologic observation of villous colonization; demonstration of K88, K99, 987P, or F41 pilus antigens in intestinal scrapings by immunofluorescence or other immunologic procedures; and isolation of the organism from the small intestine. Because *E coli* is a common secondary agent, the possibility of involvement of other agents such as viruses or coccidia should be considered.

Treatment and Control: Therapy includes prompt treatment with antibacterials and restoration of fluid and electrolyte balance. Bacterial antibiotic sensitivity testing is helpful to identify effective

medication. Prevention includes reducing predisposing factors, such as dampness and chilling; improving sanitation, such as by replacing solid or slatted concrete flooring with wire-mesh flooring; and vaccinating gestating sows with pilus-specific vaccines. Pigs lacking receptors for K88 have been shown to be resistant to disease caused by enterotoxin-positive K88-positive *E coli*.

HEMORRHAGIC BOWEL SYNDROME

(Mesenteric torsion of the small intestine)

Hemorrhagic bowel syndrome affects rapidly growing swine 4–6 mo old. Pigs die suddenly without evidence of diarrhea, but the small intestine is thin-walled on necropsy and filled with either clotted or unclotted blood. The large intestine usually contains tarry fecal material but no lesions suggestive of swine dysentery, salmonellosis, proliferative enteritis, or intestinal spirochetosis. The condition can be prevented by the administration of either bacitracin or chlortetracycline in the feed. When performing a necropsy, the mesenteric root should be palpated before opening the abdomen. A peracute form of proliferative enteritis may have similar clinical and gross lesions; however, histology and culture of the intestine will discern the presence or absence of epithelial proliferation and *Lawsonia intracellularis*.

The cause in most cases is believed due to intestinal volvulus. Predisposing factors may include vigorous exercise, handling, fighting, piling, or irregular feeding. Long-loined pigs may be more likely to develop mesenteric torsion than shorter pigs. Rotation of the entire intestine, including the posterior part of the duodenum and the anterior part of the rectum, around the root of the mesentery obstructs venous outflow of blood, which causes blood to pool and stagnate in the intestine and soon results in infarction. Rotation may be only partial and difficult to demonstrate at necropsy, which makes diagnosis more challenging.

INTESTINAL SALMONELLOSIS

Enteropathogenic salmonellae cause inflammation and necrosis of the small and large intestines, resulting in diarrhea that may be accompanied by generalized sepsis. All ages are susceptible, but the disease is most common in weaned and growing-finishing pigs.

Etiology and Pathogenesis:

Salmonella Choleraesuis kunzendorf (*S* Choleraesuis) is one of the most common *Salmonella* species affecting pigs. It sometimes produces necrotizing enterocolitis but far more common is a septicemic disease characterized by hepatitis, pneumonia, and cerebral vasculitis. *S* Typhisuis infection of the intestine results in necrotizing, nonsuppurative inflammation of the mucosa and submucosa of the ileum, cecum, and colon; frequently, the mucosa is ulcerative. Usually, there is extension to regional lymph nodes and, occasionally, generalized septicemia. Sources of infection for *S* Choleraesuis and *S* Typhisuis are primarily asymptomatic carrier pigs but also may include rodents and contaminated feed and premises. (See also SALMONELLOSIS, p 195.)

Numerous other serotypes of salmonellae are seen in pigs, some of which have been associated with human foodborne illness. Common serotypes seen in pigs are *S* Typhimurium, *S* Derby, *S* Heidelberg, *S* Worthington, and *S* Infantis. These serotypes may cause mild to moderate diarrhea in swine and may be resistant to multiple drugs.

Clinical Findings: Nursing pigs may develop diarrhea but usually succumb to generalized septicemia. Weanling or growing-finishing pigs are febrile and have liquid feces that may be yellow and contain shreds of necrotic debris.

Lesions: Pigs infected with *S* Choleraesuis have an inflamed, slightly thickened ileum and colon, usually with necrotic debris on the mucosal surface. Mesenteric lymph nodes are enlarged, edematous, and sometimes red. Mucosal ulceration may or may not be evident. A small amount of hemorrhage may be seen in acute cases. Occasionally, rectal strictures (see p 300) may develop. Other enteropathogenic salmonellae, except for *S* Typhisuis, produce lesions similar to but less severe than those of *S* Choleraesuis. Lesions of *S* Typhisuis enteritis are distinctive, typically yellow, round (button) ulcers in the colon, cecum, and less commonly the ileum.

Diagnosis: Culture of feces or intestinal mucosa in a selective medium may yield the organism. However, salmonellae often are isolated (and more reliably) from enlarged mesenteric lymph nodes by direct streaking on a selective medium such as brilliant green agar or by inoculation of enrichment media. Histologic examination of affected

intestine and liver to differentiate salmonellosis from proliferative enteritis and swine dysentery is a valuable adjunct procedure.

Treatment and Control: Live avirulent vaccines administered either intranasally or via the water are very effective for prevention of disease caused by *S* Choleraesuis. Avirulent vaccines may also effectively reduce levels of salmonellae in the tissues of swine at slaughter. Parenteral administration of antibacterials to acutely ill pigs and medication of the affected group via water or feed may decrease the severity of the outbreak. Neomycin and lincomycin-spectinomycin are the most often used water medications. Carbadox in the feed is often used as a preventive. Susceptibility testing of the isolated organism is useful to select an appropriate antibacterial. Thorough cleaning and disinfection of contaminated facilities and elimination of the source of the organism decrease the likelihood of repeated epidemics.

INTESTINAL SPIROCHETOSIS

Intestinal spirochetosis is a disease of the large intestine seen in the absence of *Brachyspira hyodysenteriae* (see SWINE DYSENTERY, p 301). This disease syndrome is being recognized more frequently worldwide.

Etiology and Pathogenesis: The primary cause of intestinal spirochetosis is *Brachyspira pilosicoli*. Other weakly β -hemolytic *Brachyspira* associated with the condition are *B* *intermedia* and *B* *murdochii*. *B* *innocens* appears not to cause disease at all. *B* *pilosicoli* is emerging as a significant pathogen of people, especially in indigenous populations, homosexuals, and immunosuppressed patients. The organism is transmitted orally and survives extremely well in the environment. *B* *pilosicoli* has been isolated from a wide variety of animals, including waterbirds, rodents, and dogs. It has been shown to cause diarrheal disease in pigs, chickens, and people by experimental inoculation and in natural occurrence. The pathogenesis is not well studied, but apparently the end-on attachment of the spirochete to the mucosal surface interferes with the absorptive capacity of the colon, resulting in diarrhea.

Clinical Findings: Pigs initially have sticky feces on the perineum. The feces will appear as wet cement, and a mild diarrhea

may result. Affected pigs may be inappetent and grow slowly.

Lesions: The lesions in the large intestine are milder than those caused by *B hyodysenteriae* in swine dysentery. The volume of the large intestine may be increased and distended with thickening of the mucosa. In some pigs, a mucohemorrhagic colitis develops in association with enlarged mesenteric lymph nodes. Microscopically, spirochetes may be seen attached end-on to the mucosal surface and give the appearance of a false brush border. The mucosal surface has focal erosions with mild catarrhal exudate. Colonic crypts are often dilated, containing numerous spirochetes.

Diagnosis: Important differential diagnoses include salmonellosis, proliferative enteritis, swine dysentery, and whipworm infection. *B pilosicoli* and other weakly β -hemolytic *Brachyspira* can be isolated on selective agar under anaerobic conditions. Biochemical tests and preferably PCR should be performed on *Brachyspira* isolates to confirm species identification.

Treatment and Control: Treatment and prevention of intestinal spirochetosis is similar to that of swine dysentery. Drugs such as tiamulin, lincomycin, and carbadox are effective. It is unknown whether the agent can be eradicated without total depopulation, as in swine dysentery, but because of the reservoir hosts and environmental survival it is doubtful.

PARASITISM

See also p 320 and see p 208.

Ascaris suum is the most common intestinal nematode of pigs. Adults in the intestine reduce feed efficiency, and heavy infections cause emaciation. Larval migration incites inflammation in the liver and lungs.

Cryptosporidium sp is a coccidium that attaches to the mucosal epithelium of the intestine of pigs ≥ 10 days old. It causes villous atrophy in the lower small intestine. Malabsorption and diarrhea may result.

Eimeria spp are common in pigs, but overt disease is seldom seen. Heavy infections may cause significant enterocolitis in young growing pigs.

Hyoststrongylus rubidus is the common stomach worm found in pasture-raised pigs. It usually causes little harm.

Isospora suis is a common and important cause of coccidiosis in piglets 6 days to 3 wk

old. Infection causes necrosis and villous atrophy of the ileum and jejunum. Secondary bacterial infection of the injured intestinal mucosa is common. Mortality often is 20%–25%, and many pigs are stunted. Diagnosis can be based on identification of immature coccidial forms in the intestinal mucosa by direct mucosal smear (Giemsa stain) or by histologic examination of the affected intestine. Successful prevention most commonly depends on thorough cleaning of farrowing facilities to minimize the number of oocysts. After cleaning, thorough disinfection with 50% bleach has been useful. Coccidiostats are sometimes fed to sows 2 wk before farrowing or administered PO to pigs from birth to 3 wk of age.

Adult nodular worms of *Oesophagostomum* spp in the large intestine cause little harm, but heavy infection by larvae encysted in the intestinal wall may lead to emaciation.

Strongyloides ransomi (intestinal threadworm) larvae can be transmitted via colostrum or acquired from contaminated skin of the dam. Heavily infected piglets develop severe diarrhea when 10–14 days old, with high mortality. Diagnosis is based on direct microscopical observation of mucosal scrapings.

Trichuris suis (whipworms) penetrate the mucosa of the cecum and colon and cause multifocal inflammation. Heavy infections cause diarrhea and emaciation. The feces are hemorrhagic; therefore, heavy whipworm infections may be confused clinically with swine dysentery or proliferative enteritis. Diagnosis is based on direct observation of whipworms in the large intestine or on fecal flotation.

PORCINE EPIDEMIC DIARRHEA

This coronaviral diarrhea affects pigs of all ages and clinically resembles transmissible gastroenteritis (TGE, see p 302) in several respects.

Etiology and Epidemiology: The porcine epidemic diarrhea (PED) virus is not related to any other member of the Coronaviridae. Pigs are the only known host. Antibodies to the virus have not been found in wild pigs or in other animal species. Infections have been seen in most European countries and in China. In April 2013, disease due to PEDV was diagnosed in the USA for the first time. Large epidemics occurred in Europe in 1969; no antibodies have been found in sera collected before 1969. Since then, the virus has become

widespread and endemic in several European countries, and acute outbreaks have become rare. On large breeding farms, the virus persists in consecutive litters of pigs after weaning and after they lose their immunity from antibody in the milk. On these farms, the virus may be associated with weaning diarrhea. In Belgium, the virus is most frequently associated with diarrhea in feeder pigs, which develops shortly after they are gathered from different breeding farms and assembled in large fattening units. The virus was demonstrated in fecal material in 80% of these groups. Outbreaks in the USA caused 60%–100% mortality in suckling pigs and mild to severe diarrhea in all pigs of all ages; they were initially believed to be outbreaks of TGE. Spread of the virus mainly occurs directly through infected pigs and indirectly through virus-contaminated fomites and via transport trucks.

Pathogenesis: The pathogenesis and immune mechanisms are similar to those reported for TGE. Oral infection results in viral replication in the epithelial cells of the small intestinal villi. Cells on colonic villi also become infected. No other tissue tropisms have been shown. Virus is excreted in the feces.

Clinical Findings: Diarrhea is the only direct virus-induced clinical sign seen. An acute outbreak on a susceptible breeding farm resembles a TGE outbreak and is characterized by watery diarrhea in pigs of all ages. However, as compared with TGE, the incubation period is longer (3–4 days), not all the litters of suckling pigs may become sick, and mortality in neonatal pigs is lower (average 50%). Also, the disease within the farm spreads more slowly. In all outbreaks, signs are most consistently seen in feeders, finishers, and adults, which appear to be most susceptible because outbreaks often start in these age groups. Older pigs are more lethargic and depressed with PED than with TGE. Sick pigs appear to have colic.

Acute outbreaks in susceptible finishing pigs are characterized by watery diarrhea, but a markedly increased number of acute deaths may be seen, particularly in pigs infected toward the end of the finishing period and in stress-sensitive breeds. Death may even occur during the incubation period.

Lesions: Macroscopic lesions are confined to the small intestine, with villous shortening as the main characteristic. These lesions closely resemble those seen with

TGE. No lesions have been described in the colon. A consistent finding is acute necrosis of back muscle.

Diagnosis: Clinical differentiation from TGE is difficult. TGE in its typical epidemic form causes a rapidly spreading diarrhea in animals of all ages, with high mortality in neonates. With PED, the diarrhea spreads at a slower rate, and although diarrhea is seen in most of the litters, some litters may remain healthy even in the absence of immunity. Morbidity is 100% in older pigs, and they are severely sick. Acute deaths in adults and finishing pigs due to muscle necrosis and that occurs during an outbreak of diarrhea are typical of PED and are not seen with any other infectious diarrhea.

Laboratory diagnosis in neonates is made by PCR and/or direct immunofluorescence on cryostat sections of small intestine or colon. ELISA to detect viral antigens in feces or intestinal contents is more useful for older pigs. Antibodies can be detected in paired serum samples through ELISA-blocking.

Control: No specific treatment is available. Measures taken during an outbreak are of a general nature. Pigs with diarrhea should have free access to water, and finishing pigs should have feed withheld for 1–2 days.

PED virus can be eliminated from herds without total depopulation by maximizing immunity with planned infection of the sow herd; an “all-in/all-out” management of farrowing, nursery, and grower rooms; and good sanitation.

Because PED virus is easily spread during an epidemic by people, animals, and fomites, special care should be taken to prevent spread to unexposed groups of pigs and to neighboring herds. The use of vaccines for prevention has not been well documented.

PORCINE PROLIFERATIVE ENTERITIS

(Porcine intestinal adenomatosis, Proliferative hemorrhagic enteropathy, Ileitis)

Porcine proliferative enteritis is a common diarrheal disease of growing-finishing and young breeding pigs characterized by hyperplasia and inflammation of the ileum and colon. It often is mild and self-limiting but sometimes causes persistent diarrhea, severe necrotic enteritis, or hemorrhagic enteritis with high mortality.

Etiology and Pathogenesis: The etiology is *Lawsonia intracellularis*, an intracellular, gram-negative, small rod-shaped bacterium. The organism has been cultivated only in cell cultures, and attempts to propagate it in cell-free medium have failed. Koch's postulates have been fulfilled by inoculation of pure cultures of *L. intracellularis* into conventionally reared pigs; typical lesions of the disease were produced, and *L. intracellularis* was reisolated from the lesions. Inoculation of *L. intracellularis* into gnotobiotic pigs does not cause the disease; therefore, other factors in the conventionally reared pig may contribute to development of lesions.

Clinical Findings: The more common, nonhemorrhagic form of the disease often affects 40- to 80-lb (18- to 36-kg) pigs and is characterized by sudden onset of diarrhea. The feces are watery to pasty, brownish, or faintly blood stained. After ~2 days, pigs may pass yellow fibrinonecrotic casts that have formed in the ileum. Most affected pigs recover spontaneously, but a significant number develop chronic necrotic enteritis with progressive emaciation. The hemorrhagic form is characterized by cutaneous pallor, weakness, and passage of hemorrhagic or black, tarry feces. Pregnant gilts may abort.

Lesions: Lesions may be seen anywhere in the lower half of the small intestine, cecum, or colon but are most frequent and obvious in the ileum. The wall of the intestine is thickened, and the mesentery may be edematous. The mesenteric lymph nodes are enlarged. The intestinal mucosa appears thickened and rugose, may be covered with a brownish or yellow fibrinonecrotic membrane, and sometimes has petechial hemorrhages. Yellow necrotic casts may be found in the ileum or passing through the colon. Diffuse, complete mucosal necrosis in chronic cases causes the intestine to be rigid, resembling a garden hose. Proliferative mucosal lesions often are in the colon but are detected only by careful inspection at necropsy. In the profusely hemorrhagic form, there are red or black, tarry feces in the colon and clotted blood in the ileum.

Diagnosis: Confirmation is based on histologic observation of characteristic proliferation and inflammation of mucosal crypts. *L. intracellularis* (comma-shaped, resembling *Campylobacter*) can usually be demonstrated by silver stains. A PCR test

has been developed and is useful for confirmation of the presence of *L. intracellularis* in lesions. Bacterial culture of intestine and lymph nodes to exclude *Salmonella* infection, together with histologic examination and culture of cecum and colon to exclude swine dysentery, are essential additional procedures. The colon also should be examined for whipworms. *L. intracellularis* is present in most swine herds, so demonstration of the organism in feces by PCR or the presence of antibody in clinically normal pigs is of little diagnostic value.

Treatment and Control: Various antibacterials administered parenterally to acutely affected pigs and by feed or water to the remainder of the group help reduce severity of the enteritis and prevent development of chronic, irreversible, necrotic enteritis. Porcine proliferative enteritis is one of the first diseases to be seen in new herds established by surgical derivation. A live avirulent vaccine administered via the water is highly effective. It should be administered to gilts and boars during acclimatization before introduction into a herd.

RECTAL STRICTURES

In growing pigs, rectal strictures are sequelae of severely traumatized rectal prolapses (see p 189) or of infections that interfere with rectal blood supply. The former cause sporadic cases; the latter may be epidemic. One cause is *Salmonella* Typhimurium infection (see p 296), which produces an ulcerative proctitis that heals in such a manner that normal function is not restored. The stricture is reportedly the result of fibrosis of the rectal tissue due to persistent ischemia caused by infection in an area of limited blood supply.

Clinical Findings: Several bloated pigs in varying stages of emaciation are generally seen in a group of growing pigs. Other clinical signs, including prior outbreaks of severe debilitating diarrhea, are common but not always reported. An index finger rarely can be passed into the rectum without considerable resistance.

Lesions: At necropsy the colon is grossly distended, and the intestine is filled with gas and green feces. The predominant lesion is a narrowed rectal canal, due to annular fibrotic ulcers or rectal strictures found 2–5 cm cranial to the anus.

Diagnosis: An epidemic of rectal strictures without prior rectal prolapses is indicative of *S Typhimurium* infection. Culture of feces and regional lymph nodes usually yields *S Typhimurium*. However, it is not possible to determine whether the lesion or the infection occurred first.

Treatment and Control: Early diagnosis and treatment of diarrhea is imperative for control. Good housing, management, and sanitation, with "all-in/all-out" movement of pigs is the best method to prevent further outbreaks. Surgery is not thought to be economically feasible.

ROTAVIRAL ENTERITIS

Rotaviral enteritis is a common disease of the small intestine of pigs. All ages are susceptible, but significant diarrheal disease usually is seen in nursing or post-weaning pigs.

Etiology and Pathogenesis: The causal rotavirus infects and destroys villous enterocytes throughout the small intestine, but lesions are most severe in the middle third of the intestine. Loss of villous epithelium results in partial villous atrophy, malabsorption, and osmotic diarrhea. Four antigenic groups (A, B, C, E) of rotavirus are found in pigs. They are easily spread by direct contact. Healthy carrier sows may be fecal shedders during the periparturient period, thereby exposing their litters to infection.

Clinical Findings: If neonatal pigs do not receive protective levels of maternal antibody, they are likely to develop profuse watery diarrhea in 12–48 hr. More commonly, the infection is endemic in a herd, and sows have varying levels of antibody in the colostrum and milk, which provide varying degrees of passive protection to nursing pigs. Diarrhea often begins in pigs 5 days to 3 wk old or immediately after weaning. The feces of nursing pigs often are yellow or gray and pasty in the early stages and progress to gray and pasty after ~2 days. Diarrhea persists for 2–5 days. Diarrheic pigs become gaunt and rough-haired, but mortality usually is low. Weaned pigs have watery feces that contain poorly digested feed. Weaners become inappetent and noncompetitive, which results in emaciation, stunting, and probably predisposition to pneumonia and other diseases.

Lesions: The small intestine appears thin walled, and the cecum and colon contain liquid feces.

Diagnosis: Laboratory procedures are required. Confirmation is based on histologic demonstration of villous atrophy in the jejunum, electron microscopic demonstration of virions in the intestinal contents, PCR, and immunodiagnostic procedures to demonstrate viral antigen in the intestinal mucosa or feces. Differential diagnoses include endemic transmissible gastroenteritis, porcine epidemic diarrhea, *Isospora suis* enteritis, and enteric colibacillosis.

Treatment and Control: There is no specific treatment. Minimizing heat loss and providing adequate water to maintain hydration are helpful. Concurrent infection by enterotoxigenic *Escherichia coli* is common; therefore, antibiotic therapy may reduce mortality. Providing diarrhea weaned pigs with a warm, dry, draft-free environment and frequent limited feedings help prevent starvation, secondary diseases, and permanent stunting. Vaccine for group A rotavirus appears beneficial when given to sows before farrowing. Vaccines for groups B, C, and E have not been developed because of difficulty in virus propagation. A serotyping scheme based on virus neutralization indicates a lack of cross-protection between isolates within groups.

SWINE DYSENTERY

(Bloody scours)

Swine dysentery is a mucohemorrhagic diarrheal disease of pigs that affects the large intestine.

Etiology and Pathogenesis: The essential causal agent is *Brachyspira hyodysenteriae*, an anaerobic spirochete that produces a hemolysin, although other organisms may contribute to the severity of lesions. *B hyodysenteriae* produces strong β hemolysis on blood agar under anaerobic incubation conditions. Other strongly β -hemolytic *Brachyspira* have been described that produce lesions of swine dysentery when inoculated into pigs, namely *B suanatina*, some strains of *B intermedia*, *Brachyspira* sp SASK 30446, and *B hamptonii*. The *Brachyspira* proliferate in the large intestine and cause degeneration and inflammation of the superficial mucosa, hypersecretion of mucus by mucosal epithelium, and multifocal bleeding points on the mucosal surface. The organism does not penetrate beyond the intestinal mucosa. Decreased ability of the mucosa to reabsorb endogenous secretions from the unaffected small intestine results in diarrhea.

Clinical Findings: The first signs are partial anorexia, passage of soft feces, and possibly fever. The course is variable. Some pigs die peracutely. More commonly, a mucoid diarrhea with flecks of blood and mucus develops and progresses to a watery mucohemorrhagic diarrhea. After several days, the feces are brown and contain flecks of fibrin and debris. Diarrheic pigs are dehydrated, profoundly weak, gaunt, and emaciated.

Lesions: The diffuse lesions are confined to the cecum, spiral colon, and rectum. The affected mucosa is covered with a layer of transparent or gray mucus, often with suspended flecks of blood in early stages, with a mixture of blood, fibrin, and necrotic debris in more advanced cases, and a yellow, necrotic debris late in the course.

Diagnosis: Clinical signs and necropsy findings are usually sufficient for a presumptive diagnosis. Confirmation is based on demonstration of typical histologic lesions in the large intestine and isolation of strongly β -hemolytic *Brachyspira* by anaerobic culture. Concurrent diseases are not uncommon. Differential diagnoses include intestinal spirochetosis, proliferative enteritis, salmonellosis, and heavy whipworm infections.

Treatment and Control: Therapeutic use of antibacterials is effective if started early. Water medication is preferred at first. Because drug-resistant strains are prevalent, it is essential to choose a drug to which the organism is sensitive. Bacitracin, carboxox, lincomycin, tylosin, tiamulin, and virginiamycin are commonly used. The disease may be eradicated from infected premises without total depopulation by a persistent and carefully planned program that includes treatment of carrier pigs with bactericidal drugs and thorough cleaning and disinfection of vacated facilities. Mice are an important reservoir of infection for *B. hyodysenteriae*, and any eradication attempt must include elimination/reduction of the mouse population on the farm. In addition, *B. hyodysenteriae* will survive >60 days in pig waste at refrigerator temperatures.

TRANSMISSIBLE GASTROENTERITIS

Transmissible gastroenteritis (TGE) is a common viral disease of the small intestine that causes vomiting and profuse diarrhea in pigs of all ages.

Etiology and Pathogenesis: The causal coronavirus infects and destroys villous epithelial cells of the jejunum and ileum, which results in severe villous atrophy, malabsorption, osmotic diarrhea, and dehydration. The incubation period is ~18 hr. The infection spreads rapidly by aerosol or contact exposure. Severe epidemics are more common during winter because of survival of the virus in colder temperatures.

Clinical Findings: In nonimmune herds, vomiting often is the initial sign, followed by profuse watery diarrhea, dehydration, and excessive thirst. Feces of nursing pigs often contain curds of undigested milk. Mortality is nearly 100% in piglets <1 wk old, whereas pigs >1 mo old seldom die. Gestating sows occasionally abort, and lactating sows often exhibit vomiting, diarrhea, and agalactia. Diarrhea in surviving nursing piglets continues for ~5 days, but older pigs may be diarrheic for a shorter period.

In large herds with endemic TGE, clinical signs are variable, depending on the level of immunity and magnitude of exposure. Immunity from antibody in the sow's milk usually is sufficient to protect piglets until they are 4–5 days old. As the antibody level in milk decreases, infection and mild disease may occur. Depending on the level of immunity and exposure, diarrhea may be mild in some litters but severe in others. If passive protection is sufficient to protect pigs throughout the nursing period, diarrhea often develops during the first few days after weaning.

Lesions: Piglets dying of TGE are severely dehydrated, and the skin is soiled with liquid feces. The stomach usually contains milk curd but may be empty. The small intestine is thin walled, and the entire intestine contains greenish or yellow watery fluid and clumps of undigested milk. Older pigs have few remarkable lesions, except that the colon contains liquid rather than formed feces. Villous atrophy can be seen by examining the mucosa of the small intestine with a hand lens.

Diagnosis: Clinical signs in the epidemic form of TGE usually justify a presumptive diagnosis. In the mild endemic form, laboratory procedures are required. Histologic and immunofluorescent examinations of the small intestine to demonstrate typical lesions and the presence of TGE viral antigen provide confirmatory evidence. In some outbreaks, hemagglutinating encephalomyelitis (see p 728) may cause similar signs.

Treatment and Control: There is no specific treatment. Increasing farrowing room temperature to minimize loss of body heat and providing electrolyte solutions to combat dehydration are helpful. Administration of swine immunoglobulins has been reported to be beneficial. Weaning older nursing pigs that are consuming creep feed may reduce mortality.

Protective immunity depends on presence of antibody in the small intestine. Passive protection of piglets is provided by continual nursing of immune sows. Active, protective immunity develops after infection of the intestinal mucosa with virulent TGE virus. Active infection of the intestine with virulent virus provides protective immunity for 6–18 mo due to a secretory IgA response. Vaccination of naturally immune sows boosts immunity sufficiently to protect neonates and is particularly useful in endemically infected herds. Vaccination of swine in herds free of TGE may not be economically beneficial because vaccines do not induce complete immunity.

Planned infection of pregnant sows at least 2–4 wk before farrowing in herds known to be infected with virulent virus usually provides adequate immunity. This may be accomplished by mixing ground,

TGE virus–infected intestine and feces in the gestation ration. Because of the obvious hazards associated with this procedure, it should be undertaken only if a later epidemic in the farrowing house seems inevitable. The infectious material should be used only in the same herd from which it was collected, and the tissues should be as free as possible from other pathogens of pigs. TGE virus can be eliminated from herds without total depopulation by maximizing immunity with planned infection of the sow herd; an “all-in/all-out” management of farrowing, nursery, and grower rooms; and good sanitation.

Because TGE virus is easily spread during an epidemic by people, animals, and fomites, special care should be taken to prevent spread to unexposed groups of pigs and to neighboring herds.

OTHER INTESTINAL VIRUSES OF PIGS

Other viruses have been isolated from the intestines of pigs but appear not to be associated with economically significant disease. These include adenovirus and enterovirus.

GASTROINTESTINAL PARASITES OF RUMINANTS

Clinical Findings and Diagnosis: The clinical signs associated with GI parasitisms are shared by many diseases and conditions; however, a presumptive diagnosis based on signs, grazing history, and season is often justified. Infection usually can be confirmed by demonstrating nematode eggs or tapeworm segments on fecal examination. However, in clinical evaluation of fecal examinations, two points should be remembered: 1) a fecal worm egg count (number of worm eggs per gram (EPG) of feces is not always an accurate indication of the number of adult worms present, and 2) specific identification of certain nematode eggs (eg, “strongyles”) is impractical except in specialized laboratories. EPG counts can be negative or deceptively low in the presence of large numbers of immature worms; even when many adult parasites

are present, the count can be low if egg production has been suppressed by host immune reaction or recent anthelmintic treatment. Variations in the egg-producing capability of different worms (significantly lower for *Trichostrongylus*, *Ostertagia*, and *Nematodirus* than for *Haemonchus*) may also distort the true picture. The ova of *Nematodirus*, *Bunostomum*, *Strongyloides*, and *Trichuris* are distinctive, but reliable differentiation of the more common species of ruminant strongyle ova is difficult. Fecal culture of strongyle eggs can produce distinctive third-stage larvae if differentiation is important premortem.

The advent of safe and effective broad-spectrum anthelmintics has largely reduced the need to differentiate the genera and species of these parasites. In areas where *Ostertagia* spp predominate, the

analysis of sera for increased plasma pepsinogen levels is a useful diagnostic aid. Generally, increased levels of pepsinogen activity (tyrosine levels >3 IU) are associated with clinical abomasal parasitism. Problems of interpretation may arise in immune animals under challenge, in which there are no clinical signs but the pepsinogen levels may be increased because of a hypersensitivity-type reaction in the abomasal mucosa. Where *Haemonchus* spp predominate, the traditional estimation of PCV as an indicator of anemia has been largely replaced by use of the FAMACHA test (see below). In some countries, serologic diagnosis (ELISA) of important species, such as *Ostertagia* in cattle, is also used and based on antibody titers in bulk tank milk samples in dairy herds. Such information is used as an indicator of pasture challenge at a herd level, as an indirect indicator of productivity, and is linked with the effectiveness of parasite control strategies.

In many management situations, high levels of infection can be expected, particularly after favorable temperature and rainfall conditions. "Diagnostic drenching" may be recommended when eggs are few or absent, yet history and signs suggest infections, although care should be taken not to treat animals indiscriminately to minimize the risk of anthelmintic resistance developing.

Routine postmortem examinations can provide valuable parasitologic data about the status of the rest of the herd or flock: On necropsy, *Haemonchus*, *Bunostomum*, *Oesophagostomum*, *Trichostrongylus*, *Chabertia* adults (or advanced immature worms) can be seen easily. *Ostertagia*, *Trichostrongylus*, *Cooperia*, and *Nematodirus* are difficult to see except by their movement in fluid digesta, and clinically important infections are easily overlooked. In such cases, the total contents and all washings should be combined to a known volume, and a worm count established to evaluate the severity of the infection. The number of worms found in aliquots of the gut contents and scrapings of the mucosa will enable the total worm count to be calculated. However, the smaller nematodes may be difficult to see against a background of digesta, so they can be stained (5 min) with a strong iodine solution. Once the digesta and any tissue have been decolorized with 5% sodium thiosulfate, the iodine-stained worms can be seen easily. The significance of the numbers of worms present varies according to worm and host species. For example, only 100 *Haemonchus* are of

clinical significance in lambs, whereas 5,000–10,000 *Ostertagia* are typically required before clinical signs are seen. If the animals have been diarrheic for a few days, worms may have been expelled and so the location, type, and severity of gross lesions may also be of considerable diagnostic value.

Mixed parasite infections should be considered when evaluating clinical, laboratory, and necropsy findings, because grazing animals rarely have mono-specific infections in the field.

The diagnosis of ostertagiosis in cattle during the period of larval inhibition (aka arrested development, hypobiosis, diapause) presents technical problems, particularly for the feedlot industry in the USA. Fecal egg counts and plasma pepsinogen analysis do not provide useful information because inhibition occurs within a few days of larval ingestion, before either the egg-laying adult stage has been reached or plasma pepsinogen levels increase. Predisposing factors for inhibition of larvae include age and geographic source of cattle, time of year or season of arrival, previous grazing history and management, weather conditions prevailing during the last grazing period, and prevalence of *Ostertagia ostertagi* in the source region.

Information on such factors is not usually available for feedlot cattle. If cattle have arrived after spring grazing in the south of the USA or fall grazing in the north, they could have heavy burdens of inhibited larvae. Lighter calves from areas where prevalence of parasites is high may also have such a problem. It is becoming more widely accepted that a significant cause of clinical disease or feed efficiency problems in feedlot cattle is parasitism, possibly ostertagiosis. When cattle are brought in from a suspect area and at a suspect time of year, it may be advisable to treat the new arrivals promptly with an anthelmintic effective against inhibited larvae.

Treatment: Effective worm control cannot always be achieved by drugs alone; however, anthelmintics play an important role. (See also ANTHELMINTICS, p 2637.) They may be used to reduce pasture contamination, particularly at times when seeding of the pasture with parasite eggs is a prerequisite for development of an infective challenge necessary to cause clinical parasitism. Coordination with other methods of control, such as alternate or mixed grazing with different host species, integrated rotational grazing of different age groups within a single host species

(including creep grazing), inclusion of tannin-rich forages in pasture, and alternation of grazing and cropping, are other management techniques that can help to provide safe pasture and give economic advantage when combined with anthelmintic treatment.

The "ideal" anthelmintic should be safe, highly effective against adult and immature stages (including inhibited larvae) of the important worms, available in convenient formulations, economical, and compatible with other commonly used compounds.

Broad-spectrum anthelmintics currently available belong to five different chemical groups: 1) benzimidazoles (white drenches), 2) imidazothiazoles (yellow drenches), 3) macrocyclic lactones (clear drenches), 4) amino-acetonitrile derivatives, and 5) spiroindoles. The benzimidazoles include thiabendazole, the forerunner of modern broad-spectrum anthelmintics, which set a new standard in efficacy and is still widely used today.

Thiabendazole's ineffectiveness against inhibited *Ostertagia* larvae in cattle and one or two specific worm species led to the development of other benzimidazoles (such as fenbendazole, oxfendazole, and albendazole) and the probenzimidazoles (thiophanate, febantel, and netobimin). These compounds are effective against most of the major GI parasites of ruminants and have varying levels of activity against inhibited larvae. The imidazothiazoles include levamisole, morantel, and pyrantel, which also are highly effective, safe, broad-spectrum anthelmintics but have little activity against inhibited larvae in cattle. The macrocyclic lactones, which include the avermectins and milbemycins, often administered as pour-on products or by injection, are highly effective against adult and larval stages, including inhibited larvae of all the common GI nematodes of ruminants and some of the important ectoparasites. The latter group may persist in some ruminant species for several weeks after a single subcutaneous or topical administration and confer protection against reinfection during this period. Moxidectin is also persistent after oral administration. Unlike many other anthelmintics, eprinomectin may also be used in lactating cows without the need for a milk withdrawal period. The amino-acetonitrile derivatives (monepantel) and the spiroindoles (derquantel) are given as oral drenches in sheep, the latter in combination with abamectin in New Zealand. Both of these drugs have been used in the control of multiresistant GI

nematode populations, although they require careful administration if their useful life is to be preserved.

Some narrow-spectrum anthelmintics, such as the salicylanilides, closantel, and rafoxanide, bind strongly to plasma proteins and have excellent activity against *Haemonchus contortus* in sheep and remain in the host for a long time, conferring prolonged prophylactic activity after administration.

Routes of administration other than drenching or injection (eg, incorporating into feed, drinking water, and mineral or energy blocks) are used to reduce labor costs and may be useful under drylot conditions or when grazing animals are being given supplemental feed. Another advantage of these "in-feed" routes is that continual low-level administration of a drug can be achieved and pasture contamination reduced during periods that are optimal for free-living development of the parasites. Disadvantages include erratic consumption of anthelmintic, tissue residues (requiring observance of recommended withdrawal periods), and possible encouragement of drug resistance by continual exposure. Another labor-saving route of administration is the "pour-on" topical treatment, used for some of the organophosphates (eg, trichlorfon), levamisole, and avermectins. A number of bolus preparations (eg, morantel, levamisole, ivermectin, or benzimidazoles) release drug in a sustained fashion or in pulses at intervals approximately equal to the prepatent period of the most important GI parasites. The boluses used in cattle have been designed to give entire grazing season protection in temperate areas if administered at turn-out to set-stocked herds. Boluses are also available that provide treatment and subsequent prophylaxis of animals already exposed to contaminated pasture and harboring parasites. Boluses in sheep may be used to reduce the periparturient rise in fecal egg output and thus the pasture contamination responsible for disease in their offspring later in the grazing season. Despite their efficacy, some boluses used in either cattle or sheep have been withdrawn from the market because they are not commercially viable.

Nicosamide, morantel, praziquantel, and the newer benzimidazoles (albendazole, fenbendazole, and oxfendazole) are effective against tapeworms (*Moniezia* spp) in cattle and sheep. Successful treatment of the fringed tapeworm, *Thysanosoma actinoides*, has been reported using either fenbendazole or praziquantel.

When treating clinically affected animals, the following should be considered: 1) provide adequate nutrition; 2) treat all animals in the group, as a preventive measure and to reduce further pasture contamination; and 3) either house or move stock to "clean" pastures to minimize reinfection. The definition of safe pastures varies in different climates and depends on local knowledge of the seasonal mortality of infective larvae. Some authorities have suggested treating only the most severely affected animals in a flock or herd, ie, targeted selective treatment (TST). Where *Haemonchus* is a problem in sheep or goats, animals most likely to benefit from such treatment can be identified using the FAMACHA score card. This links the color of the ocular mucous membranes, measured using a color chart, with the degree of anemia associated with the blood-sucking parasite. Animals with the palest mucous membranes are those likely to have the heaviest worm burdens and be chosen for treatment. The severity of diarrhea and/or the quantitative fecal egg count for parasitic gastroenteritis in sheep or cattle can also be used to determine the need for individual treatment. The rationale behind TST is that a very large proportion of worm egg output (and thus pasture contamination) is produced by a relatively small proportion of the host animal population. Treatment of only these animals significantly reduces pasture contamination and reduces the overall selection pressure, exerted by the use of an anthelmintic, for resistant parasite genes. Untreated animals will continue to pass low numbers of worm eggs onto the pasture and so maintain a "susceptible" parasite gene pool "in refugia" (ie, unexposed to anthelmintic treatment). In contrast, the established practice of blanket treatment and movement of stock onto a clean pasture may encourage emergence of anthelmintic resistance. Any worms carrying resistance genes surviving the treatment will then seed the previously clean pasture with a largely resistant parasite population.

Finally, the development of multiple drug resistance in populations of *Haemonchus contortus*, *Trichostrongylus* spp, and *Ostertagia* spp in sheep and goats to benzimidazoles, levamisole, and avermectins/milbemycins has been demonstrated. Although such resistance is currently a problem only in certain areas, it should be considered when other factors have been excluded, such as improper dosage, rapid reinfection, poor nutrition, or some disease state other than parasitism. Drug resistance

in parasites of cattle has been demonstrated, although much less frequently than in small ruminants; overuse and otherwise indiscriminate treatment should be avoided.

If anthelmintic resistance is suspected on a farm, a fecal egg count reduction test may be conducted onsite that will indicate the likelihood of resistance. Fifteen to twenty animals should be randomly selected and assigned to either control or treatment groups, one for each anthelmintic group selected. Fecal samples are collected before treatment from all groups and then again either 7 days (after levamisole treatment) or 14 days (after benzimidazole or macrocyclic lactone treatment) later. Pre- and post-treatment fecal worm egg counts are then compared and anthelmintic resistance suspected if the reduction in output after dosing is <95%.

The high cost of developing new anthelmintic drugs has encouraged researchers to look for alternative approaches to GI parasite control, such as development of a "hidden antigen" vaccine against *Haemonchus*; the use of tannin-rich forages (such as clover and lucerne or alfalfa), which have some anthelmintic action; and nematophagous fungi.

General Control Measures

"Control" generally implies the suppression of parasite burdens in the host below that level at which economic losses occur. To do this effectively requires a comprehensive knowledge of the epidemiologic and ecologic factors that govern pasture larval populations and the role of host immunity in combating infection.

The goals of control are as follows:

1) prevent heavy exposure in susceptible hosts (recovery from heavy infection is always slow), 2) reduce overall levels of pasture contamination, 3) minimize the effects of parasite burdens, and 4) encourage the development of immunity in the animals (less important in fattening animals than in those to be kept for breeding purposes).

The strategic use of anthelmintics is designed to reduce the build up of worm burdens and, as a result, pasture contamination. The timing of anthelmintic treatment is based on knowledge of the seasonal changes in infection and the regional epidemiology of the various helminthoses. Prompt recognition of circumstances likely to favor development of parasitic disease, eg, weather, grazing behavior, and loss of weight and condition, is essential.

For example, in the UK, where the pattern of disease caused by *Nematodirus battus*

infection in sheep is clearly defined, strategic treatments with two or three doses of an anthelmintic at 2- to 3-wk intervals, beginning just before the disease characteristically appears, are recommended. The timing of these treatments is designed to coincide with peak numbers of *Nematodirus* larvae on pasture in the spring; timing of the latter can be predicted accurately using a simple formula that incorporates soil temperatures 1 ft below the surface during March. Similarly, in the northern USA, Canada, and western Europe, pasture levels of *Ostertagia* and other parasites increase substantially after mid-July, ie, the general pattern of infectivity is minimal in spring but increases rapidly to peak levels in late summer and early fall. Current practices in these areas indicate the effectiveness of two or more carefully timed anthelmintic treatments given during the first grazing season after turnout in the spring. Calculating the interval between treatments requires knowledge of the parasite's prepatent period (3 wk in the case of *Ostertagia* in cattle) and the duration of residual (or prolonged) activity of the anthelmintic being used, ie, the period of protection provided after a single treatment; the treatment interval is calculated as the sum of the two. For example, treatment with a macrocyclic lactone with a 5-wk period of residual activity at turnout and again 8 wk later should result in highly effective control of worm egg output and minimal numbers of larvae appearing on pasture during the fall. No further treatment is likely to be required, because any larvae surviving on pasture from the previous year would have died by the time the prophylactic effect of the second treatment had worn off.

In other countries, with either a cool or warm temperate climate, similar controls may be used if the seasonal pattern of the disease is known, but in most regions a tactical use of anthelmintics is used, eg, during warm, moist conditions.

Cattle—Special Considerations

Worm problems are seen most frequently in young beef cattle from time of weaning and several months thereafter, and in segregated groups of dairy calves during the first season at grass. Immunity to GI nematodes is acquired slowly; two grazing seasons may be required before a significant level is attained. In endemic areas, cows may continue to harbor low burdens, which may contribute to suboptimal production on some farms. GI parasitism in young stock may be controlled by use of broad-spectrum

anthelmintics in conjunction with pasture management to limit reinfection; the latter includes a move to "clean" pastures (eg, grass conservation areas or silage or hay aftermath, although anthelmintic resistance concerns should be noted [above]), alternate grazing with other host species, or integrated rotational grazing in which susceptible calves are followed by immune adults. Alternate grazing with other host species may be ineffective in areas where parasite species (eg, *Nematodirus*) infect both hosts; simple pasture rotation is not effective, because the bovine fecal mass can protect larvae from adverse environmental conditions for several months, infecting rotating calves at a later date.

In beef herds, anthelmintic treatment at weaning is of value, particularly if the young cattle are to be retained, eg, as replacement heifer stock or as steers to be fed. Cattle finished on grass should receive treatment at weaning and at intervals throughout the next 12 mo and, if possible, should be moved to safe pastures to maximize liveweight gain.

When cattle cannot be moved readily to other pastures, strategic treatments (described earlier) may be given to limit contamination of pastures and rapid reinfection. Alternatively, intraruminal boluses may be used in countries where approved. In warm temperate regions of the world, such as Australia and New Zealand, the southern USA, and the large cattle-raising regions of southern Brazil, Uruguay, and Argentina, young cattle may be given two or more treatments from late summer and into fall for prevention of large increases in pasture contamination and infection during winter and spring. Two or three strategic treatments, administered with a short interval, from the time of weaning in such regions could be just as effective as spring treatments in cool temperate regions. However, survival of infective larvae on pasture from the time of fall weaning in warm temperate regions is most often persistent, and longer intervals between treatments (eg, at weaning, during winter, and in late spring) may be more applicable. In many areas, anthelmintics are simply given at regular intervals after weaning. Intervals between treatments must necessarily vary according to local parasite epidemiology and the duration of prolonged activity exhibited by the anthelmintic. When Type II ostertagiosis is a problem, treatment with an anthelmintic effective against inhibited larvae is recommended before the expected time of outbreak.

Sheep—Special Considerations

A special strategic treatment is required in most regions to counter the postparturient relaxation of immunity (resulting in the periparturient rise in worm egg output) seen in breeding ewes. The precise timing of such treatment varies between regions and for different species of parasites and will, in temperate regions, depend on whether ewes and lambs are turned out onto clean or contaminated pasture. On clean grazing, only the ewes (with an existing parasite burden) act as a source of worm eggs and, therefore, require treatment to prevent pasture contamination and subsequent infection of their lambs. Ewes treated during the month before lambing should not only exhibit a drop in worm egg output but may also show improved productivity. On contaminated pasture, both ewes and lambs pass worm eggs in their feces (ewes from their existing worm burden and lambs from larvae overwintering on pasture). The aim of treating ewes should be to prevent fecal worm egg output; this can be achieved by treating with an albendazole or ivermectin anthelmintic bolus (available in some countries), injectable long-acting moxidectin, or medicated feed blocks. In temperate areas, lambs should be dosed at weaning before a move to clean grazing.

A treatment 2 wk before breeding, as part of a “flushing” program, is another strategic application of anthelmintics. Supportive management after treatment includes movement of sheep from contaminated pastures to cattle pastures, grass conservation areas, root crops, or pasture not grazed by sheep for several months. The latter period varies according to the seasonal pattern of larval mortality in different countries and may be as long as 1 yr in some temperate countries.

Sheep are more consistently susceptible to the adverse effects of worms than other livestock, and clinical disease is more common. Immunity to the parasites is acquired slowly and is generally incomplete. Frequent treatments may be required, particularly during the first year of life, although a good understanding of local parasite epidemiology will ensure that such treatments are appropriately timed.

large stomach worm, wire worm), *Ostertagia ostertagi* (medium or brown stomach worm), and *Trichostrongylus axei* (small stomach worm, see p 319). In some tropical countries, *Mecistocirrus digitatus*, a large worm up to 40 mm long, is present. *H. placei* is primarily a parasite in tropical regions, whereas *O. ostertagi* and, to a lesser extent, *T. axei* are found in more temperate climates. Adult male *Haemonchus* are up to 18 mm long, females up to 30 mm. *Ostertagia* adults are 6–9 mm long, and *Trichostrongylus*, ~5 mm.

The preparasitic life cycles of the three groups are generally similar. Larvae hatch shortly after the eggs are passed in the feces and reach the infective stage in ~2 wk under optimal temperatures (~75°F [24°C]). Development to the infective stage is delayed during cold weather. In areas with narrow diurnal temperature variations, those months with a mean maximum temperature of 65°F (18°C) and with rainfall >2 in. (5 cm) are favorable for development of the free-living stages of *H. placei*, but where wide fluctuations occur, a mean minimum temperature of 50°F (10°C) may effectively limit development. The preparasitic forms of *O. ostertagi* and *T. axei* develop and survive better in cooler conditions, and their upper limits for survival are lower than those for *H. placei*. If the temperature is unfavorable or drought conditions exist, infective larvae may remain dormant in the feces for weeks until conditions become favorable again, eg, after heavy rainfall, when large numbers of infective larvae emerge onto the surrounding grass.

The prepatent period of *O. ostertagi* is normally ~3 wk. Ingested larvae enter the lumen of the abomasal glands and molt by the fourth day; they remain there during the prepatent period, growing and undergoing a final molt before emerging as young adult

GASTROINTESTINAL PARASITES OF CATTLE

Haemonchus, *Ostertagia*, and *Trichostrongylus* spp

The common stomach worms of cattle are *Haemonchus placei* (barber's pole worm,

Abomasal lesions due to *Ostertagia*. Courtesy of Dr. Sameeh M. Abutarbush.

worms from the gastric glands onto the abomasal mucosa. During this time, the specialized cells (pepsinogen-producing zymogen cells, acid-producing parietal cells) lining parasitized glands are lost and replaced by hyperplastic, undifferentiated cuboidal cells, resulting in nodules that may be discrete or confluent. Around the time of worm emergence, the changes seen in parasitized glands also appear in neighboring nonparasitized glands, rapidly extending the effects of the parasite burden. As a result, in heavy infections, abomasal pH may rise from 2 to >6; from a clinical viewpoint, when pH rises above 4.5, digestion in the abomasum ceases. A protein-losing gastropathy results and, together with anorexia and impaired protein digestion, leads to hypoproteinemia and weight loss. Diarrhea is persistent. In **Type I ostertagiosis**, which results from recent infection, most worms present are adults, and the response to anthelmintic treatment is good. Type I disease is seen primarily in calves 7–15 mo old. It is most common from time of weaning and ensuing months in warm temperate regions and in young cattle during summer and early fall in cool temperate regions.

In **Type II ostertagiosis**, large numbers of larvae, which had become dormant or inhibited in development at the early fourth larval stage, emerge from the glands weeks or months later. This is seen primarily in cattle 12–20 mo old. In warm temperate regions, inhibition-prone larvae are acquired in spring, and disease may result when large numbers of larvae resume development to the adult stage in late summer or fall. In cold temperate regions, inhibition-prone larvae are acquired during late autumn and mature during late winter or early spring.

Larval inhibition in *O. ostertagi* and other nematodes is thought to be analogous to diapause in insects. It has been interpreted as a survival mechanism in which the preparasitic stages on pasture avoid the adverse conditions of winter in cool regions and of hot and dry (or hot and alternately wet and dry) conditions of many warm regions. The factors that cause and later “switch off” inhibition are not completely known, but prolonged experimental cold conditioning of infective larvae was found to be important in a cool temperate region. In warm regions of both northern and southern hemispheres, conditioning of preparasitic stages to inhibition develops principally during spring before the hot and dry conditions of summer. The resumed development or maturation of the parasites is likely to be genetically predetermined and may be influenced by

parturition, nutrition, concurrent infection, and host immune response.

H. placei may also become inhibited over winter; they then resume development in the spring and infect the pastures with eggs at a time suitable for their development. Both the larval and adult stages are pathogenic because of their blood-sucking ability. *T. axei* causes gastritis with superficial erosion of the mucosa, hyperemia, and diarrhea. Protein loss from the damaged mucosa and anorexia cause hypoproteinemia and weight loss. Inhibition does not occur to the same degree.

Clinical Findings: Young animals are more often affected, but adults not previously exposed to infection frequently show signs and succumb. *Ostertagia* and *Trichostrongylus* infections are characterized by profuse, watery diarrhea that usually is persistent. In haemonchosis and *Mecistocirrus* infection, there may be little or no diarrhea but possibly intermittent periods of constipation. Anemia of variable degree is a characteristic sign of both these infections.

Concurrent with the diarrhea of *O. ostertagi* and *T. axei* infections, and with the anemia of heavy *Haemonchus* infection, there is often hypoproteinemia and edema (rare in *O. ostertagi* infections), particularly under the lower jaw (bottle jaw) and sometimes along the ventral abdomen. Heavy infections can result in death before clinical signs appear. Other variable signs include progressive weight loss, weakness, rough coat, and anorexia.

Lesions: Worms can readily be seen and identified in the abomasum, and small petechiae may be visible where the worms have been feeding. The most characteristic lesions of *Ostertagia* infection are small, umbilicated nodules 1–2 mm in diameter. These may be discrete, but in heavy infections they tend to coalesce and give rise to a “cobblestone” or “morocco leather” appearance. Nodules are most marked in the fundic region but may cover the entire abomasal mucosa and may be accompanied by a rise in gastric pH to 6–7. As a result, pepsinogen will no longer be converted to pepsin and may leak across the damaged epithelium, leading to high plasma levels. There is also evidence that adult *Ostertagia* can cause direct hypersecretion of pepsinogen. The increased abomasal pH may also stimulate production of gastrin and thus hypergastrinemia, which is closely associated with the inappetence that may accompany infection. This parasite-associated drop in

intake has been shown to be largely responsible for impaired weight gain. Edema is often marked and, in severe cases, may extend over the abomasum and into the small intestine and omentum.

In *T. axei* infections, the mucosa of the abomasum may show congestion and superficial erosions, which are sometimes covered with a fibrinonecrotic exudate.

Diagnosis, Treatment, and Control:

See p 303 et seq.

Cooperia spp

Several species of *Cooperia* are found in the small intestine of cattle; *C. punctata*, *C. oncophora*, and *C. pectinata* are the most common. The red, coiled adults are 5–8 mm long, and the male has a large bursa. They may be difficult to observe grossly. Their life cycle is essentially the same as that of other trichostrongylids. These worms apparently do not suck blood. Most of them are found in the first 10–20 ft (3–6 m) of the small intestine. The prepatent period is 12–15 days.

The eggs usually can be differentiated from those of the common GI nematodes by their practically parallel sides, but a larval culture of the feces is necessary to definitively diagnose *Cooperia* infection in the living animal. In heavy infections with *C. punctata* and *C. pectinata*, there is profuse diarrhea, anorexia, and emaciation, but no anemia; the upper small intestine shows marked congestion of the mucosa with small hemorrhages. The mucosa may show a fine lace-like superficial necrosis. *C. oncophora* produces a milder disease but can be responsible for weight loss and poor productivity. It is usually necessary to make scrapings of the mucosa to demonstrate *Cooperia* spp, which must be differentiated from *Trichostrongylus* spp, *Strongyloides papillosus*, and immature *Nematodirus* spp.

For diagnosis, treatment, and control, see p 303 et seq.

Bunostomum sp

The adult male *Bunostomum phlebotomum* is ~15 mm long and the female ~25 mm. Hookworms have well-developed buccal capsules into which the mucosa is drawn; cutting plates at the anterior edge of the buccal capsule are used to abrade the mucosa during feeding. The prepatent period is ~2 mo. Infection is by ingestion or skin penetration; the latter is more common in animals kept in poor conditions.

Larval penetration of the lower limbs may cause uneasiness and stamping, particularly in stabled cattle. Adult worms cause anemia

and rapid weight loss. Diarrhea and constipation may alternate. Hypoproteine-mic edema may be present, but bottle jaw is rarely as severe as in haemonchosis. During the patent period, a diagnosis may be made by demonstrating the characteristic eggs in the feces.

On necropsy, the mucosa may appear congested and swollen, with numerous small hemorrhagic points where the worms were attached. The worms are readily seen in the first few feet of the small intestine, and the contents are often blood-stained. As few as 2,000 worms may cause death in calves. Local lesions, edema, and scab formation may result from penetration of larvae into the skin of resistant calves.

For diagnosis, treatment, and control, see p 303 et seq.

Strongyloides sp

The intestinal threadworm *Strongyloides papillosus* has an unusual life cycle. Only the female worms are found in the intestine. They are 3.5–6 mm long and are embedded in the mucosa of the upper small intestine. Small, embryonated eggs are passed in the feces, hatch rapidly, and develop directly into infective larvae or free-living adults. The offspring of these free-living adults may develop into another generation of infective larvae or free-living adults. The host is infected by penetration of the skin or by ingestion; infective larvae can be transmitted in colostrum as in other species of the genus. The prepatent period is ~10 days.

Infections are most common in young calves, particularly dairy stock. Although signs are rare, they may include intermittent diarrhea, loss of appetite and weight, and sometimes blood and mucus in the feces. Large numbers of worms in the intestine produce catarrhal enteritis with petechiae and ecchymoses, especially in the duodenum and jejunum.

For diagnosis, treatment, and control, see p 303 et seq.

Nematodirus spp

Nematodirus helvetianus is generally recognized as the most common bovine species, although other species, eg, *N. spathiger* and *N. battus*, can also infect cattle. The adult males of *N. helvetianus* are ~12 mm long and the females 18–25 mm. The eggs develop slowly; the infective third stage is reached within the egg in 2–4 wk and may remain within the egg for several months. Eggs may accumulate on pasture and hatch in large numbers after rain to produce heavy infections over a short period. The eggs are

highly resistant, and those passed by calves in one season may remain viable and infect calves the next season. After ingestion of infective larvae, the adult stage is reached in ~3 wk. Worms are most numerous 10–20 ft (3–6 m) from the pylorus.

Signs, which include diarrhea and anorexia, usually develop during the third week of infection before the worms are sexually mature; clinical infections may be seen in dairy calves from 6 wk onward. Diagnosis is difficult during the prepatent period, but during the patent period it is easily made on the basis of the characteristic eggs. Relatively small numbers of eggs are produced. Fecal sampling of both healthy and sick calves in an affected group will increase the chance of making a diagnosis. Immunity to reinfection develops rapidly. Necropsy may show only a thickened, edematous mucosa.

For diagnosis, treatment, and control, *see* p 303 et seq.

Toxocara sp

The ascarid *Toxocara vitulorum* is a stout, whitish worm (males 20–25 cm, females 25–30 cm) found in the small intestine of calves <6 mo old; older calves are resistant. Larvae hatching from ingested eggs pass to the tissues and, in pregnant cows, are mobilized late in pregnancy and passed via the milk to calves. Eggs appear in the feces of calves from 3 wk of age and are easily recognized by their thick, pitted shells and dark brown center. In some parts of the world, the infection is considered serious, particularly in buffalo calves.

For diagnosis, treatment, and control, *see* p 303 et seq.

Oesophagostomum sp

Adults of *Oesophagostomum radiatum* (nodular worm) are 12–15 mm long, and the

head is bent dorsally. Because the eggs are very similar to those of *Haemonchus placei*, they are often grouped together on routine fecal examination. The life cycle is direct. The larvae penetrate primarily into the wall of the lower 10–20 ft (3–6 m) of the small intestine but also into the cecum and colon, where they remain for 5–10 days and then return to the lumen as fourth-stage larvae. The prepatent period in susceptible animals is ~6 wk. However, in subsequent reinfections, larvae become arrested for some time, and many never return to the lumen (host encystment).

Young animals suffer from the effects of adult worms, whereas in older animals, the effect of nodules enclosing larval worms is more important. Infection causes anorexia; severe, constant, dark, persistent, fetid diarrhea; weight loss; and death. In older, resistant animals, the nodules surrounding the larvae become caseated and calcified, thus decreasing the motility of the intestine. Stenosis or intussusception occasionally occurs. Nodules can be palpated per rectum, and the worms and nodules can be seen readily at necropsy.

For diagnosis, treatment, and control, *see* p 303 et seq.

Chabertia sp

Adults of the large-mouth bowel worm, *Chabertia ovina*, are ~12 mm long and bent ventrally at the anterior end. There is a typical direct life cycle. The larvae penetrate the mucosa of the small intestine shortly after ingestion and later emerge and pass to the colon. The prepatent period is ~7 wk. Larvae and adults may cause small hemorrhages with edema in the colon and passage of feces coated with mucus. Clinical chabertiosis is seldom, if ever, seen in cattle.

For diagnosis, treatment, and control, *see* p 303 et seq.

Toxocara canis egg. Courtesy of Dr. Mark Fox.

Trichuris ovis attached to intestinal wall of a sheep. Courtesy of Dr. Raffaele Roncalli.

Trichuris spp

Trichuris spp infections are common in young calves and yearlings, but the numbers of worms are seldom large. The eggs are resistant, and infections are likely to persist on problem premises. Clinical signs are unlikely, but in occasional heavy infections, dark feces, anemia, and anorexia may be seen.

For diagnosis, treatment, and control, see p 303 et seq.

Tapeworms

The anoplocephalid tapeworms *Moniezia expansa* and *M benedeni* are found in young cattle. The worms of this group are characterized by the absence of a rostellum and hooks, and the segments are wider than they are long. The eggs are triangular or rectangular and are ingested by the intermediate host, free-living oribatid mites, which live in the soil and grass. After 6–16 wk, infective cysticeroids are present in the mites. Infection occurs after ingestion of infected mites; the prepatent period is ~5 wk. *Moniezia* are commonly considered nonpathogenic in calves, but intestinal stasis has been reported.

For diagnosis, treatment, and control, see p 303 et seq.

GASTROINTESTINAL PARASITES OF SHEEP AND GOATS

Many species of nematodes and cestodes cause parasitic gastritis and enteritis in sheep and goats. The most important of these are *Haemonchus contortus*, *Teladorsagia (Ostertagia) circumcincta*, *Trichostrongylus axei*, intestinal species of *Trichostrongylus*, *Nematodirus* spp, *Bunostomum trigonocephalum*, and *Oesophagostomum columbianum*. *Cooperia curticei*, *Strongyloides papillosus*, *Trichuris ovis*, and *Chabertia ovina* also may be pathogenic in sheep; these and related species are discussed under GI parasites of cattle (see p 308).

Haemonchus, Ostertagia, and Trichostrongylus spp

The principal stomach worms of sheep and goats are *Haemonchus contortus*, *Teladorsagia (Ostertagia) circumcincta*, *Ostertagia trifurcata*, *Trichostrongylus axei* (see GASTROINTESTINAL PARASITES OF CATTLE, p 308), and in some tropical regions, *Mecistocirrus digitatus*. Cross-transmis-

sion of *Haemonchus* between sheep and cattle can occur but not as readily as transmission between homologous species. Sheep are more susceptible to the cattle species than cattle are to the sheep species. For descriptions and life cycles, see p 308.

Haemonchus is most common in tropical or subtropical areas or in those areas with summer rainfall, whereas *Ostertagia* and *T axei* are more common in cooler winter rainfall areas. The latter species predominate in temperate zones.

Haemonchosis in sheep may be classified as hyperacute, acute, or chronic. In the hyperacute disease, death may occur within 1 wk of heavy infection without significant signs. The acute disease is characterized by severe anemia accompanied by generalized edema; anemia is also characteristic of the chronic infection, often of low worm burdens, and is accompanied by progressive weight loss. Diarrhea is not a sign of pure *Haemonchus* infection; the lesions are those associated with anemia. In cases in which diarrhea is present, there may be mixed infection with other worm genera. The abomasum is edematous and, in the chronic phase, gastric pH increases, which causes abomasal dysfunction. Mature sheep may develop heavy, even fatal, infections, particularly during lactation.

The lesions, pathogenesis, and signs of *Ostertagia* and *T axei* infections are similar to those found in cattle. Even subclinical infection depresses appetite, impairs gastric digestion, and reduces use of metabolizable energy and protein. *Ostertagia* is the principal genus involved in the periparturi-

Haemonchus contortus, heavy infestation, abomasum of a sheep. Courtesy of Dr. Raffaele Roncalli.

ent rise in fecal egg counts in sheep, and heavy infections may cause diarrhea and depress milk production in ewes. This output of eggs serves as the main source of contamination for the lambs. The same type of inhibited development seen in cattle has been seen with both *Ostertagia* and *Haemonchus* in sheep.

For diagnosis, treatment, and control, *see* p 303 et seq.

Intestinal Trichostrongylosis

The life cycle of intestinal *Trichostrongylus* (*T. colubriformis*, *T. vitrinus*, *T. rugatus*) is direct. The developing larvae burrow superficially in the crypts of the mucosa and develop to egg-laying adults in 18–21 days.

Anorexia, persistent diarrhea, and weight loss are the main signs. Villous atrophy (or stunting of villi) results in impaired digestion and malabsorption; protein loss occurs across the damaged mucosa. There are no diagnostic lesions; a total worm count should be done to evaluate the condition.

For diagnosis, treatment, and control, *see* p 303 et seq.

Bunostomum and Gaigeria spp

Adult *Bunostomum trigonocephalum* (hookworm) are found in the jejunum. The life cycle and clinical findings are essentially the same as for the cattle hookworm (*see* p 310), with as few as 100 worms causing clinical signs. *Gaigeria pachyscelis* is found in Africa and Asia and resembles *Bunostomum* in size and form (2–3 cm). Larvae of *G. pachyscelis* infect the host only by skin penetration. *G. pachyscelis* is a voracious bloodsucker and probably the most pathogenic hookworm.

For diagnosis, treatment, and control, *see* p 303 et seq.

Nematodirus spp

The species of *Nematodirus* found in the small intestine of sheep are similar in morphology and life cycle to *N. helvetianus* (*see* p 310). Clinical infections are of considerable importance in the UK, New Zealand, and Australia, where lamb mortality may reach 20% in affected flocks if animals are untreated. The parasites are also endemic in some parts of the Rocky Mountain states of the USA, where they occasionally cause clinical disease in lambs.

In areas where clinical infections are common, the disease has a characteristic seasonal pattern. Many of the eggs passed by affected lambs lie dormant through the remainder of the grazing season and the

winter, with large numbers of larvae appearing during the early grazing period of the following year. Thus, the lambs of one season contaminate the pastures for the next season's lambs; fortunately, the life cycle can be broken if the same area is not used for lambing each year. Most clinical infections are seen in lambs 6–12 wk old.

N. battus is seen in the UK and other parts of Europe and also in North America. Eggs hatch after a period of chill and then a rise in ambient temperature to a day/night mean of 10°C (50°F). This occurs in late spring in temperate areas. The hatching requirements mean that there is generally one generation of *N. battus* per year, although in the UK, occasional outbreaks in the autumn have been reported. The parasite can be highly pathogenic, because large numbers of larvae hatch over a short period at a time when young lambs are beginning to take in significant quantities of grass. Disease may be associated with developing larval stages and may be seen within 2 wk of challenge, ie during the prepatent period (15 days).

Other *Nematodirus* spp often are found in low-rainfall regions (eg, the Karroo in South Africa and inland Australia) where other parasites are rarely seen.

Nematodiosis is characterized by sudden onset, "loss of bloom," unthriftiness, profuse diarrhea, and marked dehydration, with death as early as 2–3 days after an outbreak begins. Nematodiosis is commonly confined to lambs or weaner sheep, but in low-rainfall country where outbreaks are sporadic, older sheep may have heavy infections. The lesions usually consist of dehydration and a mild catarrhal enteritis, but acute inflammation of the entire small intestine may develop. Counts of $\geq 10,000$ worms, together with characteristic signs and history, are indicative of clinical infections. Affected lambs may pass large numbers of eggs, which can be identified easily; however, because the onset of disease may precede the maturation of the female worms, this is not a constant finding.

For diagnosis, treatment, and control, *see* p 303 et seq.

Oesophagostomum spp

The nodular worm of sheep, *Oesophagostomum columbianum*, has a similar morphology and life cycle to those of the nodular worm of cattle (*see* p 311).

Diarrhea usually develops during the second week of infection. The feces may contain excess mucus as well as streaks of blood. As the diarrhea progresses, sheep become emaciated and weak. These signs

often subside near the end of the prepatent period, but the continuing presence of numerous adult worms may result in a chronic infection in which signs may not develop for several months. The sheep become weak, lose weight despite a good appetite, and show intermittent diarrhea and constipation.

As immunity develops, nodules form around the larvae; they may become caseated and calcified. Nodule formation usually is more pronounced in sheep than in cattle. Affected sheep walk with a stilted gait and often have a humped back. Stenosis and intussusception may develop in severe cases. Diagnosis is difficult during the prepatent period, at which time it must be based largely on clinical signs.

For diagnosis, treatment, and control, *see* p 303 et seq.

Chabertia sp

Adult worms cause severe damage to the mucosa of the colon, with resulting congestion, ulceration, and small hemorrhages. Infected sheep are unthrifty; the feces are soft, contain much mucus, and may be streaked with blood. Immunity develops quickly, and outbreaks are seen only under conditions of severe stress.

For diagnosis, treatment, and control, *see* p 303 et seq.

Strongyloides sp

Heavy infections with adult worms cause a disease resembling trichostrongylosis. Infection is usually by skin penetration but can also occur via the milk. Damage to the

skin between the claws, produced by skin-penetrating larvae, resembles the early stages of footrot and may aid penetration of the causal agents of footrot. Most infections are transitory and inconsequential.

For diagnosis, treatment, and control, *see* p 303 et seq.

Trichuris spp

Heavy infections with whipworms are not common but may be seen in very young lambs or during drought conditions when sheep are fed grain on the ground. The eggs are very resistant. Congestion and edema of the cecal mucosa, accompanied by diarrhea and unthriftiness, are seen.

For diagnosis, treatment, and control, *see* p 303 et seq.

Tapeworms

The pathogenicity of *Moniezia expansa* in sheep has long been debated. Many earlier observations, which associated this infection with diarrhea, emaciation, and weight loss, did not accurately differentiate between tapeworm infections and infection with certain small nematodes (eg, *Trichostrongylus colubriformis*). Tapeworms are relatively nonpathogenic, but heavy infections can result in mild unthriftiness and GI disturbances. Diagnosis may be made by finding individual segments (which are much wider than long) in the feces or lengths of adult tapeworm protruding from the anus or by demonstrating the characteristic eggs on fecal examination. The life cycle involves an oribatid mite that lives in the pasture mat. The prepatent period is 6–7 wk. Infections are seasonal, in accordance with mite activity, and unusual in animals older than ~4–5 mo of age.

Thysanosoma actinioides, the “fringed tapeworm,” inhabits the small intestine, the bile ducts, and the pancreatic ducts. It is commonly found in sheep from the southern and western parts of the USA and also South America. Although it has not been associated with clinical disease, it is of economic importance because livers are condemned when tapeworms are found in the bile duct.

For diagnosis, treatment, and control, *see* p 303 et seq.

GASTROINTESTINAL PARASITES OF HORSES

GASTEROPHILUS SPP

Horse bots, which are found in the stomach, are the larvae of bot flies, *Gasterophilus* spp. Three major species are distributed worldwide, and a number of minor species are found in parts of Europe, Africa, and Asia. The adult flies are not parasitic and cannot feed; they survive long enough to mate and lay eggs and die as soon as the nutrients remaining from the larval stage are used, usually in ~2 wk. The three important species can be differentiated in any stage of their development. The eggs of *G. intestinalis* (the common bot) are glued to the hairs of almost any part of the body but especially the forelimbs and shoulders. The larvae hatch in ~1 wk when stimulated, usually by the animals' licking. The eggs of *G. haemorrhoidalis* (the nose or lip bot) are attached to the hairs of the lips. The larvae emerge in 2–3 days without stimulation and crawl into the mouth. *G. nasalis* (the throat bot) deposits eggs on the hairs of the submaxillary region. They hatch in ~1 wk without stimulation.

The larvae of all three species apparently stay embedded in the tongue or the mucosa of the mouth for ~1 mo, after which they pass to the stomach, where they attach themselves to the cardiac or pyloric portions and, in the case of *G. nasalis*, to the mucosa of the first part of the small intestine. After development for ~8–10 mo, they pass out in the feces and pupate in the soil for 3–5 wk, after which the adult emerges. The main pathogenic effect is caused by larvae, which attach by oral hooks to the lining of the stomach. This induces erosions and ulcerations at the site of attachment and a hyperplastic reaction around it. However, oral stages may cause sinus tracts in which mucopurulent discharges form, especially along the lingual border of the upper, more posterior cheek teeth.

Clinical Findings and Diagnosis: Bots cause a mild gastritis, but large numbers may be present with no clinical signs. The first instars migrating in the mouth can cause stomatitis and may produce pain on eating. The adult flies may annoy horses when they lay their eggs. Specific diagnosis of *Gasterophilus* infection is difficult and can be made by demonstrating larvae as

they pass in the feces. In the USA, the presence of gastric infections during the winter months is often assumed. History of the individual horses, knowledge of the local seasonal cycle of the fly, and observation of the yellow to cream-white bot eggs (1–2 mm) on the horse's hairs all help identify the presence of the parasite in a given herd.

Treatment: In temperate areas, it is assumed that most animals are infected by the end of summer. Ivermectin is effective against oral and gastric stages of bots and, when used as part of a routine parasite control program, provides effective bot control throughout the season. In subtropical or tropical areas, some transmission may occur throughout the year. Moxidectin is effective against gastric stages. Current recommendations for control include at least one treatment annually, at the end of the bot fly season. In some locations where the bot fly season is long, additional treatments may be necessary. Although there is no satisfactory method to protect exposed horses from attack by the adult flies, bot control programs, when applied on a regional basis to all horses, markedly reduce fly numbers and larval infections.

HABRONEMA SPP

The stomach worms *Habronema muscae*, *H. microstoma*, and *Draschia megastoma* are widely distributed. The adults are 6–25 mm long. *Draschia* are found in tumor-like swellings in the stomach wall along the margo plicatus. The other species are free on the mucosa. The eggs or larvae are ingested by larvae of house or stable flies, which serve as intermediate hosts. Horses are infected by ingesting flies that contain infective larvae or by free larvae that emerge from flies as they feed around the lips. (See also CUTANEOUS HABRONEMIASIS, p 904.)

A catarrhal gastritis may result from heavy infections with adult worms. *Draschia* produces the most severe lesions—tumor-like enlargements up to 10 cm in diameter. These are filled with necrotic material and a large number of worms and are covered by intact epithelium, except for a small opening through which the eggs pass. Rarely, these nodules rupture and cause fatal peritonitis. Larvae of

Habronema spp and *Draschia* have been found in the lungs of foals associated with *Rhodococcus equi* abscesses (see p 1451). Clinical signs usually are absent except when, rarely, granulomas associated with *Draschia* infection lead to mechanical obstruction or rupture.

Antemortem diagnosis is difficult, because the eggs are not easily detected using standard fecal flotation methods. Molecular methods have recently been developed for this purpose but would not be useful for routine use. Worms and eggs may be found by gastric lavage. Most anthelmintics have not been tested against *Habronema* spp or *Draschia* sp, although ivermectin is effective against their cutaneous larvae and against adults of *H. muscae*. Moxidectin is also effective against adult *H. muscae*.

OXYURIS SP

Adult pinworms, *Oxyuris equi*, are more common in horses <18 mo old and are found primarily in the terminal portion of the large intestine. The females are 7.5–15 cm long; males are smaller and fewer in number. The gravid females pass toward the rectum to lay their eggs, “cementing” them to the perineum around the anus. Masses of eggs and cement around the anus appear as a white to yellow, crusty mass. The eggs, which are flattened on one side, become embryonated in a few hours and are infective in 4–5 days.

Adult pinworms are of little significance in the intestine but cause perineal irritation after egg laying. Rubbing of the tail and anal regions, with resulting broken hairs and bare patches around the tail and buttocks, is characteristic and suggests the presence of pinworms. Fecal examination may or may not reveal a pinworm infection. Samples collected around the perineal region may contain dried female worms or eggs. Application of cellophane tape to the skin of the perineum or scraping the area with a tongue depressor may recover ova for microscopic examination, but false-negative tests are common.

Most of the broad-spectrum drugs recommended for treatment of strongyles (see below) are effective against pinworms.

PARASCARIS SP

Adult *Parascaris equorum* are stout, whitish worms, up to 30 cm long, with three prominent lips. The life cycle is similar to that of *Ascaris suum* (the roundworm of pigs, see p 320), with a prepatent period of

10–12 wk. Large numbers of infective eggs can remain viable for years in contaminated soil. Adult animals usually harbor very few if any worms. The principal sources of infection for young foals are pastures, paddocks, or stalls contaminated with eggs from foals of the previous year.

In heavy infections, the migrating larvae may produce respiratory signs (“summer colds”). In heavy intestinal infections, foals show unthriftiness, loss of energy, and occasionally colic. Intestinal obstruction and perforation have been reported. Intestinal stages compete for absorption of essential amino acids. Diagnosis is based on demonstration of eggs in the feces. If disease due to prepatent infection is suspected, diagnosis may be confirmed by administration of an anthelmintic, after which large numbers of immature worms may be seen in the feces.

On farms where the infection is common, most foals become infected soon after birth. As a result, most of the worms are maturing when the foals are ~4–5 mo old. Treatment should be started when foals are ~8 wk old and repeated at 6- to 8-wk intervals until they are yearlings. All broad-spectrum equine anthelmintics are effective against the adult and immature worms in the small intestine and, therefore, ascarids are readily controlled by routine anthelmintic administration. However, there have been reports of resistance of *P. equorum* to ivermectin and moxidectin in North America and Europe. Efficacy on any given farm should be monitored using a fecal egg count reduction test. In cases in which verminous pneumonia due to *Parascaris* migration has developed, therapeutic benefit may be achieved by treatment with ivermectin or fenbendazole (the latter at 10 mg/kg/day for 5 consecutive days) concurrent with appropriate antimicrobial therapy. *Parascaris* infection can be effectively prevented by daily administration of pyrantel tartrate once foals are eating grain regularly.

LARGE STRONGYLES

The large strongyles of horses are also known as blood worms, palisade worms, sclerostomes, or red worms. The three major species are *Strongylus vulgaris* (up to 25 mm), *S. edentatus* (up to 40 mm), and *S. equinus* (up to 50 mm). (See also *Triodontophorus* spp, below.) Under favorable conditions, the larvae develop to the infective stage within 1–2 wk after the eggs are passed. Infection is by ingestion of infective larvae, which exsheath in the intes-

tine and migrate extensively before developing to maturity in the large intestine. The prepatent period is 6–11 mo. The larvae of *S vulgaris* migrate extensively in the cranial mesenteric artery and its branches, where they may cause parasitic thrombosis and arteritis. Larvae of the other two species may be found in various parts of the body, including the liver, perirenal tissues, retroperitoneal tissues, and pancreas. These species do not produce lesions in the mesenteric arteries. Mixed infections of large and small strongyles are the rule.

Clinical Findings: Adult large strongyles have large buccal capsules and are active blood feeders; they ingest mucosal plugs as they move about in the intestine. The associated blood loss may lead to anemia. Weakness, emaciation, and diarrhea are also common. *S vulgaris* is important because of the damage it does to the cranial mesenteric artery and its branches. As a result of the interference with the flow of blood to the intestine and thromboembolism, any of several conditions may follow, including colic; gangrenous enteritis; or intestinal stasis, torsion or intussusception, and possibly rupture. Cerebrospinal nematodiasis (see p 1312) can cause a variety of lesions and signs depending on the part of the CNS affected.

Diagnosis and Treatment: Diagnosis of mixed strongyle infection is based on demonstration of eggs in the feces. Specific diagnosis can be made by identifying the infective larvae after fecal culture. Serologic diagnosis based on a rise in β -globulins has been recommended but is not specific for *S vulgaris*. Parasitic arterial lesions have been demonstrated using arteriography in ponies and small horses. Efforts have been made to utilize molecular methods and antibody measurements for prepatent diagnosis of *S vulgaris* infections, but these techniques are not yet available for standard use.

Colic due to arterial lesions has been successfully controlled by anthelmintic treatments. Ivermectin and moxidectin at standard dosages are effective against the larval stages (L_1 and L_6) of *S vulgaris*; fenbendazole and oxfendazole, at dosages higher than that for adult parasites, are also effective against larval infections. Daily administration of pyrantel tartrate effectively prevents establishment of arterial stages of *S vulgaris*. A number of anthelmintics, including the benzimidazoles, pyrantel, and ivermectin, are active against adult large strongyles. Large

strongyle infections have been eliminated from closed herds with ivermectin treatment.

Parasite control programs are designed to minimize the level of pasture contamination and thereby reduce the risks associated with migrating larvae. Routine anthelmintic treatments do this by preventing fecal excretion of strongyle eggs. (See also SMALL STRONGYLES, below.)

SMALL STRONGYLES

More than 40 species of small strongyles in several genera have been found in the cecum and colon of domestic equids, each with its own site of preference. They have been referred to as trichonemes, cyathostomes, and currently cyathostomins. They belong to the subfamily Cyathostominae of the family Strongylidae, and ~10 species are particularly prevalent. Most are appreciably smaller than the “large strongyles,” but *Triodontophorus* spp (sometimes classified as nonmigratory large strongyles) are almost as long as *Strongylus vulgaris*.

Unlike the large strongyles, small strongyles do not migrate extraintestinally, because early development is confined to the wall of the intestine. Third-stage larvae may progress to the fourth stage without interruption, or they may undergo hypobiosis and resume development only after prolonged periods of dormancy or hypobiosis. When L_4 emerge from the gut wall, they feed superficially on the mucosa and may rupture capillaries but are less pathogenic than the large strongyles. They molt to the adult stage. An exception is *T tenuicollis*, which is found in clusters and can produce severe ulcers in the wall of the colon. Generally, however, the resulting erosions of the mucosa are slight and hard to visualize. Consequently, it is common to recover thousands of adult worms from apparently healthy horses that have received limited anthelmintic treatment. In heavier infections, however, disruption may be extensive enough to disturb digestive and absorptive function, resulting in loss of condition and even a catarrhal enteritis of the large intestine.

Larval Cyathostominosis: An acute syndrome of sudden weight loss, often with severe diarrhea, is seen in temperate areas in late winter and spring, particularly in young ponies and horses (<5 yr old). This is associated with mass emergence of previously hypobiotic larvae from the intestinal wall as L_4 . Although of relatively low incidence, larval cyathostominosis is

nevertheless of concern because response to treatment is variable, and prognosis must be guarded even with intensive therapy. It is reported more frequently in the UK and Europe than in the USA.

Horses with larval cyathostomiasis generally have a neutrophilia and hypoalbuminemia. Hyperglobulinemia, particularly involving the β -globulin fraction described as characteristic in some reports, has been a less consistent finding. Eosinophilia is not a consistent finding. Often, strongyle eggs are not seen on fecal examination. However, gross observation of L_1 or L_3 larvae, which are often bright red, in the feces is helpful in making a diagnosis. Biopsy of large intestine via laparotomy also may assist in diagnosis; rectal biopsy is less reliable. Gross pathologic findings include typhlitis or colitis with mucosal hyperemia, hemorrhage, congestion, ulceration, or necrosis; in protracted cases, there may be only mucosal thickening. At necropsy, cyathostomin larvae can be seen as small, gray dots (1–2 mm) in the mucosa, giving it a gritty sensation on palpation. Transillumination of the mucosa from the serosal surface may help in visualizing the larvae.

Treatment: Adult cyathostomins are easily removed from the gut lumen by a wide range of anthelmintics, provided that the worm population is susceptible to the chosen drug. Benzimidazole-resistant strains of small strongyles are common in some regions, and pyrantel resistance has been demonstrated in some locations. Resistance to the macrocyclic lactones has yet to be demonstrated, but concerns exist. Drug efficacy and the presence of anthelmintic resistance may be determined by comparing the worm egg count at the time of treatment and 10–14 days later. An effective drug should reduce the egg count to zero or to very low levels. If resistance is present, a different anthelmintic class must be used, because side resistance occurs within chemical groups.

Small-strongyle larvae in the intestinal mucosa are much more difficult to effectively remove with anthelmintics. Ivermectin has been used with mixed results; lack of efficacy has been reported at and above label dosages. Treatment with large dosages of fenbendazole (10 mg/kg for 5 consecutive days) or with moxidectin has been reported as effective and can be used during the winter to reduce the risk of larval cyathostomiasis. Horses already suffering from this disease may not respond to treatment if submucosal inflammation is too severe. Consequently, treatment must be

augmented by corticosteroids and other appropriate supportive therapy.

Prevention: Routine or interval treatments are traditional and are intended to minimize the level of pasture contamination, thereby reducing the risks associated with accumulation of mucosal larvae and adult worms. Alternatively, infection may be prevented by daily administration of pyrantel tartrate. The interval between routine treatments depends on the duration a particular drug keeps the feces free of eggs and varies from 4–13 wk. The frequency of treatment is also influenced by the value of the horses and the perceived level of risk, which varies with access to pasture, stocking density, and management practices. In most cases, these procedures are ineffective in the face of widespread drug resistance to most compounds except ivermectin and moxidectin. Control measures should be designed to minimize the risk of resistance developing in the worm population. This includes preserving the refugia population of the worms, ie, worms not exposed or affected by the anthelmintic, and thus reducing the drug selection pressure. These populations are the arrested L_4 found in the mucosa and L_3 larvae on the pasture. Fewer treatments may be effective if given strategically according to local epidemiologic and climatic considerations. Most adult horses >3–4 yr old have developed some immunity to reinfection; thus, only a small portion of the herd harbors the adult worm populations and is responsible for contamination of the pasture with eggs. Selective treatment of only these infected horses will also reduce the exposure of the worm population to anthelmintics and selection for resistance. Removal of feces from paddocks and pastures aids in control and may also reduce the number of anthelmintic treatments required.

Generally in parasite control programs, all horses on a farm should be treated at some time, and those commingled on the same pasture or paddock should be treated at the same time. Boarded horses or horses returning after having been off the premises for an extended time should be quarantined and dewormed before being admitted to the herd. In administering the anthelmintic, all horses should receive the proper dose, as determined by body weight or an accurate estimation. Rotating different classes of anthelmintics in a fast rotation scheme (eg, every few months) or a slow rotation scheme (annually) is widely practiced to

prevent development of resistant parasite strains, but there is little evidence to support the utility of this procedure. Whatever program is used, fecal samples should be examined periodically to monitor the effectiveness of the program and the presence of drug resistance. Treatment can be restricted to those horses in a group that routinely have positive egg counts >100–200 eggs per gram of feces.

STRONGYLOIDES SP

Strongyloides westeri is found in the small intestine in foals. Adult horses rarely harbor patent infections, but mares often have larval stages within their tissues that are activated by parturition to move into the mammary tissue and, subsequently, are transmitted to foals in the milk. However, the relationship of *S. westeri* infection with diarrhea in foals from 10 days of age has not been clearly established. The life cycle of the worm in horses is not known to differ significantly from that of *Strongyloides* in pigs (see p 323). Diagnosis can be made based on observation of eggs somewhat more oval and about one-third the length of strongyle eggs that contain larvae. Ivermectin and oxi-bendazole effectively remove *S. westeri*. Transmission of larvae to foals via mare's milk may be prevented by routine treatment of mares with ivermectin within 24 hr after foaling.

TAPEWORMS

Three species of tapeworms are found in horses: *Anoplocephala magna*, *A. perfoliata*, and *Paranoplocephala mamillana*. They are 8–25 cm long (the first usually being the longest, and the last the shortest). *A. magna* and *P. mamillana* usually are in the small intestine; *A. perfoliata* is found mostly at the ileocecal junction, in the cecum, and in the ileum. The life cycle is similar to that of *Moniezia* spp in ruminants (see p 312) and involves free-living oribatid mites as intermediate hosts. Diagnosis is by demonstration of the characteristic eggs in the feces, but because the discharge of proglottids is sporadic, a single fecal examination may not be diagnostic. In light infections, no signs of disease are present; in heavy infections, GI disturbances may be seen. Unthriftiness and anemia have been reported. Ulceration of the mucosa is quite common in the area of attachment of *A. perfoliata* and has been suggested as one cause of intussusception. Intestinal perforation, peritonitis, and subsequent colic have been associated with *Anoplo-*

cephala infections. Colic from disturbances of the ileocecal area is more likely in horses with tapeworm infections than in those not infected. Colic associated with tapeworm infections often recurs. The site of attachment of tapeworms frequently becomes secondarily infected or abscessed. *Anoplocephala* spp can be effectively treated with pyrantel salts; normal dosages (6.6 mg/kg) of pyrantel pamoate are 87% effective, while double the normal dosage is >93% effective. Daily administration of pyrantel tartrate (2.65 mg/kg) removes *Anoplocephala* spp. Praziquantel (0.75–1 mg/kg) is 89%–100% effective in the removal of *A. perfoliata*. Praziquantel (at 1 mg/kg) appears to effectively remove *P. mamillana*; pyrantel salts do not. Mixtures of the macrocyclic lactones ivermectin or moxidectin with praziquantel are available and are highly effective against *A. perfoliata*.

On facilities where tapeworms are prevalent, clinical signs of tapeworm infections can be prevented by pyrantel salts administered daily during the grazing season, or by administration of effective oral anthelmintics within an interval deworming program. Treatment of horses according to the latter program immediately before turn out and at the end of the grazing season is likely to be most beneficial.

TRICHOSTRONGYLUS SP

The small stomach worm (hairworm) of horses, *Trichostrongylus axei*, is also found in ruminants (see p 308) and, consequently, is generally a clinical problem only in horses commingled or rotated on pasture with ruminants. Adult *T. axei* are slender and measure up to 8 mm long. Details of the life cycle in Equidae have not been carefully studied, but it is known that the larvae penetrate the mucosa. These worms produce a chronic catarrhal gastritis, which may result in weight loss. The lesions comprise nodular areas of thickened mucosa surrounded by a zone of congestion and covered with a variable amount of mucus. The lesions may be rather small and irregularly circumscribed, or they may coalesce and involve most or all of the glandular portion of the stomach, and erosions and ulcerations may be seen.

Definitive diagnosis based on fecal examination is difficult, because the eggs are similar to strongyle eggs. The feces can be cultured and, in ~7 days, the infective larvae identified. Some of the benzimidazoles and ivermectin are effective against *T. axei*.

GASTROINTESTINAL PARASITES OF PIGS

See also COCCIDIOSIS OF PIGS, p 208.

In pigs, GI helminths are almost always present; their main effects are loss of appetite, reduction in daily gain, poor feed utilization, and potentiation of other pathogens. Only rarely do they cause death. Adequate nutrition helps reduce the adverse effects of parasitism on feed efficiency and average daily gain.

Management and control of GI helminths depends entirely on the production system in place, with individual programs developed for the circumstances of the specific farm, including the knowledge of which parasites are present. Maintaining pigs on concrete or entirely on slatted floors, as on intensive farms, can successfully control those parasites that have intermediate hosts or that require pasture conditions for transmission. Steam cleaning is highly effective in killing eggs and larvae. The management approach for outdoor situations and nonconcrete floors is aimed at avoiding a buildup of eggs and larvae within the area. Good sanitation is critical because fecal-oral transmission, through the contamination of food, soil, or bedding, is the primary route by which pigs become infected. Direct sunlight or dry conditions shorten the survival of some eggs and larvae because moisture and warmth are needed for their development and survival, which probably accounts for decreased transmission during hot and cold months. Thermophilic composting of feces and/or bedding before use as fertilizer inactivates *Ascaris suum* and *Trichuris suis* eggs.² Both can survive for a few hours at 50°C but only a few minutes at 55°C. Most disinfectants in use on farms, unfortunately, are not effective against parasite eggs, especially those of *A. suum* and *T. suis*. Moving "clean" animals to safe pastures will help reduce parasite buildup, but it must be remembered that eggs of *A. suum* and *T. suis* are capable of surviving 6–9 and 5–11 yr, respectively, in the environment, and reinfection will occur even with 2–3 yr of pasture rest. If it is not possible to rotate pastures, pigs may occupy uncleanable ground for many years. In these situations, parasites can build up quickly, and control may be impossible without the regular use of anthelmintics. Anthelmintic treatments can be incorporated into any broader

program as needed but should not be the sole basis of a control program.

Various anthelmintics are available, although not all are available in every country. Benzimidazoles, including fenbendazole and flubendazole, are available for in-feed administration. Flubendazole is available for in-water and top dressing use, whereas fenbendazole has an oral formulation. Two avermectin compounds, ivermectin and doramectin, are available as injectables, whereas only ivermectin can be used in-feed. Both pyrantel tartrate and levamisole are available as in-feed formulations, but only levamisole can be used in water. Dichlorvos, an organophosphate compound, was the first broad-spectrum dewormer available for pigs and is still in use as an in-feed formulation. Piperazine salts are an older generation of anthelmintic. Despite its narrow spectrum of activity, it is still widely used, available as an in-feed or in-water formulation.

Although anthelmintic-resistant populations of *Oesophagostomum* sp were identified as early as 1987, resistance does not appear to be a widespread problem. In addition, there is no justification for routinely rotating classes of dewormers; rather, choice of product should be made on the expected efficacy against the parasites present (including ectoparasites).

ASCARIS SUUM

Adults of the large roundworm, *Ascaris suum*, are found in the small intestine and transiently in the large intestine during expulsion of the worms. Males are up to 25 cm and females up to 40 cm long, whitish, and quite thick. Large numbers of eggs are produced (as many as 200,000 to 1 million/day/female) although shed intermittently; they can develop to the infective stage (eggs containing L₃ larva) in 3–4 wk under optimal conditions. In temperate regions, the eggs stay dormant in winter (<15°C) and resume development when temperature rises in the spring. The eggs are highly resistant to chemical agents, but conditions with low humidity, heat, or direct sunlight reduce their survival significantly. Under optimal conditions, eggs may survive for 5–11 yr. When the eggs are ingested, the larvae hatch

in the intestine, penetrate the wall, and enter the portal circulation. After a short period in the liver, they are carried by the circulation to the lungs, where they pass through the capillaries into the alveolar spaces. Approximately 9–10 days after ingestion, the larvae pass up the bronchial tree, are swallowed, and return to the small intestine by ~10–15 days after infection, where they mature into adult worms. The first eggs are passed ~6–7 wk after infection. Lifespan is ~6–9 mo. Earthworms and dung beetles can serve as paratenic hosts.

Distribution and Host Range: *A. suum* is found in pigs worldwide. Occasionally, nematodes may establish in sheep; however, ingestion of infective eggs while grazing generally results in pneumonia and liver lesions in sheep. Infections can also be seen in cattle and manifest as an acute, atypical interstitial pneumonia. Whether the human nematode *Ascaris lumbricoides* and *A. suum* of pigs are the same is still debated. Current evidence indicates there is a single interbreeding population of *Ascaris*, and the populations occurring in pigs or people have only slight phenotypical and genotypical adaptive changes. Regardless, it is clear the pig ascarid is zoonotic, having been found in people from various areas of the world, particularly those in close contact with pigs. Visceral larva migrans due to migrating larvae has been described.

Clinical Findings: Adult worms may significantly reduce the growth rate of young pigs; in rare cases, they may cause mechanical obstruction of the intestine. Migration of larvae through the liver causes hemorrhage, fibrosis, and accumulation of lymphocytes seen as white spots (called “milk spots”) under the capsule and leading to condemnation of the liver at slaughter. These lesions become visible 7–10 days after infection and will regress within 1–4 wk; therefore, their presence indicates recent infection/reinfection. In resistant pigs, only a few larvae will reach the liver and the number of white spots will be low, despite continual reinfection. Therefore, the number of white spots and the liver condemnation rate are both poor measures of herd infection level. In heavy infections, the larvae can cause pulmonary edema and consolidation, as well as exacerbate swine influenza and endemic pneumonia. Heavily exposed susceptible pigs show abdominal breathing, commonly referred to as “thumps.” In addition to the respiratory

signs, marked unthriftiness and weight loss may be seen. Infection generally induces development of acquired resistance to reinfection, and prevalence is highest in young growing pigs. If the treatment rate is very low and the level of herd immunity is also low, prevalence may be highest in breeding animals.

Diagnosis: During the patent period, diagnosis can be made by demonstrating the typical eggs (golden brown, thick pitted outer wall, 50–70 × 40–60 µm) by fecal analysis or by observation of large worms in feces. Pigs are coprophagic; thus, low egg counts (<200 eggs/g) may indicate coprophagy rather than actual infection. A presumptive diagnosis can be made at necropsy based on demonstration of the typical milk spots; however, other migrating parasites (eg, larvae of *Toxocara canis*, *Stephanurus dentatus*) may cause similar lesions. Worms may be demonstrated in the lungs (small immatures) and the small intestine (large immatures, adults) at necropsy.

Treatment: Supportive therapy, including treatment for secondary bacterial invaders, may be necessary during the respiratory phase of infection. Many drugs have been used to remove adult ascarids. Piperazine preparations have low toxicity and are moderately priced. The benzimidazoles and probenzimidazoles, dichlorvos, ivermectin, levamisole, and pyrantel are effective and have a broader spectrum of activity than piperazine. Hygromycin is active against ascarids when administered as a low-level additive to the feed. Less information is available concerning the control of migratory stages; pyrantel and fenbendazole show activity.

MACRACANTHORHYNCHUS SP

Adult *Macracanthorhynchus hirudinae* (thorny-headed worms) are usually seen in the small intestine. They are 10 cm (males) to 65 cm (females) long, 3–9 mm thick, and slightly pink with a transversely wrinkled outer covering; superficially, they resemble ascarids. However, unlike ascarids, the anterior end bears a spiny, retractable proboscis or rostellum used for firm attachment to the intestinal wall. There is a granulomatous inflammation at the site of attachment resulting in nodule formation, which will regress ~1 mo after the parasite is no longer present. The eggs (dark brown, embryonated, with three embryonic envelopes, 90–110 × 50–65 µm) passed in the

feces are ingested by the grubs of various beetles that serve as intermediate hosts. Pigs become infected by ingesting either grubs or adult beetles, and the infection is thus restricted to pigs with pasture access. The prepatent period is 2–3 mo, and longevity is ~1 yr. The female can lay ~260,000 eggs/day for several months.

Signs are generally absent; when present, they are nonspecific. Antemortem diagnosis is difficult, because the ova do not float reliably in many conventional salt solutions and thus should be looked for in the sediment if using solutions of low specific gravity. At necropsy, nodules usually can be seen through the serosa. Because the proboscis is longer than the jejunal wall is thick, perforations may occur; however, the inflammatory response generally seals off any perforation. Clinical signs are not generally present; however, when perforations do occur a fatal peritonitis can result.

Levamisole and ivermectin are effective for treatment. Control depends on avoiding use of contaminated hog lots or pastures or by regular removal of feces when pigs are kept in sties or small runs.

OESOPHAGOSTOMUM SPP

Oesophagostomum spp are prevalent worldwide; *O. dentatum* is the most common species, whereas *O. quadrispinulatum* appears to be slightly more pathogenic. The adults are found in the lumen of the large intestine; they are 8–15 mm long, slender, and white or gray. The life cycle is direct. Eggs are passed in the feces; infective L₃ are found on pasture within 1 wk and can survive for ~1 yr under optimal conditions. Infection results from ingestion of L₃, which penetrate the mucosa of the large intestine within a few hours after ingestion and return to the lumen in 6–20 days. The prepatent period is ~3–6 wk. A periparturient rise in worm egg output has been observed in sows from 2 wk before parturition to weaning; however, this phenomenon is far less constant in pigs than sheep and its epidemiologic importance is questionable. Most infections are asymptomatic, but heavily infected pigs may show anorexia, emaciation, and GI disturbances.

The serosa shows small nodules, their size reflecting species and previous exposure. In severe cases, the intestinal wall may be thickened and necrotic. Heavy infections may reduce the lactation capacity of sows and the body weight of growing pigs. Infection induces only moderate immunity; hence, prevalence of nodular worms tends to be higher in the older age

groups (sows, boars). In patent infections, typical strongyle eggs (66–80 × 38–47 μm) are found in feces, often in large numbers. These can be differentiated from those of *Hyostrongylus* by larval culture. At necropsy, the worms and lesions are readily visible. The benzimidazoles, levamisole, piperazines, dichlorvos, pyrantel tartrate, and ivermectin are effective, but anthelmintic resistance has been observed for benzimidazoles, levamisole, and pyrantel. A diet composed of highly degradable carbohydrates may support worm control by creating unfavorable conditions, which decrease worm establishment and fecundity.

STOMACH WORMS

Five genera of nematodes are found within the stomach of pigs. The trichostrongylid *Hyostrongylus* is relatively common, whereas the other four spirurids (*Ascarops*, *Gnathostoma*, *Physocephalus*, *Simondsia*) are less common or geographically limited. Although some (eg, *Ascarops strongylina*, *Physocephalus sexalatus*) are more obvious grossly, only *Hyostrongylus rubidus* is considered to be pathologically significant. *H. rubidus* (the red stomach worm) is ~6 mm long, quite slender, and has a direct life cycle, features similar to those of *Ostertagia ostertagi* of cattle. The prepatent period is ~3 wk unless larval inhibition occurs; this may be induced by seasonal changes or repeated infections, explaining why hypobiotic larvae are usually found in older animals. As with *Haemonchus contortus* of sheep, relaxation of immunity associated with parturition allows inhibited larvae to resume development, leading to a periparturient rise in fecal egg counts. *A. strongylina* and *P. sexalatus*, the thick stomach worms, are 10–20 mm long, are much stouter than *H. rubidus*, and have coprophagous beetles as intermediate hosts. The prepatent periods for the spirurids are in the range of 4–6 wk. Because of the free-living larval requirements (*H. rubidus*) or the need for an intermediate host (all others), infections are confined to animals with pasture access or those kept in straw yards.

Clinical Findings: The pathogenesis of hyostrongylosis is similar to that of ostertagiosis of cattle, including the replacement of parietal cells by rapidly dividing undifferentiated cells, giving rise to nodules on the mucosal surface. Gastric pH increases as does mucus production, resulting in a catarrhal gastritis. Occasion-

ally, gastric ulcerations of the glandular stomach occur but whether this is a direct result of the nematode infection is unclear. Light infections are usually asymptomatic. However, when present in large numbers or when the host's condition is reduced by poor nutrition or other factors, these worms may cause variable appetite, anemia, diarrhea, or weight loss, and may contribute to a thin sow syndrome. *H. rubidus* characteristically is found under a heavy catarrhal or mucousexudate. Resumed development of inhibited larvae may cause severe gastritis and, in addition, contaminate the environment of the young pigs. Egg excretion per female *Hyostromylos* worm is generally much lower than that of other nematode genera.

Diagnosis: Clinical signs other than unthriftiness are not obvious. Fecal examinations may show the distinctive ova of *Physocephalus* and *Ascarops*—small ($35\text{--}40 \times 17\text{--}20$ mm), thick-shelled eggs containing active larvae. *Hyostromylos* ova resemble those of other strongyle worms (eg, *Oesophagostomum*), and fecal cultures are required to obtain infective larvae for differential diagnosis.

At necropsy, adult worms, especially *Physocephalus* and *Ascarops*, are readily seen. Mucosal scrapings for microscopic examination are essential for detection of immature *Hyostromylos*.

Treatment and Control: The same principles used for control of parasitic gastroenteritis of ruminants apply to the control of hyostromylosis and should not depend solely on anthelmintic use. As an example, in temperate climates, an annual rotation of pastures with other livestock or crops would reduce pasture contamination. Care must be taken with rotating livestock if the pigs also harbor ascarid infections. Integration of anthelmintics depends on their availability and the season, as well as on other farming activities. The newer benzimidazoles, probenzimidazoles, and ivermectin are highly effective against adult and immature stages (including hypobiotic larvae) of *Hyostromylos*. Implementing measures to control the intermediate hosts of the spirurid nematodes is usually not required or unproductive. Treatment for most has not been reported, although ivermectin has activity against adult *Ascarops*.

STRONGYLOIDES SP

Strongyloides ransomi (pig threadworm) is a ubiquitous and common nematode

parasite of pigs; it is particularly pathogenic in suckling pigs, especially in tropical and subtropical climates. It is of less importance in adults. Threadworms are unique among helminths, having both parasitic generations (females in the small intestine) and free-living generations (males and females in the surrounding environment). Transmission occurs either by skin penetration, emphasizing the importance of good hygiene, or via infective larvae in the colostrum of lactating sows. Lactogenic transmission is highly efficient in infecting newborn piglets. Even without reinfection of the sow, dormant larvae in the udder may be transmitted to several consecutive litters of piglets. The adult female worms burrow into the wall of the small intestine, being found in tunnels in the epithelium at the base of the villi. The prepatent period is 4–9 days, depending on the mode of infection. In light and moderate infections, the pigs usually show no signs. In heavy infections, diarrhea, anemia, and emaciation may be seen, and death may result. Infection induces strong immunity; hence, older pigs are usually not clinically affected.

Diagnosis is determined by demonstration of the characteristic small, thin-shelled, embryonated eggs ($20\text{--}35 \times 40\text{--}55$ μm) in the feces. It is important that feces are collected from the rectum, because fecal droppings often are contaminated by free-living nematodes, which may have eggs indistinguishable from the *Strongyloides* eggs. Furthermore, feces must be cooled immediately to prevent hatching. At necropsy, adults may be found in scrapings from the intestinal mucosa, and immature worms may be recovered from minced tissues using the Baermann techniques.

The benzimidazoles and levamisole are effective against intestinal infections. If administered in the feed for several days before and after parturition, they reduce lactogenic transmission to suckling piglets. Ivermectin is effective against adults and, if given to the sow 1–2 wk before farrowing, suppresses larval excretion in the milk. A high level of hygiene is necessary to diminish larval development as well as multiplication of free-living generations in the pens.

TRICHURIS SP

Trichuris suis is found worldwide in pigs. The adult worms are 5–6 cm long and whip-shaped; the anterior slender portion embeds within the epithelial cells of the large intestine, especially the cecum, with the thickened posterior third lying free in

the lumen. Infection is by ingestion of eggs containing an infective first-stage larva. The larva hatches and penetrates the distal ileum, cecal, and colonic mucosa. The nematodes complete all four molts, after which the posterior end begins to protrude into the lumen. The prepatent period is 6–8 wk; longevity is 4–5 mo. Light infections, with no clinical signs, are generally the case. Heavy infections may cause inflammatory lesions in the cecum and adjacent large intestine and may be accompanied by diarrhea and unthriftiness. Clinical infection is most often seen in young animals; resistance is both acquired and age-related. The double-operculated brown eggs (50–68 × 21–31 mm) are diagnostic. Eggs are heavy; thus, good technique with media of proper specific gravity is essential. Trichurids have

a short period of egg-laying (2–5 wk) before the worms are expelled by immune-mediated reactions, and thus little significance can be given to percentage of egg excretors and numbers of eggs per gram of feces. Clinical trichurosis is usually associated with the larval stages before eggs are passed in the feces; in these cases, examining mucosal scrapings taken at necropsy for smaller stages of the parasite is recommended. Mature parasites are easily found after ingesta is washed away and can be identified by their size and whip-like form. Dichlorvos, levamisole, some benzimidazoles, ivermectin, and doramectin are effective against the adult worms. Biologically, the eggs are comparable to *Ascaris* eggs—they are highly resistant to chemicals and may remain infective for 3–4 yr; control relies on thorough cleaning of the affected area and moving the animals to clean plots. *Trichuris* eggs develop rather slowly (10–12 wk under optimal conditions), and because they do not develop at temperatures <16°C, there is only one generation per year in temperate regions.

T suis larvae may hatch in the large intestine of people, in which the larvae seem to be able to establish transiently. It is this feature that has led to intense research interest in the treatment of inflammatory bowel disease, including ulcerative colitis and Crohn's disease, of people through administration of infective *T suis* eggs.

FLUKE INFECTIONS IN RUMINANTS

Fasciola hepatica, the most important trematode of domestic ruminants, is the most common cause of liver fluke disease in temperate areas of the world. In the USA, it is endemic along the Gulf Coast, the West Coast, the Rocky Mountain region, and other areas. It is present in eastern Canada, British Columbia, and South America and is of particular economic importance in the British Isles, western and eastern Europe, Australia, and New Zealand. *Fasciola gigantica* is economically important in Africa and Asia and is also found in Hawaii. *Fascioloides magna* has been reported in at least 21 states (USA) and in Europe. In North America, *Dicrocoelium dendriticum* is confined mainly to New York, New Jersey,

Massachusetts, and the Atlantic provinces of Canada. It is also widespread in some areas in Europe and Asia. *Eurytrema* spp, the pancreatic flukes, parasitize sheep, pigs, and cattle in Brazil and parts of Asia. Several species of paramphistomes or rumen flukes are found throughout much of the world.

FASCIOLA HEPATICA

(Common liver fluke)

Etiology: *Fasciola hepatica* (30 × 2–12 mm and leaf-shaped) is distributed worldwide and has a broad host range, including people. Economically important infections

Adult *Fasciola hepatica* (Corazza stain).

Fasciola hepatica egg found on sedimentation. Adding a drop of methylene blue to the sediment provides contrasting background, making the eggs easier to see. Courtesy of Dr. Lora Ballweber.

are seen in cattle, sheep, alpacas, and llamas in three forms: chronic, which is rarely fatal in cattle but often fatal in sheep, alpacas, and llamas; subacute or acute, which is primarily in sheep, alpacas, and llamas, and often fatal; and in conjunction with "black disease" (INFECTIOUS NECROTIC HEPATITIS, see p 603), which is most common in sheep and usually fatal.

Eggs are passed in the feces, and miracidia develop within as little as 9–10 days (at 22°–26°C [71.6°–78.8°F]); little development occurs below 10°C [50°F]). Hatching only occurs in water, and miracidia are short-lived (~3 hr). Miracidia infect lymnaeid snails, in which asexual development and multiplication occur through the stages of sporocysts, rediae, daughter rediae, and cercariae. After 6–7 wk (or longer if temperatures are low), cercariae emerge from snails, encyst on aquatic vegetation, and become metacercariae. Snails may extend the developmental period by hibernating during the winter. Metacercariae may remain viable for many months unless they become desiccated.

After ingestion by the host, usually with herbage, young flukes excyst in the duodenum, penetrate the intestinal wall,

and enter the peritoneal cavity, where they migrate to the liver. The time required for this transit can vary and results in delayed development rates, which affects the efficacy of some treatments because many are effective against flukes only later in their development. The young flukes penetrate the liver capsule and tunnel through the parenchyma for 6–8 wk, growing and destroying tissue. They then enter small bile ducts and migrate to the larger ducts and, occasionally, the gallbladder, where they mature and begin to produce eggs. The prepatent period is usually 2–3 mo, depending on the fluke burden. The minimal period for the completion of one entire life cycle is ~17 wk. Adult flukes may live in the bile ducts of sheep for years; most are shed from cattle within 5–6 mo.

Clinical Findings: Fasciolosis ranges in severity from a devastating disease in sheep, alpacas, and llamas to an asymptomatic infection in cattle. The course usually is determined by the number of metacercariae ingested. Acute disease occurs 2–6 wk after the ingestion of large numbers of metacercariae (usually >2,000) over a short period. In sheep, acute fasciolosis occurs seasonally and is manifest by a distended, painful abdomen; anemia; and sudden death occurring 2–6 wk after infection. The acute syndrome can be complicated by concurrent infections with *Clostridium novyi*, resulting in "black disease" (clostridial necrotic hepatitis), although this is now less common due to vaccination against clostridial diseases. In subacute disease, large numbers (500–1,500) of metacercariae are ingested over longer periods of time; survival is longer (7–10 wk), even in cases with significant hepatic damage, but deaths occur due to hemorrhage and anemia. Chronic fasciolosis can be seen in all seasons but manifests primarily in late fall and winter. It occurs as a result of ingesting moderate numbers (200–500) of metacercariae over longer periods of time; signs include anemia, unthriftiness, submandibular edema, and reduced milk production, but even heavily infected cattle may show no clinical signs although their immunity to other pathogens (eg, *Salmonella* spp) may be reduced and reactions to the single intradermal test for tuberculosis modified. Heavy chronic infection is fatal in sheep, alpacas, and llamas.

Sheep do not appear to develop resistance to infection, and chronic liver damage is cumulative over several years. In cattle, a partial acquired resistance develops beginning 5–6 mo after infection.

Lesions: Severity depends on the number of metacercariae ingested, the phase of development in the liver, and the species of host involved. During the first phase, immature, wandering flukes destroy liver tissue and cause hemorrhage. The second phase occurs when the flukes enter the bile ducts, where they ingest blood and damage the mucosa with their cuticular spines. In acute fasciolosis, damage is extensive; the liver is enlarged and friable with fibrinous deposits on the capsule. Migratory tracts can be seen, and the surface has an uneven appearance. In chronic cases, cirrhosis develops. The damaged bile ducts become enlarged, or even cystic, and have thickened, fibrosed walls. In cattle but not sheep, the duct walls become greatly thickened and often calcified. Aberrant migrations occur more commonly in cattle, and encapsulated flukes may be found in the lungs. Mixed infections with *Fascioloides magna* can be seen in cattle.

Tissue destruction by wandering flukes may create a microenvironment favorable for activation of clostridial spores.

Diagnosis: The oval, operculated, golden brown eggs (130–150 × 65–90 µm) must be distinguished from those of paramphistomes (rumen flukes), which are larger and clear. Eggs of *F. hepatica* cannot be demonstrated in feces during acute fasciolosis. In subacute or chronic disease in cattle, the number varies from day to day, and repeated fecal sedimentation may be required. Diagnosis can be aided by an ELISA (commercially available in Europe) that enables detection ~2–3 wk after infection and well before the patent period. Plasma concentrations of γ-glutamyltransferase, which are increased with bile duct damage, are also helpful during the late maturation period when flukes are in the bile ducts. At necropsy, the nature of the liver damage is diagnostic. Adult flukes are readily seen in the bile ducts, and immature stages may be squeezed or teased from the cut surface.

Control: Control measures for *F. hepatica* ideally should involve removal of flukes in affected animals, reduction of the intermediate host snail population, and prevention of livestock access to snail-infested pasture. In practice, only the first of these is used in most cases. Although molluscicides can be used to reduce lymnaeid snail populations, those that are available all have disadvantages that restrict their use. Copper sulfate, if applied before the snail population multiplies each year, is effective but toxic

to sheep, which must be kept off treated pasture for 6 wk after application. Other such chemicals are generally too expensive and have ecologically undesirable effects. Prevention of livestock access to snail-infested pasture is frequently impractical because of the size of the areas involved and the consequent expense of erecting adequate fencing.

Several drugs are available to treat infected ruminants, including triclabendazole, clorsulon (cattle and sheep only), albendazole, netobimin, closantel, rafoxanide, and oxcyclozanide. Not all are approved in all countries (eg, only clorsulon and albendazole are approved in the USA; none are approved for alpacas and llamas), and most have long withdrawal periods before slaughter if used in meat-producing animals and before milk from treated livestock can be used for human consumption. Anthelmintic resistance by *F. hepatica* to various compounds, including albendazole, clorsulon, and triclabendazole, has been demonstrated, further complicating control programs based only on anthelmintic usage. The timing of treatment is also important so that the pharmacokinetics of the drug used will result in the optimal removal of flukes—each flukicide has varying efficacy against different ages of fluke. Timing of treatments is determined by local epidemiologic factors and additional treatments by unusually suitable conditions for parasite multiplication. For example, in the Gulf Coast states of the USA, cattle should be treated before the fall rainy season and again in the late spring. In northwestern USA and in northern Europe, cattle should be treated at the end of the pasture season and, if not housed, again in late January or February. In European countries with large susceptible sheep populations, computerized prediction systems based on rainfall, evapotranspiration, number of wet days per month, and/or prevalence are used to predict the timing and severity of disease. In areas where heavy infections are expected, sheep may require treatment in September or October, January or February, and again in April or May to reduce both the chances of acute or chronic infections and the output of fluke eggs for development of future disease.

FASCIOLA GIGANTICA

(Giant liver fluke)

Fasciola gigantica is similar in shape to *Fasciola hepatica* but is longer (75 mm), with less clearly defined shoulders, and is

12 mm wide. It is found in warmer climates (Asia, Africa) in cattle and buffalo, in which it is responsible for chronic fasciolosis, and in sheep, in which the disease is frequently acute and fatal. The life cycle is similar to that of *F. hepatica*, except most parasitic phases are longer, the prepatent period is 10–16 wk, and the species of snail intermediate hosts are different. The pathology of infection, diagnostic procedures, and control measures are similar to those for *F. hepatica* (see p 324).

FASCIOLOIDES MAGNA

(Large American liver fluke, Giant liver fluke)

Fascioloides magna is up to 100 mm long, 2–4.5 mm thick, 11–26 mm wide, and oval; it is distinguished from *Fasciola* spp by its large size and lack of an anterior projecting cone. It is found in domestic and wild ruminants; deer are the reservoir host. The life cycle resembles that of *Fasciola* spp.

Although flukes will mature in cattle, the intense encapsulation response forms a closed cyst, so eggs rarely pass out of the animal. Pathogenicity is low, and losses are confined primarily to liver condemnations. In sheep and goats, encapsulations do not occur, and the parasites migrate in the liver and other organs, causing tremendous damage. A few parasites can cause death due to extensive migrations. Infection with *F. magna* appears to be rare in alpacas and llamas, in which the response mirrors that seen in cattle. In deer, there is little tissue reaction, and the parasites are enclosed in thin, fibrous cysts that communicate with bile ducts. Histologically, infected livers of all species show black, tortuous tracts formed by migrations of young flukes.

While the eggs of *F. magna* resemble those of *Fasciola hepatica*, this is of limited use; eggs usually are not passed by cattle and sheep and probably not by alpacas and llamas. Recovery of the parasites at necropsy as well as differentiation of *F. hepatica* is necessary for definitive diagnosis. When domestic ruminants and deer share the same grazing, the presence of disease due to *F. magna* should be kept in mind. Mixed infections with *F. hepatica* are seen in cattle.

Oxyclozanide has been reported to be effective against *F. magna* in white-tailed deer, and triclabendazole has been used in captive and free-ranging red deer. Rafoxanide has been used successfully against natural infections in cattle. Albendazole

(7.5 mg/kg), clorsulon (15 mg/kg), and closantel (15 mg/kg) have shown efficacy against this fluke in sheep. Currently, no products are approved for use against this fluke in the USA. Deer are required for completion of the life cycle; if they can be excluded from the areas grazed by cattle and sheep, control may be effected. Control of the intermediate host (limnaeid snails) may be possible once it has been identified in a region and the nature of its habitat examined. However, environmental concerns are the same as those for *F. hepatica*.

DICROCOELIUM DENDRITICUM

(Lancet fluke, Lesser liver fluke)

Dicrocoelium dendriticum is slender (6–10 mm long × 1.5–2.5 mm wide). It is found in many countries and infects a wide range of definitive hosts, including domestic ruminants. Another species, *D. hospes*, is common in West Africa.

The first intermediate host is a terrestrial snail (*Cionella lubrica*, in the USA), from which cercariae emerge and are aggregated in a mass of sticky mucus (slimeball). The slimeballs of cercariae are ingested by the second intermediate host, which is an ant (*Formica fusca*, in the USA), with metacercariae forming in the abdominal cavity. One or two metacercariae in the subesophageal ganglion of the ant cause abnormal behavior in which the ants climb up and remain on the tips of the herbage where they attach themselves, which increases the probability of ingestion by the definitive host. Once ingested, the metacercariae excyst in the small intestine, migrate up the main bile duct, and then on to smaller ducts. They begin laying eggs ~10–12 wk after infection. The total life cycle takes ~6 mo.

In cattle, sheep, and goats there appears to be no immunity, and heavy infections may accumulate (up to 50,000 flukes in a mature sheep) with minimal pathologic or clinical changes. Cirrhosis can develop, and the bile ducts may be thickened and distended. Economic loss is due primarily to condemnation of livers. Clinical signs are not obvious but may be seen in massive infections. Infections in alpacas and llamas are associated with an acute decline in condition, recumbency, hypothermia, and anemia. Liver enzyme values tend to be within normal limits. Severe pathologic changes occur within the liver and bile ducts, including cirrhosis, abscesses, and granulomas.

The eggs contain a miracidium and are very small ($40 \times 25 \mu\text{m}$), lopsided, and yellowish brown. Fecal flotation with a solution of high specific gravity (1.30–1.45) is recommended to detect *D dendriticum*.

The complex life cycle makes control of intermediate hosts almost impossible, because widespread chemical use has damaging ecologic effects on other similar organisms. However, keeping ducks, turkeys, or chickens to eat the snails can effectively reduce the intermediate host populations in small areas. Because infected ants are usually found within 30–50 cm of the base of the nest, covering nests with tree branches to keep animals away from the base can also be useful. Effective anthelmintic treatments are available, but most must be administered at dosages higher than those recommended for *F hepatica*. Effective anthelmintic treatments in both cattle and sheep are albendazole at 15–20 mg/kg in a single dose or two doses of 7.5 mg/kg on successive days, or netobimin at 20 mg/kg. Praziquantel (50 mg/kg) has been shown to decrease egg shedding by ~90% in llamas.

EURYTREMA SPP

(Pancreatic fluke)

Pancreatic flukes have a thick body and are 8–16 mm long $\times$ 6 mm wide. They are parasites of the pancreatic ducts and occasionally of the bile ducts of sheep, pigs, and cattle in Brazil and Asia. Three species, *Eurytrema pancreaticum*, *E coelomaticum*, and *E ovis* are recognized. The first intermediate hosts are terrestrial snails (*Bradybaena* spp), and the cercariae are released onto herbage and ingested by grasshoppers (*Conocephalus* spp) or tree crickets (*Oecanthus* spp), which are the second intermediate host. After the animal ingests a metacercarial-infected grasshopper, the immature flukes excyst in the duodenum and migrate to the pancreatic duct, where they mature. The prepatent period of *E coelomaticum* in cattle is 3–4 mo.

There are no obvious clinical signs, but a general weight loss may occur in heavy infections. *Dicrocoelium*-like eggs can be demonstrated in feces. Light infections cause proliferative inflammation of the pancreatic duct, which may become enlarged and occluded. In heavy infections, fibrotic, necrotic, and degenerative lesions develop. These result in increased plasma

concentrations of γ -glutamyl transpeptidase and AST. Losses are reported due to condemned pancreas, but the pathogenesis suggests an additional loss of production.

The control of intermediate hosts may not be practical. Treatment with praziquantel (20 mg/kg, for 2 days) or albendazole (7.5 mg/kg for sheep, 10 mg/kg for cattle) have reportedly been effective.

PARAMPHISTOMES

(Amphistomes, Rumen flukes, Conical flukes)

There are numerous species of paramphistomes (*Paramphistomum*, *Calicophoron*, *Cotylophoron*) in ruminants worldwide. The adult parasites are pear-shaped, pink or red, up to 15 mm long, and attach to the lining of the rumen. Immature forms are found in the duodenum and are 1–3 mm long.

Eggs are passed in the feces, and miracidiae hatch in the water and infect planorbid or bulinid snails. Development in the snail is similar to that in the life cycle of *Fasciola hepatica*, with the snail shedding cercariae that encyst on the herbage. In the ruminant host, the young flukes excyst and remain in the small intestine for 3–6 wk before migrating forward through the reticulum to the rumen. Eggs are produced 7–14 wk after infection.

Adult flukes do not cause overt disease, and large numbers may be encountered. The immature flukes attach to the duodenal and, at times, the ileal mucosa by means of a large posterior sucker and cause severe enteritis, possibly necrosis, and hemorrhage. Affected animals exhibit anorexia, polydipsia, unthriftiness, and severe diarrhea. Extensive mortality may occur, especially in young cattle and sheep. Older animals can develop resistance to reinfection but may continue to harbor numerous adult flukes.

The large, clear, operculated eggs are readily recognized, but in acute paramphistomosis there may be no eggs in the feces. Examination of the fluid feces may reveal immature flukes, many of which are passed in these cases. Diagnosis is commonly made at necropsy.

Control measures to reduce the host snail population are as for control of fasciolosis (see p 326). Treatments with reported success (efficacies >90%) are oxcylozanide (two doses 3 days apart) and the combination of bithional and levamisole.

HEPATIC DISEASE IN LARGE ANIMALS

Hepatic disease is common in large animals. Increases in serum hepatic enzymes and total bile acid concentration may indicate hepatic dysfunction, insult, disease, or failure. Although liver disease is especially common in horses and foals, progression to liver failure is not.

Diseases that frequently result in hepatic failure in horses include Theiler disease, Tyzzer disease (foals), pyrrolizidine alkaloid toxicosis, hepatic lipidosis, suppurative cholangitis or cholangiohepatitis, cholelithiasis, and chronic active hepatitis. Obstructive disorders (biliary stones, right dorsal colon displacement, neoplasia, duodenal ulceration and stricture, hepatic torsion, portal vein thrombosis), aflatoxicosis, leukoencephalomalacia, pancreatic disease, kleingrass or alsike clover poisoning, portal caval shunts, hepatic abscess, and perinatal herpesvirus 1 infections sporadically result in hepatic failure. Less frequently, hepatic failure is associated with endotoxemia, steroid administration, inhalant anesthesia, systemic granulomatous disease, drug-induced amyloidosis, hyperammonemia in Morgan foals, parasite damage, iron toxicity, or after neonatal isoerythrolysis.

In ruminants, hepatobiliary disease is associated with hepatic lipidosis, hepatic abscesses, endotoxemia, pyrrolizidine alkaloid and other plant toxicoses, certain clostridial diseases, liver flukes, mycotoxicosis, and mineral toxicosis (copper, iron, zinc) or deficiency (cobalt). Vitamin E or selenium deficiency (hepatosis dietetica), aflatoxicosis, ascarid migration, bacterial hepatitis, and ingestion of toxic substances (eg, coal tar, cyanamide, blue-green algae, plants, gossypol) are associated with hepatic injury in swine.

Although the exact incidence of hepatic disease in camelids (llamas, alpacas) is unknown, it appears to be common in North America. Hepatic lipidosis (secondary more often than primary) is reportedly the most common liver disease in llamas and alpacas, occurring in both crias and adults. Bacterial (*Salmonella* spp, *Escherichia coli*, *Listeria* spp, *Clostridium* spp) cholangiohepatitis, adenoviral hepatitis and pneumonia, fungal hepatitis (coccidioidomycosis), toxic hepatopathy (copper), halothane-induced hepatic necrosis, hepatic neoplasia (lymphosarcoma, hemangiosarcoma,

adenoma), and liver fluke infestation have also been reported in camelids.

The liver can respond to insult in only a limited number of ways. Fat droplets in the liver may be an early and often reversible change. Biliary hyperplasia is also reversible if the insult is removed early. Necrosis of hepatocytes indicates more recent damage. The dead cells are removed by an inflammatory process and replaced with either new hepatocytes or fibrosis. Unless the dysfunction is acute and hepatocellular regeneration is evident, prognosis for animals with liver failure is usually unfavorable. Early hepatic fibrosis may be reversible with prompt recognition and intervention. Chronic disease with extensive loss of hepatic parenchyma and fibrosis, especially with portal bridging, warrants a poor prognosis.

Clinical Findings: Clinical signs of hepatic disease may not be evident until >60%–80% of the liver parenchyma is nonfunctional or when hepatic dysfunction is secondary to disease in another organ system. Clinical signs may vary with the course of the disease (acute or chronic), primary site of injury (hepatocellular, biliary), and specific cause. Onset of signs of hepatic encephalopathy and liver failure is often acute regardless of whether the hepatic disease process is acute or chronic. Clinical signs and severity of hepatic pathology reflect the degree of compromise of one or more of the liver's vital functions, including blood glucose regulation; fat metabolism; production of clotting factors, albumin, fibrinogen, nonessential amino acids, and plasma proteins; bile formation and excretion; bilirubin and cholesterol metabolism; conversion of ammonia to urea; polypeptide and steroid hormone metabolism; synthesis of 25-hydroxycholecalciferol; and metabolism and/or detoxification of many drugs and toxins.

Icterus, weight loss, or abnormal behavior are common in horses with liver disease and hepatic failure. CNS signs are often the initial and predominant sign in horses with acute hepatic failure, whereas weight loss is a prominent sign in most but not all horses with chronic liver disease and failure. Photosensitization and, less commonly, bilateral pharyngeal paralysis, causing inspiratory stridor, diarrhea, or

constipation, may be present. Affected cattle usually show inappetence, decreased milk production, and weight loss. Tenesmus and ascites are seen in cattle but are not common in affected horses. Weight loss may be the only sign associated with liver abscesses. Icterus, which is most pronounced when the biliary system is diseased, is also common in horses with acute liver failure. It is more variably present in horses with chronic liver failure or in ruminants. Fasting hyperbilirubinemia is a more common cause of icterus in horses and is not associated with hepatic disease. Occasionally, persistent hyperbilirubinemia (primarily indirect or unconjugated bilirubin) may be seen in healthy horses (especially Thoroughbreds) without evidence of hemolysis or hepatic disease. In ruminants, icterus is more commonly due to hemolysis and primarily involves increases in indirect bilirubin. Hyperbilirubinemia caused by obstructive biliary conditions is rare in goats and sheep.

Hepatic encephalopathy is associated with behavioral changes in horses, ruminants, and swine. The severity of hepatic encephalopathy often reflects the degree of hepatic failure but does not differentiate between acute or chronic liver failure. Signs of hepatic encephalopathy range from nonspecific depression and lethargy to head pressing, circling, aimless walking, dysphagia, ataxia, dysmetria, persistent yawning, pica, increased friendliness, aggressiveness, stupor, seizures, or coma. Pharyngeal or laryngeal collapse with loud, stertorous inspiratory noises and dyspnea occurs in some cases of hepatic failure, especially in ponies. The pathogenesis of hepatic encephalopathy is unknown, but proposed theories include ammonia as a neurotoxin, alterations in monoamine neurotransmission (serotonin, tryptophan) or catecholamine neurotransmitters, imbalance between aromatic and short branch chain amino acids resulting in increased inhibitory neurotransmitters (γ -aminobutyric acid, L-glutamate), neuroinhibition due to increased cerebral levels of endogenous benzodiazepine-like substances, increased permeability of the blood-brain barrier, and impaired CNS energy metabolism. Although the signs can be dramatic, hepatic encephalopathy is potentially reversible if the underlying hepatic disease can be resolved.

Photosensitization, which may be seen secondary to acute or chronic liver failure, must be differentiated from primary photosensitization (see p 976). Hepatogenous photosensitization develops when

compromised hepatic function results in phyloerythrin, a photodynamic metabolite of chlorophyll, entering the skin. Phyloerythrin in the skin reacts with ultraviolet light and releases energy, causing inflammation and skin damage. Signs of photosensitization are varied but include uneasiness, pain, pruritus, mild to severe dermatitis with erythema, extensive subcutaneous edema, skin ulceration, sloughing of skin and ophthalmia with lacrimation, photophobia, and corneal cloudiness. Dermatitis and edema are particularly evident on nonpigmented, light-colored or hairless areas of the body and areas exposed to sun. Mucocutaneous junctions and patches of white hair are the most common sites of photosensitization in cattle. Occasionally, the underside of the tongue may be affected. Blindness, pyoderma, loss of condition, and occasionally death are possible sequelae. Pruritus may result from photosensitization or from deposition of bile salts in the skin secondary to alterations in hepatic excretion.

Diarrhea or constipation may be seen in animals with hepatic disease. Diarrhea is more commonly seen in cattle than in horses with chronic liver disease or in animals with chronic fascioliasis and hepatotoxic plant poisonings. Ponies and horses with hyperlipemia and hepatic failure may develop diarrhea, laminitis, and ventral edema. Some animals with liver disease have alternating diarrhea and constipation. Horses with liver failure and hepatic encephalopathy frequently develop colonic impaction due to decreased water intake. Constipation is characteristic of *Lantana* poisoning in goats and other ruminants.

Recurrent colic, intermittent fever, icterus, weight loss, and hepatic encephalopathy may be seen in horses with choleliths that obstruct the common bile duct. Infectious or inflammatory hepatic disease or failure of the liver to prevent endotoxin from gaining access to the systemic circulation may also result in intermittent fever and colic. Abdominal pain, due to pressure on the liver capsule from parenchymal swelling, often is seen in animals with acute diffuse hepatitis or trauma to the capsule itself. Affected animals stand with an arched back, are reluctant to move, or show signs of colic. In ruminants, pain may be localized to the liver by palpation over the anterior ventrolateral aspect of the abdomen or the last few ribs on the right side. Tenesmus followed by rectal prolapse is seen in some ruminants with liver disease. It may be associated with

diarrhea, hepatic encephalopathy, or edema of the bowel from portal hypertension.

Hypoalbuminemia is not as frequently associated with liver disease in horses as previously thought. Due to the long half-life (~19–20 days in horses, ~16 days in cows) and liver reserve for albumin production, hypoalbuminemia is usually a very late event in the disease process. Serum total protein concentrations may be normal or increased because of an increase in β -globulins in horses with liver disease. Hypoalbuminemia and hypoproteinemia most commonly develop in chronic liver disease, and they are common findings in llamas with liver disease. Generalized ascites or dependent edema may result. Ascites is related to portal hypertension caused by venous blockage and increased hydrostatic pressure and to protein leakage into the peritoneal cavity. The abdominal fluid present with liver disease usually is a modified transudate. Hypoalbuminemia can aggravate the ascites, but if it is seen alone, it more likely will cause intermandibular, brisket, or ventral edema. Ascites is difficult to appreciate in horses and adult cattle unless it is extensive. Ascites is a common finding in calves with liver cirrhosis.

Anemia may be seen in animals with liver dysfunction due to parasitic diseases, chronic copper toxicity (in ruminants), some plant poisonings, or chronic inflammatory disease. Anemia in acute fasciolosis results from severe hemorrhage into the peritoneal cavity as the larvae penetrate the liver capsule. Trauma and feeding activity of adult flukes within the bile ducts cause anemia and hypoproteinemia in animals with chronic fasciolosis. Chronic inflammatory disease (eg, hepatic abscesses, neoplasia) may cause anemia without accompanying hypoproteinemia.

Clinical signs of severe or terminal hepatic failure include coagulopathies and hemorrhage due to decreased production of clotting factors by the liver and possibly increased utilization in septic or inflammatory processes. A prolonged prothrombin time is usually seen first because factor VII has the shortest plasma half-life. Horses may develop a terminal hemolytic crisis caused by increased RBC fragility. This has not been reported in ruminants.

Fecal color rarely changes in adult herbivores with liver disease. In young ruminants and monogastric animals, cholestasis may result in lighter color feces being passed because of loss of stercobilin, a metabolite of bilirubin.

Liver disease should always be considered when nonspecific clinical signs, such

as depression, weight loss, intermittent fever, and recurrent colic, are present without an apparent cause. Differentiation between acute and chronic hepatitis or failure based on the duration of clinical signs before presentation may be misleading, because the disease process is often advanced before clinical signs are evident. Early vague signs of depression and decreased appetite may be overlooked. Liver biopsy to determine the type of pathology, degree of hepatic fibrosis present, and the regenerative capabilities of the liver parenchyma is necessary to develop a treatment plan and give an accurate prognosis.

Diagnostic Testing: Laboratory tests often detect liver disease or dysfunction before hepatic failure occurs. Routine biochemical tests such as serum enzyme concentrations are sensitive indicators of liver disease, but they do not assess hepatic function. Dynamic biochemical tests that assess hepatic clearance provide quantitative information regarding hepatic function. Tests of hepatic function are useful diagnostic and prognostic tools and provide a guide for the modification of drug-dosing regimens.

Serum Enzyme Concentrations: Serum concentrations of liver-specific enzymes are generally higher in acute liver disease than in chronic liver disease. They may be within normal limits in the later stages of subacute or chronic hepatic disease. The magnitude of increases in hepatic enzymes (especially γ -glutamyl transpeptidase) should not be used to determine prognosis. Hepatic enzymes are used to determine the presence of disease but not necessarily the degree of hepatic dysfunction. Careful interpretation of laboratory values in conjunction with clinical findings is essential.

Sequential measurements of serum γ -glutamyl transpeptidase or transferase (GGT), sorbitol dehydrogenase (SDH; also called iditol dehydrogenase [IDH]), AST, bilirubin, and bile acids are commonly used to assess hepatic dysfunction and disease in large animals. Serum GGT, bilirubin and total bile acid concentrations, and sulfobromophthalein (BSP®) clearance are not sensitive indicators of liver disease in young calves. Although GGT is primarily associated with microsomal membranes in the biliary epithelium, it is also present in the canalicular surfaces of the hepatocytes, pancreas, kidneys, and udder. Because of urinary and milk excretion of GGT and the rarity of pancreatitis in large animals,

increased serum GGT concentrations most commonly indicate bile duct or liver disease. Some consider GGT to be the single test of highest sensitivity for liver disease in adult large animals. Increase of GGT is most pronounced with obstructive biliary disease. In acute hepatic disease in horses, GGT may continue to increase for 7–14 days despite clinical improvement and return toward normal of other laboratory tests. Reportedly, serum GGT concentrations become increased within a few days of liver damage and remain increased until the terminal phase. Chronic hepatic fibrosis is the only liver disease in which an abnormal increase in GGT might not be seen. Neonatal foals have higher GGT concentrations due to GGT present in colostrum and milk. Younger adult horses, especially those in active training, may show a nonspecific increase in GGT that is not associated with liver disease or other increases in liver enzymes or serum bile acid concentration. GGT is of little value in diagnosing liver disease in neonatal calves or lambs, because it is present in colostrum and milk. GGT activity may also be increased with colonic displacement or administration of drugs (eg, corticosteroids, rifampin, benzimidazoles, anthelmintics). Some liver-derived enzymes are higher in young calves (GGT, alkaline phosphatase [AP], glutamate dehydrogenase, lactate dehydrogenase) and foals (AP, GGT, SDH, AST), because they are transiently increased or come from sources other than the liver. Serum levels of hepatic enzymes also vary in goats with age, breed, and sex. Reference ranges must be appropriate for the species and age group being evaluated.

SDH, arginase, ornithine carbamoyltransferase (OCT), AST, isoenzyme 5 lactate dehydrogenase (LDH-5), glutamate dehydrogenase (GLDH), and AP are also used to assess hepatic dysfunction and disease. Arginase, SDH, and OCT are liver-specific enzymes in horses, most ruminants, and swine. SDH is most predictive for active hepatocellular disease, with marked increases in enzyme activity after hepatocellular damage. Mild increases in SDH can also occur with obstructive GI lesions, endotoxemia, anoxia from shock, acute anemia, hyperthermia, and anesthesia. Because of their short half-lives, SDH and LDH-5 are useful in assessing resolution or progression of liver insult. Both enzymes usually return to near-normal values 4 days after liver insult, and neither is usually increased in chronic liver disease. Rarely, in severe cases of hepatic failure, SDH may return to normal in spite of a fatal outcome.

Arginase and GLDH are considered specific for acute liver disease, because both have high tissue concentrations in the liver and short half-lives in the blood. AST is highly sensitive for liver disease but lacks specificity, because high concentrations come from both liver and skeletal muscle. Other AST sources include cardiac muscle, erythrocytes, intestinal cells, and the kidneys. When CK is simultaneously measured to exclude muscle disease and the serum is not hemolyzed, increases in AST and LDH-5 are caused by hepatocellular disease. AST may remain increased 10–14 days or longer after an acute, transient insult to the liver. AST values are often normal in chronic hepatic disease. SDH and AST may be markedly increased with intrahepatic cholestasis and mildly increased with extrahepatic cholestasis. Increases in AP and GGT are associated with irritation or destruction of biliary epithelium and biliary obstruction. AP comes from the placenta, bone, macrophages, intestinal epithelium, and liver. AP is increased in very young calves and foals, probably because of the placental or bone source. In young calves, AP concentrations up to 1,000 IU/L at birth and 500 IU/L at several weeks of age are considered normal. AP concentrations of 152–2,835 IU/L are reported in foals (<12 hr old), and AP activity may remain high compared with adult levels for 1–2 mo. In calves (<6 wk old), none of the common tests (bilirubin, GGT, GLDH, AP, LDH, AST, or alanine transaminase) for liver damage or function are clinically useful for detection of hepatic disease when used alone. AST and GLDH are the most sensitive of the enzymes for hepatic injury, but AST also increases with muscle damage. AST concentrations in foals may be high compared with values of adults for many months. This increase is also likely related to muscle development. Transient and mild increases in SDH activity may be noted in some foals <2 mo old.

Serum Total Bile Acid Concentration:

Serum concentration of bile acids is highly specific for liver dysfunction but does not define the type of insult or disease present. Serum bile acid concentrations increase with hepatocellular damage, cholestasis, or shunts from the portal system to the vena cava. Increases are highest with biliary obstruction and portosystemic shunts. Serum bile acid concentrations rise early in liver disease and often remain high through the later stages.

Total bile acid concentration remains increased in **horses** with chronic liver

disease. In horses, there is no diurnal variation, no postprandial rise, and no significant hour-to-hour variation in bile acid concentrations. Serum total bile acid concentration in most healthy horses is $<10 \mu\text{mol/L}$. Concentrations of serum or plasma bile acids $>20 \mu\text{mol/L}$ have a high sensitivity and positive predictive value for determining liver disease in horses but not in ruminants. Although bile acid concentrations $>30 \mu\text{mol/L}$ can be an early predictor of liver failure, caution must be used in interpretation of mild increases, because bile acid concentrations up to $20 \mu\text{mol/L}$ may be seen in horses with anorexia. Prolonged, but not short-term ($<14 \text{ hr}$), fasting may cause increased serum bile acid concentrations in horses.

Interpretation of total bile acid concentrations is difficult in **foals** $<1 \text{ wk}$ old. Compared with those in healthy adult horses, serum bile acid concentrations in healthy foals are considerably greater during the first 6 wk of life. When measuring serum bile acid concentrations in sick foals, it is particularly important to have healthy, age-matched controls or age-dependent clinical pathology values for reference.

In **dairy cattle**, serum bile acid measurement is of little value in recognizing fatty liver or liver disease or failure because of significant hour-to-hour variations. In recently freshened cows, serum total bile acid concentrations are significantly higher than in cows in mid-lactation or in 6-mo-old heifers.

Total bile acid concentration may be the best single test for hepatic disease in young **calves**. In calves, concentrations $>35 \mu\text{mol/L}$ may indicate liver disease, bile obstruction, or a portosystemic shunt.

Reported reference intervals for serum concentration of bile acids are $1.1\text{--}22.9 \mu\text{mol/L}$ for **llamas** $>1 \text{ yr}$ old and $1.8\text{--}49.8 \mu\text{mol/L}$ for **llamas** $<1 \text{ yr}$ old. Bile acid concentrations in individual llamas may vary with feeding or sampling time of day, remaining within the reference interval.

Serum Bile Pigments: Evaluation of serum bilirubin (direct and indirect) concentration is useful to determine hepatic dysfunction in horses and ruminants. Increases in bilirubin result from hemolysis, hepatocellular disease, cholestasis, or physiologic causes. Anorexia in horses causes a physiologic increase in total serum bilirubin to usually $<6\text{--}8 \text{ mg/dL}$ and rarely as high as $10.5\text{--}12 \text{ mg/dL}$, accumulating at a rate of $\sim 1 \text{ mg/dL}$ for each day of anorexia. The indirect bilirubin increases 2- to 3-fold, while the direct bilirubin remains within the

reference range. In foals, indirect more than direct bilirubin may be increased with prematurity, neonatal isoerythrolysis, septicemia, or a portocaval shunt. Enteritis, umbilical infection, intestinal obstruction, and certain drugs (corticosteroids, heparin, halothane) may also cause hyperbilirubinemia. Mild, transient physiologic hyperbilirubinemia and icterus may be seen in newborn foals and calves. Although the mechanism(s) is not fully known, proposed causes include prebirth "loading of hepatocytes," naturally high RBC destruction at or around birth, inefficiency in bilirubin excretion, or lower hepatocellular ligandin concentrations in neonatal foals than in adult horses. In healthy calves $<72 \text{ hr}$ old, total bilirubin may be as high as 1.5 mg/dL and up to 0.8 mg/dL in 1-wk-old calves. Direct bilirubin is usually $<0.3 \text{ mg/dL}$ in young calves. In healthy foals ($<2 \text{ days}$ old), total bilirubin concentrations may range from $0.9\text{--}4.5 \text{ mg/dL}$, with most being unconjugated bilirubin ($0.8\text{--}3.8 \text{ mg/dL}$). Prematurity or illness (without liver disease) may increase unconjugated bilirubin fraction in young foals. Bilirubin concentrations in healthy foals should be within adult reference ranges by the time they are 2 wk old. Normal values for total bilirubin in goats are $0\text{--}0.1 \text{ mg/dL}$.

Horses with hepatic disease and failure most often have significant increases in both indirect and direct bilirubin. With liver damage in horses or ruminants, most of the retained bilirubin is indirect (unconjugated), and the direct-to-total ratio usually is <0.3 (more than two-thirds is indirect). Acute liver failure caused by hepatic necrosis results in increases in both indirect and direct bilirubin fractions. In horses with acute liver failure, the increase in bilirubin is primarily because of an increase in the indirect fraction. Hepatocellular disease should be considered when the indirect bilirubin fraction is $>25\%$ of the total bilirubin value. Direct-reacting bilirubin rarely exceeds $25\%\text{--}35\%$ of the total bilirubin in horses. Increases of this magnitude suggest predominant biliary disease or obstruction. With bile blockage or intrahepatic cholestasis, the direct-to-total ratio may be >0.3 in horses or 0.5 in cows. Increases in direct bilirubin may be seen in septic foals with intestinal ileus and minimal evidence of hepatocellular dysfunction.

In chronic liver disease, bilirubin concentrations are often within normal limits. Adult cattle and calves may have severe liver disease without any increase in

serum bilirubin. In cattle, goats, and sheep, circulating bilirubin concentrations increase only modestly with severe, generalized hepatic disease. The most dramatic increases in serum or plasma bilirubin concentrations are due to hemolytic crises rather than to liver dysfunction. In the absence of hemolysis, total serum bilirubin concentrations >2 mg/dL indicate impaired hepatic function in ruminants.

Urobilinogen: Urobilinogen may be detected by dipstick analysis in healthy horses. Increased concentrations of urobilinogen in urine without hemolysis are suggestive of a hepatic dysfunction, portosystemic shunting, or increased production by intestinal bacteria. Urobilinogen in the urine indicates the presence of a patent bile duct. Absence of urobilinogen may indicate complete biliary blockage, liver disease, or failure to excrete bilirubin into the intestine, reduce it by intestinal bacteria, or absorb it from the ileum. The correlation between urobilinogen and hepatocellular disease in animals is poor. Urobilinogen is unstable in urine; thus, analysis must be done within 1–2 hr, or the amount will be decreased or undetectable.

Serum and Plasma Proteins: Serum albumin and protein concentrations are variable in horses and cattle with hepatic disease. Hypoproteinemia is not common in horses with acute liver disease. Serum albumin is most likely to be reduced in chronic liver disease due to decreased functional hepatic parenchyma. In one study of 84 horses, 13% were hypoalbuminemic. Albumin concentrations were below minimum reference values in 18% of horses with chronic liver disease and 6% with acute liver disease. Globulin concentrations were increased in 64% of the horses. Hyperproteinemia due to hyperglobulinemia (polyclonal gammopathy or increase in β -globulins) may develop in horses with severe acute or chronic liver disease. Total plasma protein concentration is often normal, but the albumin to globulin ratio may be decreased.

Plasma fibrinogen concentration may not be a sensitive test in horses with hepatic insufficiency. Low fibrinogen concentrations may result from parenchymal insufficiency or disseminated intravascular coagulopathy. A high fibrinogen concentration is associated with an inflammatory response in horses with cholangiohepatitis.

Prothrombin Time: Abnormalities in prothrombin time (PT) are often the first

detected because factor VII, a liver-synthesized vitamin K–dependent factor, has the shortest half-life. Serum PT may be rapidly prolonged with hepatic failure and is one of the first function tests to return to normal with recovery from acute hepatic disease. A normal PT determination, however, does not exclude coagulopathy due to vitamin K deficiency. Prolonged activated partial thromboplastin time (APTT) or other indications of coagulopathy may be noted in animals with severe hepatic disease. Because a number of factors may influence PT or APTT values in horses, the ratio of clotting time of the horse with suspected hepatic disease to that of a healthy horse's value should be >1.3 for the test to be interpreted as abnormal.

Urea, Glucose, Ammonia, and Other Alterations: Serum concentration of urea may be decreased in both acute and chronic liver failure. Hypoglycemia is common in foals with hepatic failure. Blood glucose concentrations in adult horses with hepatic dysfunction are frequently normal or increased. Hypoglycemia, while less common in adult horses and ruminants with hepatic dysfunction, is more likely in chronic liver disease. Plasma triglyceride concentrations are markedly increased in ponies, miniature horses, donkeys, and adult horses with hepatic lipodosis. The magnitude of increase in serum triglycerides may correlate with prognosis in horses. Alterations in triglycerides, very-low-density lipoproteins, and esterified cholesterol levels are more common in ruminants than in horses with hepatic insufficiency. Neonatal foals have higher blood cholesterol and triglyceride concentrations than adult horses.

Plasma ammonia concentrations may be increased with hepatic insufficiency but do not correlate well with severity of hepatic encephalopathy except during portocaval shunts. Increased concentrations of blood ammonia and signs of hepatic encephalopathy without hepatic failure are reported in Morgan weanlings with hyperornithinemia, hyperammonemia, and normocitrullinuria syndrome and in adult horses with primary or idiopathic hyperammonemia. Ingestion of urea or ammonium salts is more likely to cause increases of blood ammonia and encephalopathy in cattle than in horses.

PCV and serum iron concentrations are often high in horses with severe liver disease. An increased PCV may persist in the face of fluid therapy and normal hydration status until the underlying liver disease is resolved. Secondary erythrocyto-

sis (with or without increased erythropoietin concentration) has been noted in some horses with hepatic neoplasia. Increased serum iron concentration is commonly seen in horses with either hepatic and/or hemolytic disease.

Dye Excretion and Clearance Tests:

Sulfobromophthalein (BSP®) or indocyanine green dyes can be used to assess hepatobiliary transport. The BSP half-life is prolonged when >50% of hepatic function is lost. The normal clearance half-life of BSP is <3.7 min in horses, 2.13 ± 0.19 min in goats, and ≤ 4 min in sheep. BSP clearance is longer in calves (5–15 min) than in adult cattle (≤ 5 min). Although dye excretion tests are usually prolonged with hepatic dysfunction, they may still be within the normal range. Hyperbilirubinemia, decreased hepatic blood flow, and significant cholestasis may falsely prolong BSP clearance, and hypoalbuminemia may falsely shorten it. BSP clearance in goats is most often prolonged with generalized hepatic lipidosis secondary to pregnancy toxemia. Determination of BSP clearance time, rather than half-life, reportedly is more useful in detection of liver disease. BSP clearance time in healthy fed and 3-day fasted horses is 10 mL/min/kg and 6 mL/min/kg, respectively. These tests, however, are of limited use in clinical practice because of the lack of commercially available pharmaceutical-grade BSP. Expense, procedural limitations, and equipment requirements for quantitation of indocyanine green clearance have limited its use as a diagnostic test.

Scintigraphy: Biliary patency and hepatocyte function, structure, and blood flow may be evaluated by hepatobiliary scintigraphy. Radionucleotide liver scans and biliary scans can detect alterations in blood flow or hepatic masses and biliary obstruction (atresia, cholangitis, cholelithiasis), respectively. Scintigraphy has been used in pigs, foals, and lambs to differentiate biliary obstruction from other causes of hyperbilirubinemia.

Ultrasonography: Ultrasonography can be used to evaluate liver size, appearance (shape, texture), and location in horses and ruminants for diagnosis of hepatomegaly, hepatolithiasis, biliary dilatation, cholelithiasis, or focal lesions. Tumors, cysts, abscesses, and granulomas may be seen. Diffuse diseases are harder to detect than focal processes, because the former cause less distortion of normal hepatic architecture. Diagnosis of diffuse liver disease should be substantiated by biopsy and

histopathology. Ultrasound can be used to guide collection of liver biopsy specimens and to perform cholecystocentesis and aspiration of abscesses, masses, or bile samples (flake eggs, bile acids, culture). It is also an accurate, noninvasive way to monitor the progression or resolution of disease. In horses, the liver should be imaged from both the right and left sides of the animal.

Liver Biopsy: Percutaneous liver biopsy is the definitive way to diagnose hepatic disease. Histologic evaluation of the liver provides valuable information regarding cause and severity of the disease process. Most cases of liver disease are diffuse, so the sample will be representative of the disease. Samples can be obtained blindly, but ultrasonographic guidance decreases the risk of complications (peritonitis due to bile leakage or intestinal puncture, hemorrhage, or pneumothorax). Liver biopsies can also be obtained during laparoscopy, which offers the additional advantage of being able to visualize the surface of the liver and other abdominal organs for evidence of disease.

Samples should be placed in media for bacterial culture and sensitivity and in formalin for histologic evaluation. Coagulation profiles (prothrombin time, partial thromboplastin time, fibrinogen, fibrin degradation products, and optional platelet count) may be performed before liver biopsy to reduce the risk of hemorrhage. Liver biopsy may not be advised in an animal with clinical or clinicopathologic evidence of a coagulopathy or a hepatic abscess, because hemorrhage or contamination of the peritoneal cavity may result.

Radiography: Contrast abdominal radiography in foals may help diagnose gastroduodenal obstructions and secondary cholangiohepatitis. Portosystemic shunts in foals or young calves can be identified with mesenteric portovenography by injecting radiopaque contrast solution into a jejunal mesenteric vein, followed by fluoroscopy or sequential survey radiographs to monitor the hepatic blood flow.

Treatment and Management: Initial treatment of animals with signs of hepatic disease or insufficiency is often supportive and started before the underlying cause and extent of hepatic damage is known. History, clinical signs, and laboratory data may give some clue as to the nature of the hepatic disease process, but liver biopsy is usually required to make a definitive diagnosis and to determine the degree of hepatic injury.

Specific therapies for hepatic disease depend on cause, presence of liver failure, chronicity, degree of hepatic fibrosis or biliary obstruction, and species affected. Increases in hepatic enzymes without hepatic disease may not require specific therapy for the liver but rather for the primary disease.

Therapy is most successful when intervention is early, hepatic fibrosis is minimal, and evidence of regeneration in the liver exists. Horses with severe or bridging fibrosis respond poorly because of inadequate potential for liver regeneration. The goals for treatment of large animals with hepatic disease or insufficiency are to control hepatic encephalopathy, to treat the underlying disease process, to provide supportive care to allow time for liver regeneration, and most importantly, to prevent injury to the animal and those working with the animal. Animals with hepatic encephalopathy often show aggressive and unpredictable behavior that can result in injury to self or handlers.

Hepatic Encephalopathy and Hepatic Failure: Horses with hepatic encephalopathy may be aggressive or demonstrate repetitive behaviors that make restraint difficult. To ensure safety of the animal and handlers, sedation is required. Because most sedatives and tranquilizers are metabolized by the liver, their elimination half-life may be prolonged in animals with hepatic failure; therefore, dosages should be minimized initially until it is determined how the animal responds to lower dosages. Xylazine or detomidine given in small doses to effect can be used to control horses exhibiting abnormal behavior. Diazepam should be avoided in animals with hepatic encephalopathy, because it may enhance the effect of γ -aminobutyric acid on inhibitory neurons and worsen neurologic signs. Acepromazine should also be avoided, because it may lower the seizure threshold.

Dehydration, acid-base and electrolyte imbalances, and hypoglycemia should be corrected with appropriate IV fluids. Initially, a balanced polyionic solution is administered for rehydration. Potassium supplementation is added (10–40 mEq/L, depending on infusion rate) if the animal is hypokalemic or hypophagic. If IV infusion is not possible in ruminants, rehydration may be attempted by oral administration of fluids if rumen motility is normal. Rarely, some horses with hepatic disease have polycythemia, making evaluation of hydration status by PCV difficult. Severe acidosis may

be present. Because rapid correction of the acidosis may exacerbate neurologic signs, acidosis should be corrected gradually by IV administration of fluids with a high concentration of electrolytes. If this fails or if blood pH is <7.1 (bicarbonate <14 mEq/L), bicarbonate may be administered cautiously. Supplemental vitamins are optional. Adequate fresh water should be available if the animal can swallow normally.

Factors that may contribute to the hepatic encephalopathy should be eliminated. Glucose as a 5%–10% solution is given to correct hypoglycemia if present. In addition, glucose supplementation helps decrease blood ammonia concentrations and reduces catabolic gluconeogenesis, protein catabolism, and need for hepatic gluconeogenesis. Unless the animal is hyperglycemic, a continuous IV infusion of glucose (5% at 2 mL/kg/hr or 10% at 1 mL/kg/hr) should be given, even to animals that are not hypoglycemic. The infusion rate should be adjusted so that euglycemia is maintained. Induction of moderate to severe hyperglycemia, rapid changes in glucose level, and glucosuria should be avoided. IV glucose should be used in combination with balanced electrolyte fluids and not as the sole fluid source.

Therapies directed toward decreasing either ammonia production or absorption from the bowel include administration of mineral oil, neomycin, lactulose, and metronidazole. Administration of mineral oil decreases absorption and facilitates removal of ammonia. Passing a nasogastric tube in an animal with hepatic encephalopathy must be done cautiously, because nasal bleeding caused by decreased clotting factors may be difficult to control. Oral administration of neomycin (10–30 mg/kg, bid-qid for 1–2 days) has been used to decrease ammonia-producing bacteria in the intestine. Lactulose (0.2 mL/kg, bid; 0.3 mL/kg, PO, qid; or 90–120 mL/450 kg, tid-qid) is metabolized to organic acids by bacteria in the ileum and colon. Reduction in colonic pH reportedly fosters an increased bacterial assimilation of ammonia, decreased ammonia production, ammonia trapping in the bowel, intestinal microflora changes, and osmotic catharsis. Reportedly, oral administration of vinegar (acetic acid) has the same effect on colonic pH and ammonia concentration in the gut. Metronidazole (10–15 mg/kg, PO, bid-qid) decreases ammonia-producing organisms in horses but should not be used in food animals. If the animal can swallow, oral drugs can be mixed with corn syrup or molasses and given via dose syringe to avoid trauma and the risk of inducing hemorrhage during

passage of a nasogastric tube. Neomycin, lactulose, and metronidazole may all potentially induce mild to severe diarrhea (salmonellosis) because of disruption of GI flora. Use of the drugs in combination is more likely to induce diarrhea than any one of the drugs given alone. Because metronidazole is metabolized by the liver, caution must be used when administering the drug to horses with hepatic failure. Neurologic signs due to metronidazole toxicosis may mimic hepatoencephalopathy.

Until the nature of the underlying hepatic disease is known, treatment with broad-spectrum antimicrobials is warranted if infectious hepatitis is suspected. A trimethoprim-sulfamethoxazole combination is a good empiric choice because of its activity against gram-negative bacteria and its high concentration in bile. Penicillin in combination with an aminoglycoside has a broad spectrum of action and may be of benefit if a *Streptococcus* sp or an anaerobic or gram-negative coliform is suspected. Enrofloxacin has also been recommended. First- and second-generation cephalosporins have been used in foals and in other species. Ceftiofur sodium also has an enterohepatic cycle, with ~15% of active drug recycled through the liver and excreted out the biliary tree. Ceftiofur has a broader spectrum than most early generation cephalosporins and has proved useful to treat acute or recurrent ascending bacterial cholangiohepatitis. Metronidazole may be administered when anaerobic infection is suspected in horses. Specific antimicrobial therapy based on culture and sensitivity of a liver biopsy is ideal.

Pain may be controlled with appropriate doses of an NSAID (eg, flunixin meglumine, 1.1 mg/kg, IV, bid, or phenylbutazone 4.4 mg/kg, IV or PO, bid). Vitamin K₁ (up to 1 mg/kg, SC; 40–50 mg/450 kg, SC) and plasma transfusions (1–2 L/100 kg) may be given when coagulopathies develop or hypoalbuminemia is present. In some horses with acute hepatic disease and failure, antioxidant (dimethyl sulfoxide, acetylcysteine, vitamin E, S-adenosylmethionine [SAMe]), and anti-inflammatory (flunixin meglumine, phenylbutazone) therapy may be useful. Mannitol has been recommended for treatment of suspected brain edema in fulminant hepatoencephalopathy. Horses with hepatic disease should be protected from sunlight.

Dietary Management: Dietary management is essential for management of animals with hepatic encephalopathy or acute or chronic hepatopathy. Affected animals should be fed carefully, because

dysphagia may be a problem. Relatively small amounts should be fed frequently, although this recommendation may prove impractical in the longterm for many clients. The diet should meet energy needs with readily digestible carbohydrates, provide adequate but not excessive protein, have a high ratio of branched-chain amino acids to aromatic amino acids, and be moderate to high in starch to decrease need for hepatic glucose synthesis. Fat and salt should not be added to the diet. Feeds used successfully in horses include grass or oat hay, corn, and sorghum. Small amounts of molasses may be added to improve palatability and add energy. Linseed meal and soybean meal have an excellent branched-chain to aromatic amino acid ratio and may be used as a protein supplement in small quantities. Beet pulp may be substituted for oat or grass hay. Beet pulp may be soaked first to allow full expansion before being fed. Choke may be a problem in some animals eating beet pulp.

The feeding of alfalfa hay, alfalfa-containing feeds, or other legume hays to horses with hepatic disease is controversial. Although alfalfa hay has a better branched-chain to aromatic amino acid ratio than grass hay, it may have too high a protein content. Feeding grass hay is preferred for animals with hyperammonemia or signs of hepatic encephalopathy. A mixed grass/alfalfa hay can be fed to horses without central neurologic signs if weight loss is a problem and the added protein is tolerated. Grazing grass pastures is allowable as long as signs of hepatic encephalopathy are controlled and exposure to sunlight is avoided.

Other feeds high in branched-chain amino acids include sorghum, bran, or milo. Parenteral or enteral supplement with branched-chain amino acids helps restore the normal ratio of branched-chain to aromatic amino acids. Supplementation with vitamins A, D, E, and K might be indicated, because these fat-soluble vitamins are not stored effectively or readily available from a diseased liver. Vitamin K₁ may be indicated in animals with a coagulopathy. Large amounts of fat should not be fed to meet energy requirements; excessive fat may lead to a fatty liver.

Transfaunation (see p 2562) with rumen fluid from a healthy cow may help reestablish normal ruminal flora and enhance the appetite of affected cattle. Animals that will not eat voluntarily must be force fed. A gruel may be given by nasogastric tube in horses and swine or by orogastric tube or rumen fistula in

ruminants. In ruminants, forced feeding of alfalfa meal (15% protein) and dried brewer's grain or beet pulp with potassium chloride and normal rumen fluid has been recommended. Alfalfa hay and alfalfa-containing feeds may be better tolerated by cattle than by horses with hepatic disease. IV polyionic fluids with 5% dextrose, potassium chloride, and B vitamins may also be needed in animals not consuming adequate amounts.

ACUTE HEPATITIS

Acute hepatitis can have an infectious, toxic, or undefined cause. Clinical signs may appear suddenly, with horses appearing lethargic, anorectic, and icteric. Photosensitization, diarrhea, and clotting abnormalities also may be seen. Neurologic signs resulting from hepatic encephalopathy and/or hypoglycemia can be most severe in animals with acute fulminant liver disease. Signs of endotoxemia may be present, depending on the underlying cause and the ability of the Kupffer cells to remove endotoxin from the systemic circulation. Increases in serum sorbitol dehydrogenase (SDH) and AST activities indicate acute hepatocellular injury. Serum γ -glutamyl transpeptidase or transferase (GGT) is increased with cholestasis secondary to hepatocyte swelling. Cholestasis results in hyperbilirubinemia, with the direct (conjugated) fraction ranging from 15%–35% of total in horses. Increased serum total bile acid concentration, decreased glucose and BUN concentrations, and prolonged coagulation times become evident as hepatic function progressively worsens. Anorexia can lead to hypokalemia. The CBC is variable, because it may reflect an inflammatory response with a neutrophilia or endotoxemia with a neutropenia, increased band neutrophils, and toxic changes.

Idiopathic Acute Hepatic Disease

(Theiler disease, Serum hepatitis, Postvaccinal hepatitis)

Idiopathic acute hepatic disease (IAHD) is the most common cause of acute hepatitis in horses. It is primarily a disease of adult horses.

Etiology and Epidemiology:

Frequently, horses with IAHD show clinical signs of hepatic failure 4–10 wk after receiving an equine origin biologic, such as tetanus antitoxin (TAT). In some cases, the affected horse may not have received TAT but may have been in contact with another horse that received TAT. Reportedly, IAHD

may develop as a potential complication of administration of any equine plasma or serum product that includes commercial equine plasma. However, other affected horses have no prior history of exposure to such a product. Subclinical IAHD can also develop after administration of TAT. Most commonly, only one horse on the premises is affected, although outbreaks may occur or other horses on the farm may have evidence of liver disease (increased enzyme levels) without clinical signs. Occurrence of the disease in groups of adult horses during the late summer or early fall (August to November) suggests an infectious (viral) or vector-spread etiology, although supporting evidence is lacking. The seasonal occurrence could reflect the fact that many foaling mares receive TAT in the spring of the year along with their newborn foals. Lactating mares that receive TAT at foaling seem to be more susceptible. A Type III (immune complex-mediated) hypersensitivity reaction also has been proposed. Recent evidence suggests a viral cause, with a "Theiler disease-associated virus" of the Flaviviridae documented in association with a naturally occurring outbreak of Theiler disease. The offending virus was identified from diseased horses and was characterized as very similar to human hepatitis viruses B and C. The newly identified virus was then administered experimentally to previously naive research horses, which developed signs of Theiler disease, proving that it could be passed from one horse to another via serum administration and resulting in similar disease.

Clinical Findings: Onset of clinical signs is acute. Acute mortality may be 50%–60%, with overall mortality as high as 88% in affected horses. Horses with IAHD typically present with anorexia, hepatic encephalopathy, and icterus. The CNS signs are variable, ranging from lethargy to aggression or maniacal behavior, central blindness, and ataxia. Photosensitivity and discolored urine due to high bilirubin concentrations may be seen. Fever is present in ~50% of cases. Weight loss (uncommon), ventral edema, jugular pulses, ileus, and acute respiratory distress have been seen in some horses with IAHD. These findings suggest there may be a subclinical phase before development of overt hepatic failure. Intravascular hemolysis with hemoglobinuria may be seen in some terminal cases. Most cases are sporadic, but outbreaks with several horses involved

have been reported. Recognition of IAHD in one horse indicates horses on the same premises should be carefully monitored for clinical or serum biochemical signs of hepatic disease.

Serum concentrations of GGT, AST, and SDH are increased. GGT is frequently further increased during the first few days of illness, despite clinical improvement and eventual recovery in an affected horse. Horses with AST values $>4,000$ IU/L have a poor prognosis. AST concentrations decrease within 3–5 days in horses that improve, and SDH concentrations decrease even more rapidly. Total serum bilirubin concentration is generally higher in horses with IAHD than in horses with anorexia. Hyperbilirubinemia is common, with the unconjugated form being $>70\%$ of the total. Serum total bile acid concentrations are increased. Moderate to severe acidosis, hypokalemia, polycythemia, increased plasma aromatic amino acids, and hyperammonemia may also be present.

Lesions: At necropsy, icterus and varying degrees of ascites are present. The liver is usually small to normal in size but may be enlarged (peracute cases), with a mottled and bile-stained surface. Histologically, there is marked centrilobular-to-midzonal hepatocellular necrosis and mild to moderate mononuclear infiltrate. Mild to moderate bile duct proliferation may be seen in some animals with more chronic disease.

Diagnosis: Diagnosis is based on history, abrupt onset of clinical signs, and laboratory alterations suggestive of hepatic insufficiency. In some cases, the liver is shrunken and difficult to visualize with ultrasonographic examination. A definitive diagnosis can be made only by liver biopsy. Differential diagnoses include acute pyrrolizidine toxicosis, hepatotoxins, acute infectious hepatitis, acute mycotoxicosis, cerebral disease, and hemolytic disease.

Treatment and Prognosis: There is no specific therapy for IAHD. Supportive therapy (IV crystalloid fluids with glucose and potassium added) and treatment of the hepatic encephalopathy may be successful. Stressful situations, such as moving the animal or weaning the mare's foal, may exacerbate the clinical signs of hepatic encephalopathy and should be avoided. Sedation should be used only to control behavior that could lead to injury of the animal or handlers and to allow therapeutic procedures.

Recovery depends on the degree of hepatocellular necrosis. Affected horses that remain stable for 3–5 days and that continue to eat often recover. Decreases in SDH concentration and prothrombin time along with improvement in appetite are the best positive predictive indicators of recovery. Horses with rapid progression of clinical signs, uncontrollable encephalopathy, hemorrhage, or hemolysis have a poor prognosis. For affected horses that do recover, the longterm prognosis is good. In some horses, progressive weight loss and death may occur during the months after the initial clinical signs.

Prevention: Use of TAT is not without risk. Routine administration of TAT to parturient mares is strongly discouraged. Use of TAT should be restricted to situations necessitating tetanus prophylaxis and in which a history of active tetanus toxoid immunization is absent or unknown.

Acute Hepatic Necrosis in Cattle

Epidemiology and Pathogenesis:

Acute hepatic disease and failure in cattle most commonly results from a toxic insult. Hepatocellular necrosis with clinical and laboratory evidence of hepatic failure may develop in cattle after mastitis or metritis with clinical signs of endotoxemia. Endotoxin induces hepatocellular necrosis through both direct and indirect effects on the liver. Endotoxin can cause Kupffer cells to release lysosomal enzymes, prostaglandins, and collagenase that damage hepatocytes, or it may interact directly with the hepatocytes, causing lysosomal damage, decreased mitochondrial function, and necrosis. Endotoxin-related hepatocellular necrosis may be due in part to decreased hepatic blood flow and liver hypoxia.

Clinical Findings and Lesions: Clinical signs include weight loss, anorexia, and cessation of milk production. Photosensitization and mild icterus are variable. Serum SDH, GGT, and AST concentrations are mildly to severely increased. Fatty liver or ketosis is not characteristic. The liver may be normal in size or mildly enlarged. Histologically, there is marked hydropic change with varying degrees of hepatic necrosis.

Diagnosis: Diagnosis is based on a history of hepatic-related signs developing concurrently or after a primary disease and endotoxemia. Increases in hepatic and biliary enzymes and absence of ketosis

support the diagnosis. Definitive diagnosis is based on liver biopsy and by excluding other infectious, toxic, and inflammatory causes of hepatic dysfunction. Differential diagnoses include other causes of subacute or chronic liver disease (eg, hepatotoxins, hepatic lipidosis) and conditions causing weight loss and hypophagia.

Treatment: Nutritional and fluid support is often successful in affected cows with acute hepatic necrosis after transient insults. Forced feeding of alfalfa meal (15% protein) and dried brewers' grain or beet pulp with potassium chloride and normal rumen fluid is recommended. IV polyionic fluids with 5% dextrose, potassium chloride, and B vitamins may also be needed. Control of endotoxemia and treatment of the primary disease condition are essential.

INFECTIOUS HEPATITIS AND HEPATIC ABSCESES

Tyzzler Disease

Tyzzler disease, due to *Clostridium piliforme* (previously *Bacillus piliformis*), causes an acute necrotizing hepatitis, myocarditis, and colitis in foals 8–42 days old. (See also p 199.) It has been reported in two calves: a 1-wk-old Jersey bull calf with enteritis and multifocal necrotizing hepatitis and a second calf with concurrent cryptosporidiosis and coronaviral enteritis. In the latter animal, *C piliforme* was identified in hepatocytes and epithelium and smooth muscle cells of the ileum and cecum. Clinical signs included hypophagia, generalized weakness, dullness, and decreased fecal passage.

Cholangiohepatitis

Cholangiohepatitis is a severe inflammation of the bile passages and adjacent liver, which sporadically causes hepatic failure in horses and ruminants. It occasionally occurs secondary to cholelithiasis, duodenitis, intestinal obstruction, neoplasia, parasitism, and certain toxins in horses. The fungal toxin sporidesmin from *Pithomyces chartarum* may cause cholangiohepatitis in sheep and cattle.

Etiology: Bacteremia due to an organism (eg, *Salmonella* spp) eliminated in the bile, an ascending infection of the biliary tract after intestinal disturbance, or ileus is thought to be related to the development of cholangiohepatitis. In foals, duodenal ulceration and duodenitis may result in

bile stasis, hepatic duct obstruction, and cholangiohepatitis. Parasite migration through the liver may predispose to cholangiohepatitis in some animals. Gram-negative organisms, including *Salmonella* spp, *Escherichia coli*, *Pseudomonas* spp, and *Actinobacillus equuli* are frequently isolated from the liver. *Clostridium* spp, *Pasteurella* spp, and *Streptococcus* spp are less frequently recovered.

Clinical Findings: Depending on the severity of infection and virulence of the organism, clinical signs may be acute with severe toxemia, subacute, or chronic. Most typically, cholangiohepatitis is a subacute or chronic disease process, with affected animals showing signs of weight loss, anorexia, intermittent or persistent fever, or colic. Icterus, photosensitivity, and signs of hyperanmonemic hepatic encephalopathy are variable. Sorbitol dehydrogenase (SDH), AST, γ -glutamyl transpeptidase or transferase (GGT), conjugated bilirubin, and total bile acid concentrations are usually increased. Peripheral WBC counts are variable, depending on the degree of inflammation and endotoxemia present. Acute, suppurative cholangiohepatitis may occasionally result in severe septicemia and death.

Lesions: In acute cases, the liver is swollen, soft, and pale. Suppurative foci may be visible beneath the capsule or on cut surface. Lesions in other systems may reflect septicemia and jaundice. Microscopically in acute cases, neutrophils are present in the portal triads and degenerate parenchyma. Purulent exudate is evident in the ducts. In subacute or chronic cholangiohepatitis, the inflammation is more proliferative and bile duct proliferation more pronounced. Areas of atrophy, regenerative hyperplasia, and periportal fibrosis may be evident.

Diagnosis: Liver biopsy should be performed to confirm the diagnosis and to obtain a liver sample for aerobic and anaerobic culture and sensitivity. Differential diagnoses include other causes of acute to chronic hepatic disease, weight loss, colic, or sepsis. If neurologic signs are present, cerebral diseases must be considered. Because cholangiohepatitis is frequently associated with cholelithiasis in horses, the presence of one or more calculi must be excluded; ultrasonography of the liver may prove valuable in this case.

Treatment: Treatment based on culture and sensitivity results from liver tissue often gives favorable results. Therapy consists of longterm (≥ 4 –6 wk) antimicrobial administration, supportive therapy with IV fluids, and management of hepatoencephalopathy, if present. Initially, broad-spectrum antimicrobials effective against gram-negative, gram-positive, and anaerobic organisms should be administered. A combination of penicillin with either a trimethoprim-sulfa or an aminoglycoside or enrofloxacin may be used. Ampicillin or a cephalosporin can be used instead of penicillin. Ceftiofur sodium has an enterohepatic cycle and broader spectrum and may prove valuable in treatment. Metronidazole can be used in horses to treat anaerobic bacteria. Antimicrobial therapy can be altered pending results of culture of tissue obtained by liver biopsy. Prognosis is good if fibrosis is not severe, but it is poor if severe periportal or bridging fibrosis is present.

Equine Rhinopneumonitis

Equine rhinopneumonitis due to equine herpesvirus 1 is a sporadic cause of interstitial pneumonia, hepatic disease, and often death in newborn foals. See p 1452 for clinical findings, diagnosis, and treatment.

Infectious Necrotic Hepatitis

(Black disease)

Infectious necrotic hepatitis, caused by *Clostridium novyi* type B, affects primarily sheep but also cattle, horses, and pigs. See p 603 for clinical findings, lesions, and control.

Bacillary Hemoglobinuria

(Red water disease, Icterohemoglobinuria)

Clostridium novyi type D (*C haemolyticum*) is the anaerobic organism that causes bacillary hemoglobinuria in cattle, other ruminants, and rarely horses. See p 601 for clinical findings, diagnosis, and control.

Hepatic Abscesses

Hepatic abscesses are generally polymicrobial infections; anaerobes are common. The primary etiologic agent of liver abscesses in cattle is *Fusobacterium necrophorum*. In goats, most abscesses are due to *Cornebacterium pseudotuberculosis*, *Trueperella pyogenes*, and *Escherichia coli*. Organisms less frequently isolated

include *Proteus* sp, *Mannheimia haemolytica*, *Staphylococcus epidermidis*, *S aureus*, *Rhodococcus equi*, *Erysipelothrix rhusiopathiae*, and the yeast *Candida krusei*. In horses, hepatic abscesses often contain *Streptococcus* spp (*S equi equi*, *S equi zooepidemicus*), *C pseudotuberculosis*, or enterobacteria after ascending cholangiohepatitis or intestinal disease, and anaerobes. In pigs, hepatic abscesses develop after migration of ascarids into the bile ducts.

The liver is particularly susceptible to abscess formation, because it receives blood from the hepatic artery, the portal system, and the umbilical vein in the fetus and the newborn. Hepatic abscesses are most prevalent in ruminants and uncommon in horses. Abscesses are associated with rumenitis (rumenitis-liver abscess complex), bacteremia, septic portal vein thrombosis, and parasite migration or extension from intestinal disease. They can also occur as sequelae of abdominal surgery. In neonates and young animals, abscesses may develop secondary to ascarid migration, bacterial septicemia, or ascending infection of the umbilical vein. In horses and cattle, signs may be similar to those seen with other abdominal abscesses and include intermittent colic, intermittent fever, and weight loss. Often, liver abscesses are subclinical in cattle. Hepatic ultrasound may prove diagnostic. Prognosis is generally poor because of lack of response to antimicrobial therapy or incomplete resolution. (See also LIVER ABSCESSES IN CATTLE, p 352.)

HEPATOTOXINS

Hepatotoxins manifest their toxicity by one or more mechanisms: periacinal (centrilobular) necrosis, midzonal necrosis, periportal necrosis, cholestasis, biliary hyperplasia, fatty or hydropic change near necrotic zones, or venous occlusion. Fatal hepatic insufficiency may result if the initial injury is acute and severe. More commonly, the hepatic damage from toxins is subacute or chronic. In chronic processes, the longterm result may be cirrhosis. Many hepatotoxins, especially those in plants, exert toxic effects on multiple organs, particularly the kidneys, lungs, and GI tract.

Definitive diagnosis may be difficult. Careful history, inspection of the environment, laboratory evaluations, liver biopsy, or necropsy may be needed to determine the offending agent. With acute plant toxicities, evidence of hepatotoxic plants may be seen in the stomach contents or rumen.

Specific antidotes for hepatotoxins are limited. Removal of the animals from the source is essential to decrease additional exposure. Administration of an absorbent (eg, activated charcoal, mineral oil) or laxatives (eg, mineral oil, magnesium sulfate) or rumenotomy may decrease absorption of toxic elements in acute poisonings. These may not be helpful in chronic intoxications (ie, pyrrolizidine alkaloid toxicity), in which the toxic agent has been ingested over weeks to months before signs of toxicosis are evident. Supportive care includes correction of electrolyte, metabolic, and glucose disorders via fluid therapy and dietary management. Hepatic encephalopathy must be controlled. Sunlight should be avoided if photosensitization is present. Antimicrobials may be considered to prevent secondary pyoderma. Prognosis is guarded and depends on the particular hepatotoxin.

Chemical and Drug-related Causes of Toxic Hepatopathy

For COAL-TAR POISONING, see p 3045.

Iron Toxicosis: Newborn foals (<3 days old) are especially sensitive to iron overload because of their high serum iron concentrations, increased ability to absorb iron, and oversaturation of transferrin at birth. In adult horses, injectable iron increases body iron concentration more substantially than most oral supplements; liver biopsy will document increased iron stores, but these are rarely if ever associated with clinical signs of liver disease. Iron toxicosis has been reported in calves and young bulls injected with a ferric ammonium citrate alone or in combination with ferrous gluconate.

Foals given iron at birth, especially before receiving colostrum, may develop acute toxicity with clinical signs of hepatic encephalopathy in 2–5 days and a fatal outcome. Serum bilirubin and blood ammonia concentrations are high, and prothrombin time is prolonged. Alterations in serum hepatic enzymes are variable. In adult horses, acute toxicosis, although less common, may cause enteric irritation and cardiovascular collapse with sudden death. Signs of more chronic hepatic failure, including weight loss, icterus, and depression, may be seen with repeated oral administration of iron. Possible sources of excess iron include inappropriate supplementation, forages high in iron, injectable iron, and leaching of iron into water or feed. Calves with iron toxicosis have trembling, vocalizing, bruxism, colic, and convulsions.

Hepatic lesions are variable. Most livers are friable and are swollen or shrunken. The liver is pale tan or mottled red-brown in color. Hemorrhages may be present in the stomach, intestines, and bladder.

Diagnosis is based on history of iron supplementation, clinical signs, and necropsy lesions. Serum and liver iron concentrations may be normal or increased. Normal iron concentrations in horses are 66–204 mcg/dL in serum and 100–300 ppm in liver tissue. Because serum iron concentration correlates poorly with total iron stores, serum ferritin levels are better used as an estimate of total iron.

Treatment is generally supportive with fluids and nutritional supplementation. Chelation therapy with deferoxamine is unlikely to be successful in either acute iron toxicosis or chronic hemochromatosis. Repeated phlebotomy has been attempted for hemochromatosis. The prognosis is poor.

Copper Toxicosis: Acute copper toxicosis with severe hepatic necrosis and death may be seen in cattle 1–4 days after injection of copper salt. Copper toxicosis is seen in sheep and young calves after excess dietary intake of copper and in young goat kids fed calf milk replacer containing copper. The primary conditions associated with copper toxicosis are hemolytic anemia and liver damage. In camelids, ingestion of inappropriate dietary iron concentrations resulted in acute death with few premortem signs and no evidence of hemolytic crisis. (See *also* COPPER POISONING, p 3073.)

Miscellaneous Chemicals and Drugs Associated with Hepatotoxicity:

Exposure to carbon tetrachloride, chlorinated hydrocarbons, hexachlorethane, carbon disulfide, arsenic, monensin, pentachlorophenols, phenol, paraquat, halothane (goats, llamas), isoflurane, phenobarbital, tannic acid, copper disodium edetate, and high doses of ivermectin may cause centrilobular necrosis and hepatic failure. Phosphorus causes primarily periportal changes. Active hepatitis to cirrhosis may be seen after use of isoniazid, nitrofurantoin, halothane, aspirin, or dantrolene in large animals. Erythronycin, rifampin, anabolic steroids, phenothiazine tranquilizers, some diuretics, quinidine sulfate, and diazepam have been associated with cholestasis and icterus.

Mycotoxicoeses

Aflatoxins and fumonisins can cause hepatic injury and failure in ruminants,

swine, and horses. Fusarium toxicosis is the most common mycotoxicosis causing liver failure in horses, whereas aflatoxins only sporadically cause hepatic failure in this species. (See MYCOTOXICOSES, p 3005.)

Blue-green Algae Intoxication

Acute hepatotoxicosis may be seen after ingestion of hepatotoxic cyanobacteria. (See ALGAL POISONING, p 2956.)

Hepatotoxic Plants

Pyrrrolizidine Alkaloid Toxicity:

Pyrrrolizidine alkaloid toxicity most commonly is a chronic, progressive hepatopathy, but acute intoxication can occur. (See PYRROLIZIDINE ALKALOIDOSIS, p 3150.)

Kleingrass Toxicosis: Kleingrass (*Panicum coloratum*) can produce toxicosis in horses and ruminants. Kleingrass toxicosis is a problem in the southwestern USA from late spring to early fall. Young growing plants are most hazardous because of their high saponin content, believed to be the toxic principle. A similar syndrome is seen in horses in the eastern USA grazing pasture or fed hay containing high concentrations of fall *Panicum*.

Clinical signs include icterus, photosensitivity, intermittent colic and fever, weight loss, and hepatic encephalopathy. Photosensitivity may develop around the coronary band and cause lameness. Lesions include hepatic and portal fibrosis and biliary hyperplasia. Bilirubin, γ -glutamyl transpeptidase or transferase (GGT), and blood ammonia concentrations are increased. Sheep with photosensitivity caused by kleingrass ingestion commonly have a crystalline material in the bile ducts, canaliculi, and macrophages.

Presumptive diagnosis of plant-induced hepatopathy is based on history of exposure to plants and multiple affected animals on a farm or in an area. Affected animals should be removed from the kleingrass source, fed good-quality hay, and protected from sunlight. Local treatment of the photodermatitis with antimicrobial or softening creams may be needed in severe cases.

Alsike Clover Toxicosis: Alsike clover (*Trifolium hybridum*) causes two syndromes in horses in the USA and Canada: photosensitivity (trifobiasis) and Alsike clover poisoning ("big liver disease"). Alsike clover grows well on heavy clay soil, and an increased incidence of toxicosis is reported during wet seasons. The disease is seen mostly when the blossom of the plant

is eaten and the predominant forage being fed is the Alsike clover. The toxic principle is an unidentified phototoxin. Photosensitivity has been reported in horses, sheep, cattle, and pigs.

Alsike photosensitivity is also known as "dew poisoning" because it is seen mostly when pastures of clover are wet and horses' skins are moist. It is characterized by reddened skin after exposure to sun, followed by dry necrosis of the skin or edema and serous discharge. The muzzle, tongue, and feet are frequently affected. If the stomatitis is severe, anorexia and weight loss develop.

Alsike clover poisoning may be fatal, with progressive loss of condition and signs of hepatic failure and neurologic disturbances. Colic, diarrhea, and other signs of GI disturbances have been noted. Affected horses may be markedly depressed or excited. Prolonged exposure is usually required before signs of hepatic insufficiency are evident. Serum chemistry alterations include increased GGT and AST activities and hyperbilirubinemia, with direct bilirubin frequently being $\geq 25\%$ of the total.

Presumptive diagnosis of plant-induced hepatopathy is based on history of exposure to plants and multiple animals on a farm or in an affected area. Horses in which photosensitivity is the primary finding may recover quickly after being removed to Alsike-free pasture. Those with severe stomatitis or dermatitis require supportive care and local treatment of the stomatitis until they heal.

Mycotoxic Lupinosis: Mycotoxic lupinosis is a worldwide disease of sheep and cattle that consume lupines containing a hepatic mycotoxin produced by the fungus *Phomopsis leptostromiformis*. See p 3018 for clinical findings, diagnosis, and control.

Xanthium (Cocklebur) Toxicosis:

Cockleburs, including *Xanthium strumarium*, may be found throughout the world. Poisoning is most frequent after ingestion of the palatable two-leaf seedling stage or ground seeds. The burs are highly toxic but rarely eaten. The mature plant is less toxic and generally unpalatable. The toxic principle is carboxyatractyloside, which directly affects the liver.

Within hours of toxin ingestion, swine, cattle, and horses develop signs of depression, nausea, weakness, ataxia, and subnormal temperature. Spasms of the cervical muscles, vomiting, dyspnea, and

convulsions may occur. Death may occur within hours of the onset of signs. Animals that survive initial acute poisoning frequently develop chronic liver disease.

Affected animals require intensive supportive care. Mineral oil or activated charcoal may be given orally to delay absorption of the toxic principle. Physostigmine (5–30 mg, IM) has also been recommended.

Miscellaneous Plant Hepatotoxicosis:

Hepatotoxins are found in numerous plants, including *Nolina texana*, *Agave lechuguilla*, *Phyllanthus abnormis*, and *Lantana camara*. (See RANGE PLANTS OF TEMPERATE NORTH AMERICA, p 3103.)

CHOLELITHIASIS, CHOLEDOCHOLITHIASIS, AND HEPATOLITHIASIS

Etiology and Epidemiology:

Cholelithiasis in horses may cause biliary obstruction and concurrent liver disease or may be an incidental finding at necropsy. It most commonly affects middle-aged (6–15 yr old) horses with no sex or breed predilection. Solitary or multiple calculi may be present in the common bile duct (choledocholithiasis), intrahepatic bile ducts (hepatolithiasis), or bile duct or gallbladder in ruminants (cholelithiasis). In large animals, choledocholithiasis is the most common cause of biliary obstruction, with horses more frequently affected. The cause of cholelith formation in horses is not known. Ascending biliary tract inflammation (cholangiohepatitis), intestinal bacterial infection resulting in bile stasis, and a change in bile composition or cholesterol concentration have been proposed. Choleliths formed around a foreign body or parasites may occlude the common bile duct. Cholelithiasis and hepatolithiasis reportedly are not well recognized as a clinical problem in sheep and goats. Incidence in camelids is unknown.

Clinical Findings: Clinical signs commonly seen in horses with choleliths or cholangiohepatitis include weight loss, abdominal pain, icterus, depression, and intermittent fever. Signs of hepatic failure, including encephalopathy, photosensitivity, and coagulopathy, occur less frequently. Clinical signs are often intermittent. Complete obstruction of the common bile duct often is accompanied by persistent abdominal pain. Laboratory abnormalities

include hyperbilirubinemia with increased direct (conjugated) bilirubin, a marked increase in serum γ -glutamyl transpeptidase or transferase (GGT) activity, and increased serum total bile acid concentration. Sorbitol dehydrogenase (SDH) and AST activities are increased but to a lesser degree. BUN, glucose, and potassium concentrations may be decreased. Metabolic tests indicate reduced hepatic function. Activated partial thromboplastin time and one-stage prothrombin time may be prolonged. Leukocytosis, anemia of chronic disease, hyperproteinemia, hyperglobulinemia, and hyperfibrinogenemia are often present due to inflammation. Histologic changes include periportal and intralobular fibrosis, moderate bile duct dilatation and proliferation, and cholestasis. Culture of the liver may reveal a bacterial infection.

Lesions: At necropsy, the liver may be enlarged or shrunken. The liver is red to green-brown and firmer than normal. Hepatic ducts and the common bile duct are dilated and may contain one or more calculi.

Diagnosis: Cholelithiasis should be considered in horses with a history of fever, icterus, and recurrent abdominal pain. Other signs of hepatic failure (encephalopathy, photodermatitis, weight loss) are less consistently seen with cholelithiasis. A marked increase in serum GGT with hyperbilirubinemia (direct bilirubin >25%) is supportive. Increases in SDH, AST, and alkaline phosphatase are often also present, but when absent despite an increased serum GGT make the presumptive diagnosis of biliary stasis more justified. Neutrophilic leukocytosis with inconsistent increase in globulin and fibrinogen concentrations are noted on leukograms. Ultrasonographic examination may reveal hepatomegaly with increased echogenicity of the liver, thickened distended bile ducts, and hyperechoic regions suggestive of choleliths. Choleliths in horses are most often visualized in the most cranioventral portion of the right lobe of the liver, especially in the sixth to eighth intercostal spaces. Choleliths may be hyperechoic, casting an acoustic shadow, or sonolucent. Stones may be seen as discrete calculi or less discrete sludge deposits within the biliary tract. The thickened distended bile ducts may appear as dilated channels adjacent to portal veins. Because of the large lung field of horses, choleliths may be missed on ultrasound examination.

Treatment: Although biliary obstruction in horses is often fatal, choledocholithotripsy and choledocholithotomy have been performed successfully. Prognosis in cases requiring choledocholithotomy depends on the severity of concurrent cholangiohepatitis and on the size of the horse. The procedure is difficult because of limited exposure and poor visibility of the common hepatic duct. Complications include bile contamination, bile peritonitis, dehiscence, bile duct stricture, cholelith reformation, and enterocolitis (eg, stress-induced, salmonellosis). The prognosis is better if the obstruction is corrected by choledocholithotripsy.

When small calculi or less discrete sludge deposits are present, resolution by medical therapy may be successful. In addition, dissolution of bilirubinate stones, which are common in horses, may be facilitated by concurrent administration of IV dimethyl sulfoxide (<20% solution at 0.5–1 mg/kg). Dimethyl sulfoxide should be used cautiously or avoided in horses with coagulopathies or signs of hemolysis. Anti-inflammatory agents are administered to reduce inflammation and provide analgesia. Because cholangitis is often present, long-term broad-spectrum antimicrobial therapy is indicated. Antimicrobial choice is best guided by culture and sensitivity of the bacteria from a liver biopsy, bile duct aspirate, or from the cholelith. Supportive care is provided to manage any degree of accompanying hepatic insufficiency.

CHRONIC ACTIVE HEPATITIS

Chronic active hepatitis describes any progressive inflammatory process within the liver. It is a histopathologic diagnosis in which there is evidence of sustained, aggressive, chronic liver disease. The histologic diagnosis is often cholangiohepatitis, because the inflammatory response is mainly in the periportal areas.

Etiology: The exact etiology of chronic active hepatitis is not known. Infectious, immune-mediated, or toxic processes are thought to be involved. The early stages are associated with inflammation of the bile ducts and portal areas of the liver. Extension of bacterial infection through the bile duct or portal venous drainage may be responsible for the lesions in animals with suppurative cholangiohepatitis. When lymphocytes and plasma cells predominate in the cellular infiltrate, an immune-mediated process is more likely. Many causes of

acute hepatic failure can progress to chronic active hepatitis.

Clinical Findings: The predominant clinical signs of chronic active hepatitis are weight loss, anorexia, depression, and lethargy. Icterus, behavioral changes, diarrhea, photosensitization, and hemorrhage are variably present. Fever may be persistent or intermittent, depending on the degree of cholangiohepatitis and fibrosis present. Dermatitis of the coronary band with regional sloughing of skin may develop. Recent or concurrent abdominal disease is often reported. Duration of clinical signs is variable, extending over days to months. Neurologic signs may seem to appear abruptly, even though there is histologic evidence of chronic disease. Alkaline phosphatase and γ -glutamyl transpeptidase or transferase (GGT) are moderately increased, as are sorbitol dehydrogenase (SDH) and glutamate dehydrogenase, which indicates ongoing hepatocyte damage. In chronic cases with marked hepatic fibrosis, enzyme activity may be normal, and BUN and albumin concentrations may be decreased. Serum total protein is either increased or normal. Globulins are usually increased. Serum total bile acid concentration is increased, and BSP[®] clearance prolonged. Cholestasis may cause hyperbilirubinemia, with >25% of total bilirubin being direct. With diminishing hepatic function, serum glucose and coagulation factors decrease, and one-stage prothrombin time and activated partial thromboplastin time become prolonged. Blood ammonia concentrations may be increased. There may be a neutrophilia or neutropenia with a left shift if endotoxemia develops. Anorexia can lead to hypokalemia. Ultrasonography generally reveals increased echogenicity in the liver, indicative of hepatic fibrosis. The liver may be smaller than normal, so much so it may be difficult to identify on ultrasonography.

Lesions: Grossly, the liver is firm, pale brown to green in color, and often small. Irregular markings may be seen on the cut surface. Histologic lesions are predominantly in the periportal areas. Inflammatory cell infiltration may consist primarily of mononuclear cells, neutrophils with bacteria (often coliforms), or lymphocytes and plasma cells. The character of the infiltrate may indicate the nature of the primary disease process. Biliary hyperplasia may be marked if there is cholangiohepatitis. Variable degrees of necrosis and fibrosis are present.

Diagnosis: Histologic examination of a liver biopsy is needed for a definitive diagnosis. The tissue should also be cultured, although in most cases significant isolates are not identified.

Treatment: Supportive care should be provided, including fluid therapy with potassium chloride, glucose, and vitamin supplementation; dietary management (a diet low in protein and high in branched-chain amino acids and carbohydrates); and prevention of exposure to the sun if photodermatitis is present.

Corticosteroid therapy has been used successfully in horses with a lymphocytic-plasmacytic infiltrate on liver biopsy. Reportedly, steroids act to enhance appetite, stabilize cell membranes, and reduce inflammation and connective tissue formation. Different therapeutic regimens using prednisolone and dexamethasone have been recommended. One recommended regimen involves initial administration of dexamethasone at 0.04–0.08 mg/kg for 4–7 days, followed by a gradual reduction in dosage over 2–3 wk depending on response to therapy. Prednisolone (0.5–1 mg/kg/day, PO) may be required for an additional 2–4 wk. The risk of inducing laminitis or abortion in pregnant animals with corticosteroids must be discussed with the owner before initiating therapy. Alternatively, an antifibrotic agent, colchicine (0.03 mg/kg/day, PO), has been recommended, but its efficacy in hepatic failure and safety in pregnant animals is unproved. Possible adverse reactions to colchicine in horses include laminitis, diarrhea, and rarely bone marrow suppression affecting all cell lines. Malaise, vomiting, diarrhea, abdominal pain, myopathy, alopecia, and bone marrow suppression have been reported in people and other species. Other drugs recommended for arresting or slowing fibrosis include pentoxifylline (7.5 mg/kg, PO, bid) and S_{AM}e (5 g/day, PO). In cases complicated with septic cholangiohepatitis, broad-spectrum antimicrobials are indicated. Ideally, antimicrobial therapy should be based on bacterial culture and sensitivity from the biopsy specimen.

Prognosis: Prognosis is variable and is best based on liver biopsy and response to therapy. Prognosis is fair to good in animals with less severe lesions, especially those with a lymphocytic-plasmacytic cellular infiltrate that responds well to corticosteroid therapy; however, it is poor in horses

with hepatic failure, widespread fibrosis (or severe bridging fibrosis), and disruption of normal hepatic parenchyma.

HYPERLIPEMIA AND HEPATIC LIPIDOSIS

Epidemiology and Pathogenesis:

Poor feed quality or decrease in feed intake, particularly during a period of high-energy requirement (eg, pregnancy, systemic disease), may result in hyperlipemia syndrome. Hyperlipemia is seen most commonly in ponies, miniature horses, and donkeys and less frequently in standard-size adult horses. Pathogenesis of hyperlipemia is complex, with a negative energy balance triggering excessive mobilization of fatty acids from adipose tissue, leading to increased hepatic triglyceride synthesis and secretion of very-low-density lipoproteins, concomitant hypertriglyceridemia, and fatty infiltration of the liver. The biochemical etiology of hyperlipemia is overproduction of triglyceride rather than failure of triglyceride catabolism.

Onset of disease is associated with stress, decreased feed intake, fat mobilization and deposition in the liver, and overproduction of triglycerides, which may be precipitated by insulin resistance. In ponies, hyperlipemia is usually a primary disease process associated with obesity, pregnancy, lactation, stress, or transportation. Hyperlipemia may develop secondary to any systemic disease that results in anorexia and a negative energy balance. Secondary hyperlipemia is more common than primary hyperlipemia in miniature breeds. Hyperlipemia secondary to a systemic disease can be seen in horses of any age and in any condition. Female, stressed, and obese donkeys are at highest risk of developing hyperlipemia regardless of pregnancy status. Hyperlipemia is most commonly seen in winter and spring.

Alpacas and llamas may develop hyperlipemia and ketonuria in late stages of gestation or secondary to disease states. Adult camelids and even young crias are susceptible to hepatic lipidosis during disease states.

Fatty liver disease is a complex metabolic disease seen primarily in dairy cattle. See p 1018.

In goats, hepatic lipidosis has been associated with cobalt deficiency. Histologic lesions are consistent with those characteristic of white liver disease in sheep.

Clinical Findings: Signs of hyperlipemia are nonspecific and variable and may not relate to loss of liver function. They include lethargy, weakness, inappetence, decreased water intake, and diarrhea. Often, there is a history of prolonged anorexia, rapid weight loss, and previous obesity. Emaciation, ventral edema, colic, and trembling may be seen. Serum biochemical values and coagulation testing in miniature horses and ponies with hyperlipemia indicate that impaired hepatic function is common. Affected animals have grossly opalescent blood and lipemic plasma. The blood concentrations of all lipids are increased, especially triglycerides, nonesterified fatty acids, and very-low-density lipoproteins. Donkeys have higher plasma triglyceride concentrations than do other equids. Hypoglycemia is a common finding in ponies but not in miniature horses with hyperlipemia. Total bile acid concentration and BSP® clearance are often normal, but BSP clearance may be prolonged in some animals. Activated partial thromboplastin time and one-stage prothrombin time may be prolonged. AST and sorbitol dehydrogenase (SDH) may be normal or increased. Increased creatinine, isosthenuria, and metabolic acidosis may develop secondary to renal disease. BUN and creatinine concentrations are variable. Anorexia can lead to hypokalemia. Animals may become neutropenic with increased band neutrophils. Concurrent pancreatitis has been reported.

Prolonged increase in serum triglyceride concentrations is associated with lipid accumulation in the liver, kidneys, myocardium, and skeletal muscles, impairing function of these organs. The liver and kidneys become friable, and death may result from acute hepatic rupture.

Alpacas and llamas may develop hyperlipemia and ketonuria in late stages of gestation, during lactation, or secondary to disease states. Nonspecific clinical signs include lethargy, anorexia, and recumbency. Hypertriglyceridemia, hypercholesterolemia, increased SDH activity, metabolic acidosis, azotemia, and ketonuria may be seen. Secondary renal failure may develop. Camelids appear to be similar to both horses (hyperlipidemia) and cattle (ketosis) in their response to severe energy imbalance in late gestation. Hepatic lipidosis is the most common liver disease found in llamas and alpacas. Camelids of various ages and energy requirements are susceptible, and the pathogenesis is multifactorial. Common clinical findings include anorexia; weight loss; high concentrations of bile

acids, nonesterified fatty acids, and β -hydroxybutyrate; high activities of γ -glutamyl transpeptidase or transferase (GGT) and AST; and hypoproteinemia.

Lesions: The liver and kidneys are often pale, swollen, and friable with a greasy texture. Microscopically, there is variable fat deposition within the hepatocytes and epithelium of the bile ducts. The hepatic sinusoids may appear compressed and anemic with severe fatty infiltration. Gross and microscopic lesions of the primary disease process in ponies and horses may predominate.

Diagnosis: Clinical diagnosis of hyperlipemia is often based on the signalment, history, clinical signs, and gross observation of a white to yellow discoloration of the plasma in equids. Plasma or serum triglyceride >500 mg/dL confirm the diagnosis. Cholesterol may be increased, indicating an increase in lipoprotein. Nonesterified fatty acids, very-low-density lipoproteins, and β -hydroxybutyrate (camelids) may also be increased. Laboratory evidence of hepatic dysfunction is supportive.

Treatment: Correction of the underlying disease, IV fluids, and nutritional support are the most essential factors in treatment of hyperlipemia. Nutritional support reverses the negative energy balance, increases serum glucose concentrations, promotes endogenous insulin release, and inhibits mobilization of peripheral adipose tissue. A polyionic electrolyte solution containing supplemental dextrose (50 g/hr/450 kg) and potassium (potassium chloride at 20–40 mEq/L) should be given IV to hypoglycemic, hypokalemic horses. Glucose administration may cause refractory hyperglycemia in animals with insulin resistance. Glucose concentrations, renal function, urine output, and serum electrolyte concentrations should be monitored closely. IV fluids and glucose must be administered cautiously in camelids with hepatic lipidosis, because many are already hypoproteinemic, and glucose regulation in camelids is often challenging. Intermittent bolus administration of polyionic IV fluids rather than continuous infusion may more effectively maintain hydration without exacerbating existing hypoproteinemia.

Voluntary enteral nutrition is preferred if the affected animal will consume adequate quantities of nutritionally valuable feeds; however, most will not. Frequent feedings

of a high-carbohydrate, low-fat diet are preferred. In animals with inadequate oral intake, supplemental tube feeding is necessary. Commercially available high-calorie enteral formulations provide adequate short-term nutritional support. Recipes for home-prepared, liquid tube-feeding diets for horses are also available. Small frequent feedings are required to meet caloric needs without overloading the GI tract. Animals should be observed after each feeding for signs of abdominal discomfort. Body weight, total fluid intake, and fecal consistency should be monitored daily. In animals that survive, hyperlipemia usually resolves in 5–10 days, but enteral feeding should be continued until voluntary feed intake is adequate. Enteral nutritional supplementation and treatment of the primary disease often reverses hyperlipemia in miniature horses and donkeys but less frequently in ponies.

For totally anorectic horses, partial parenteral nutrition may be used. The lipid portion of the solution is omitted. Blood glucose concentration should be monitored at least twice daily to ensure that euglycemia is maintained and that substantial hyperglycemia (≥ 180 mg/dL) is avoided.

In camelids, partial parenteral nutrition with enteral supplementation can be used to maintain adequate energy intake and minimize further fat mobilization. Because of the distinct metabolism of camelids, parenteral nutrition products must contain higher amounts of amino acids (relative to nonprotein calories) than traditional formulations used in other species. Glucose concentrations must be carefully monitored, because camelids do not assimilate exogenous glucose well.

Exogenous insulin administration is recommended for treatment of iatrogenic hyperglycemia and hyperlipemia, especially when these conditions are resistant to more conventional therapies. Insulin decreases mobilization of peripheral adipose tissue by stimulating lipoprotein lipase activity and by inhibiting adipocyte hormone-sensitive lipase activity. The appropriate dosage of insulin to be used in horses has not been well established. When insulin is used, response to therapy, including blood glucose concentrations, must be closely monitored and the insulin dosage adjusted accordingly. Insulin administration may fail to lower serum triglyceride or glucose concentrations in hyperlipemic animals when an insulin-resistant state is present. Insulin treatment in camelids has reportedly been effective in treatment of hepatic lipodosis.

Heparin is used in treatment of hyperlipemia because it promotes peripheral utilization of triglycerides and enhances lipogenesis via stimulation of lipoprotein lipase activity. Heparin may be given IV or SC, with recommended dosages of 40–100 IU/kg, bid. Use of heparin is questionable in affected animals with increased hepatic production of triglycerides and without impaired peripheral removal of triglycerides. Heparin administration may potentiate bleeding complications and is contraindicated in animals with coagulopathies from liver dysfunction.

Nutritional supplementation to prevent hyperlipemia is indicated in miniature horses and donkeys, ponies, horses, and camelids with systemic disease associated with hypophagia and high metabolic demands.

Prognosis: Clinical biochemical variables are not useful prognostic indicators of survival in ponies with hyperlipemia. In most instances, survival depends on the ability to successfully treat the primary disease. Prognosis is often poor in ponies, standard-size horses, and camelids.

HEPATIC NEOPLASIA

Primary hepatic tumors are uncommon in horses and ruminants. They include hepatocellular carcinoma, cholangiocarcinoma, and rarely lymphoma, hepatoblastoma (foals, young horses, alpaca crias), and mixed hamartoma. Cholangiocarcinoma is the most common and is primarily found in middle-aged or older horses. Hepatic carcinomas arise from hepatocytes, bile ducts, or metastasis. Hepatocellular carcinomas generally are found in yearlings to young adult horses and have also been reported in llamas and goats. Adenomas or adenocarcinomas of the liver have been reported in cattle. Hepatic fibrosarcoma and bile duct carcinoma with metastasis to the lungs have been reported in goats. Erythrocytosis, large areas of extramedullary hematopoiesis, and metastasis to the thoracic cavity have been reported in horses with hepatoblastoma.

Lymphosarcoma is the most common neoplasia of the hematopoietic system in horses. As many as 37% of horses with lymphosarcoma have neoplastic involvement of the spleen, and 41% have neoplastic involvement of the liver. Metastasis of lymphosarcoma of the liver has been reported in cattle, llamas, alpacas, and goats.

The predominant clinical findings with hepatic carcinoma are lethargy and weight

loss. A progressively enlarging abdomen, erythrocytosis, persistent hypoglycemia, icterus, and hepatic failure may also be seen. Cholangiocarcinoma causes pronounced weight loss before the onset of hepatic failure. Liver hepatocellular and biliary enzymes may be increased with hepatic carcinoma or cholangiocarcinoma. Serum γ -glutamyl transpeptidase or transferase (GGT) activity in affected horses is usually very high. Hepatocellular carcinomas are characteristically uniform in appearance on ultrasonographic examination.

Clinical manifestations of lymphosarcoma in horses are variable. Early in the disease, nonspecific signs such as weight loss, anorexia, and lethargy are seen. Lymphoma occasionally may diffusely infiltrate the liver and produce signs of hepatic failure, jaundice, and severe depression. Laboratory findings include hypoglycemia, mild to moderate increases in liver enzymes, hyperbilirubinemia, and abnormally low levels of IgM. Ultrasonographic examination helps to detect splenic and hepatic neoplasia. In ruminants, signs produced by tumor growth in other organs (lymph nodes, abomasum, heart, uterus, spinal cord) are often most predominant.

The presence and character of the hepatic neoplasia can be confirmed by liver biopsy and microscopic examination of the tissue. Atypical lymphocytes or lymphoblasts may be seen in peritoneal fluids and peripheral blood of some affected animals. Increased serum α -fetoprotein concentration may support hepatoblastoma; however, this is not conclusive because concentrations may also be increased with hepatocellular carcinoma.

MISCELLANEOUS HEPATIC DISORDERS

Cholangitis

Diseases of the gallbladder are rare in ruminants. Obstruction may be associated with liver fluke infestation, foreign bodies, abscesses, neoplasia, suppurative cholecystitis, or abdominal fat necrosis. Rupture of the gallbladder has been reported in a cow. Cholangitis (inflammation of the biliary system) has been reported in horses with chronic active liver disease. Mild behavior changes, weight loss, variable colic, icterus, and alterations in hepatic enzyme activity may be seen in affected horses. Treatment consists of long-term antimicrobial and supportive therapy as indicated.

Hepatic Failure in Foals

Hepatic failure in neonatal foals may follow septicemia (especially *Actinobacillus equuli*), endotoxemia, perinatal asphyxia, *Leptospira* Pomona infection, equine herpesvirus 1, hepatic duct obstruction secondary to gastroduodenal obstruction, biliary atresia, and iron toxicity. Gastric ulcers and duodenitis in foals can cause strictures of the duodenum and subsequent cholangiohepatitis due to bile stasis. Neonatal isoerythrolysis and hemolysis may cause hypoxic and cholestatic hepatic disease. Administration of total parenteral nutrition may cause cholestasis and concurrent hepatic disease.

Biliary Atresia

Biliary atresia (extrahepatic) has been reported in foals and in a neonatal lamb. Affected foals presented for anorexia, depression, lethargy, poor growth, colic, polydipsia, polyuria, pyrexia, and icterus at 1 mo of age. Markedly increased serum γ -glutamyl transpeptidase or transferase (GGT) and bilirubin with mildly increased sorbitol dehydrogenase (SDH) supported a diagnosis of biliary obstruction. Diagnosis of biliary atresia was confirmed at necropsy.

Hemochromatosis

Hemochromatosis is an iron storage disease in which hemosiderin is deposited in the parenchymal cells, causing damage and dysfunction of the liver and other tissues. The disease is either primary (idiopathic) or secondary. It is reported in people, Mynah birds, Salers cattle, and horses.

Etiology: In Salers cattle, the condition appears to be a homozygous recessive condition with inappropriate intestinal absorption of iron, excessive hepatic storage, and eventual loss of hepatic function. In horses, there is no evidence of a familial tendency or of excessive iron being consumed in the diet. Rather, it appears there is cirrhosis of the liver with secondary iron overload. In horses and cattle, increased iron is deposited in the liver.

Clinical Findings and Lesions: In horses, primary clinical signs are weight loss, lethargy, and intermittent anorexia. In cattle, signs include decreased weight gain, poor body condition, dull hair coat, and diarrhea. In both species, serum liver enzyme concentrations, including GGT, alkaline phosphatase, AST, and SDH, are increased. Serum total bile acid concentra-

tions are increased in horses, and serum iron, total iron binding capacity (TIBC), and percent saturation of the TIBC are usually normal. In some cases, serum iron and ferritin may be increased, but TIBC is not saturated. In cattle, total serum iron, TIBC, and saturation of transferrin are increased. Iron content of the liver tissue is greatly increased in horses (normal 100–300 ppm) and cattle (normal 84–100 ppm). Hepatomegaly and hemosiderin accumulation in the liver, lymph nodes, pancreas, spleen, thyroid, kidney, brain, and glandular tissue are typically present.

Diagnosis: Diagnosis is based on history, clinical signs, and laboratory findings. Finding abundant hemosiderin in the hepatocytes on histopathologic examination of a liver biopsy supports the diagnosis. High liver iron concentrations in animals with no history of excess iron intake help confirm the diagnosis. Differential diagnoses include iron toxicosis from exogenous sources and diseases causing chronic weight loss and hepatic dysfunction or disease.

Treatment: Phlebotomies to remove blood and reduce the iron stores have been used in treatment of people with hemochromatosis. Similar treatment in horses and cattle has been unsuccessful. Deferoxamine is also used in people to induce a negative iron balance and reduce the rate at which iron accumulates. The effect in cattle and horses has not been evaluated.

Right Hepatic Lobe Atrophy in Horses

The right lobe of the liver is the largest lobe in young horses but frequently atrophies in older animals and becomes fibrous. Right hepatic lobe atrophy was previously considered an incidental postmortem finding, but some consider it to be a pathologic condition.

Right hepatic lobe atrophy has been proposed to result from chronic compression of this portion of the liver by the right dorsal colon and base of the cecum. Feeding horses high-concentrate, low-fiber diets may contribute to atony of the right dorsal colon with resultant distention; this compresses the right hepatic lobe against the visceral surface of the diaphragm. Although there is no morphologic evidence of direct vascular impairment to the right hepatic lobe, vascular compromise may result secondary to compression. With chronicity, the portal circulation to the right

lobe is impaired, resulting in hepatic anoxia, deprivation of nutrients, and gradual atrophy of the right lobe of the liver. No evidence of biliary tract disease has been noted. Colic may be seen. Some horses may have signs not related to the GI tract.

Hepatic Lobe Torsion

Hepatic lobe torsion can cause colic in horses. Liver enzymes and fibrinogen are increased, but abdominal fluid analysis is variable. Bacteria, including *Clostridium* spp, may be found in the necrotic portion of liver. Exploratory celiotomy may be required for diagnosis.

Hepatic Amyloidosis

Amyloidosis refers to disease characterized by the extracellular deposition of amyloid, a proteinaceous fibril substance, in the tissue. Deposition of amyloid within an organ distorts normal tissue architecture and possibly function. In horses, the liver and spleen are the most common organs affected by systemic amyloidosis. Reactive or secondary systemic amyloidosis with deposition of amyloid A (AA) fibrils in the liver has been associated with severe parasitism and chronic infection or inflammation in horses. (See also AMYLOIDOSES, p 592.)

Congenital Hepatic Fibrosis

In a retrospective study of the records from the University of Berne, Institute of Animal Pathology, 30 Swiss Freiberger foals with pathologic lesions compatible with congenital hepatic fibrosis were identified. Affected foals were 1–12 mo old (average 3.7 mo). Most showed signs and had clinicopathologic changes reflecting severe liver damage. Pedigree analysis traced the disease back to one stallion. Results suggest that congenital hepatic fibrosis in Swiss Freiberger horses is a recessively inherited autosomal genetic defect. A similar condition has been reported in a calf.

Primary Hyperammonemia of Adult Horses

In this syndrome of hyperammonemia, blindness and severe neurologic signs are seen in adult horses. The etiology is unknown, but a primary intestinal problem with overgrowth of urease-producing bacteria within the intestine is suspected.

The syndrome is nearly always associated with enteric disease, diarrhea, or colic. Diarrhea and, in some cases, protein-losing

enteropathy may persist for several days. In most cases, diarrhea or colic precedes the neurologic signs by 24–48 hr. Laboratory abnormalities include increased blood ammonia concentrations (200–400 $\mu\text{m/L}$), severe metabolic acidosis, low plasma bicarbonate ($\leq 12 \text{ mEq/L}$) concentration, and profound hyperglycemia (250–400 mg/dL). Serum concentrations of liver enzymes, total bile acids, and bilirubin are normal.

In most horses, neurologic signs resolve within 2–3 days with supportive treatment (IV fluids, potassium chloride, glucose, sodium bicarbonate) and administration of drugs to reduce ammonia absorption (lactulose, neomycin).

Portosystemic Shunts

Portosystemic shunts are seen in foals and calves. Hyperammonemia and neurologic signs result from liver dysfunction with little laboratory or microscopic evidence of liver disease.

Clinical Findings and Lesions: Clinical signs are first seen when affected foals are ~2 mo old and start to ingest larger amounts of grain and forage. Neurologic signs include staggering, wandering, blindness, circling, and seizures. Poor growth and intermittent neurologic signs (ataxia, weakness, depression, bruxism, tenesmus) have been reported in affected 2- to 3-mo-old calves. Serum concentrations of hepatic enzymes are often normal. Blood ammonia and total bile acid concentration are increased, and BSP® clearance is prolonged.

The liver is often small, with a smooth surface, and normal in color and texture. Microscopically, the hepatocytes are small. Portal veins in the triads may be small or absent. Hepatic arteries are often prominent and multiple.

Diagnosis: A portosystemic shunt should be suspected in foals or calves exhibiting repeated episodes of cerebral signs without obvious reasons. Signs may be most pronounced and associated with feedings. Catheterizing the mesenteric vein and performing a portogram or nuclear scintigraphy can confirm and locate the shunt. In some cases, the shunt may be seen on ultrasonographic examination of the liver.

Treatment: Surgical repair may be attempted in animals in which the site of the shunt can be identified, but the prognosis is guarded. Clinical signs in some foals may be

controlled by restricting protein intake and by careful dietary management. Neomycin or lactulose are given orally to decrease ammonia production within the bowel. Supportive care with polyionic fluids, potassium, and dextrose may be needed to help decrease neurologic signs.

Hyperammonemia of Morgan Foals

A syndrome of depression, ill thrift, and hyperammonemia with a variable degree of hepatic involvement is seen in Morgan foals. Affected foals have been related, but the cause of the syndrome is undetermined. Clinical signs are usually first seen around weaning time. Encephalopathy may temporarily improve with aggressive supportive therapy but recurs after withdrawal of treatment. Liver enzymes and blood ammonia concentrations are increased. Bilirubin concentration is often normal. Pathologic hepatic lesions include portal and bridging fibrosis, bile duct hyperplasia, karyomegaly, and cytomegaly. The disease is fatal.

HYPERBILIRUBINEMIA SYNDROMES

Gilbert Syndrome

Gilbert syndrome is a congenital hyperbilirubinemia seen in people (inherited as an autosomal dominant trait) and in Southdown sheep. It is an unconjugated hyperbilirubinemia in the presence of normal erythrocyte life span. A defect in carrier proteins or conjugating enzyme is suspected. Affected Southdown sheep have increased conjugated and unconjugated plasma bilirubin concentrations. Hepatic bilirubin clearance is defective, and affected sheep cannot excrete BSP® into the bile. Icterus is variable. Histopathologic lesions are absent except for pigment in the hepatocytes.

Dubin-Johnson Syndrome

Dubin-Johnson syndrome is seen sporadically in people and Corriedale sheep. It is a failure of conjugated bilirubin to enter the bile canaliculi. Excretion of bilirubin and other conjugated organic anions may be impaired. Affected sheep may be icteric or hyperbilirubinemic. Serum conjugated and unconjugated bilirubin concentrations are increased, and BSP® clearance and bile acid excretion may be delayed in affected Corriedale sheep. Histologically, the hepatocytes contain a black, melanin-like pigment.

LIVER ABSCESSES IN CATTLE

Liver abscesses are seen in all ages and breeds of cattle wherever cattle are raised. They are most common in feedlot and dairy cattle fed rations that predispose to rumenitis. Cattle with liver abscesses have reduced production efficiency. Affected livers are condemned at slaughter, and adhesions to surrounding organs or the diaphragm may necessitate carcass trimming. Liver abscesses can also lead to disease syndromes associated with posterior vena caval thrombosis.

Etiology and Pathogenesis: *Fusobacterium necrophorum*, a gram-negative, obligate anaerobic bacterium, and a component of normal rumen microflora, is the primary etiologic agent. Infection in the liver usually originates from a necrobacillary rumenitis. Two biovars have been implicated. Biovar A (*F. necrophorum necrophorum*), the more virulent, is the predominant biovar in the rumen microflora and is isolated, usually in pure culture, from most cases of liver abscessation. Biovar B (*F. necrophorum funduliforme*) is commonly isolated from microabscesses in the rumen wall but is less commonly isolated from liver abscesses, in which it is always found in mixed culture with biovar A or other bacterial species. *Trueperella pyogenes*, streptococci, staphylococci, and *Bacteroides* spp are most frequently recovered from mixed cultures.

Rumenitis is usually the result of rapid intraruminal fermentation of dietary carbohydrate with subsequent production of lactic acid and increased acidity of the ruminal fluid ("grain overload"). Rations with high levels of carbohydrate are the principal cause in both dairy and feedlot cattle, but the texture of the feed and method of feeding can be modifying factors. The incidence of rumenitis in feedlot cattle is significantly higher when the cattle are transferred directly from a roughage ration to a finishing ration, and when there is poor feed bunk management. *F. necrophorum*, alone or with other bacteria, colonizes through the area of superficial necrosis produced by the acid rumen contents. Leukotoxin may facilitate resistance to phagocytosis. Bacterial emboli from the lesions invade the hepatic portal venous system and are transported to the liver, where they can establish infectious foci of necrobacillosis that eventually develop into abscesses.

Other sources of infection in liver abscesses include foreign body penetration

from the reticulum, direct extension of infection from omphalophlebitis in neonatal calves, and bacteremic diseases.

Clinical Findings, Lesions, and Diagnosis:

Cattle with liver abscesses seldom exhibit clinical signs. Detailed clinical examination may show periodic fever, inappetence, and evidence of pain when pressure is applied to the xiphisternum and posterior rib cage on the right side. Grunting and other signs of pain may occur with movement or when the animal lies down. An episodic drop in milk production occurs in dairy cattle. Clinical signs of omphalophlebitis are commonly present when there is liver abscessation resulting from extension of omphalophlebitis. Acute-phase proteins are increased early in the course of the disease, and serum sialic acid concentrations have been used for antemortem diagnosis. When there are several abscesses or a large abscess, leukocytosis with neutrophilia and increased fibrinogen levels develop, and serum globulin concentrations may increase. Ultrasonography is an aid to diagnosis, but abscesses in the left side of the liver may not be visualized. Feedlot cattle with abscessed livers have reduced feed efficiency, and those with severely abscessed livers gain 5%–15% less per day than cattle without abscesses. Most liver abscesses are occult lesions that regress to a sterile scar. Untoward sequelae include peritonitis after abscess rupture into the peritoneal cavity, and sudden death from an anaphylactic or toxic reaction when there is rupture of an abscess into hepatic blood vessels. Rupture into hepatic veins can also lead to thrombophlebitis of the posterior vena cava with thromboembolic disease, endocarditis, pulmonary thromboembolism, multiple pulmonary abscesses, and chronic suppurative pneumonia. Aneurysms of the pulmonary artery consequent to pulmonary thromboembolism may rupture into airways to result in hemoptysis, epistaxis, and death. Caudal vena caval thrombosis may also lead to portal hypertension with a resulting syndrome of hepatomegaly, ascites, and diarrhea.

The ruminal lesions are characterized by a marked inflammatory reaction and necrosis. Occasionally, abscesses are found in the deeper layers of the rumen wall. Hepatic necrobacillosis lesions of <6 days duration are pale yellow and spherical with irregular outlines; they are characterized by coagulation necrosis of the hepatocytes

with a surrounding intense zone of hyperemia and inflammation. Older abscesses have a core that is progressively encapsulated by fibrous connective tissue. Abscesses are usually 4–6 cm in diameter. Affected livers usually have 3–10 abscesses but may have up to 100.

Liver condemnation rates as high as 40% were recorded in a large survey of cattle slaughtered in the USA. Culture is seldom done to confirm the diagnosis. Occasionally, liver abscesses due to *F. necrophorum* must be distinguished from those resulting from traumatic reticuloperitonitis (see p 230).

Treatment and Control: Tylosin phosphate fed at 10 g/ton of feed significantly reduces the number of liver abscesses and increases feed efficiency and weight gain but has little, if any, effect on prevalence of ruminal lesions. Virginiamycin fed at 16 g/ton of feed or chlortetracycline fed continually at 70 mg/head/day during the finishing period is also used. With

dairy cattle, percutaneous drainage and longterm therapy with procaine penicillin G (22,000 IU/kg) can be attempted, but the prognosis is poor. A vaccine consisting of the leukotoxin of *F. necrophorum* combined with a bacterin of *T. pyogenes*, given when cattle enter the feedlot, reduces abscess incidence and severity.

The primary control is by managing ruminal acidosis through the method of feeding, diet composition, diligent feed bunk management, and use of buffers in the diet. Fewer ruminal lesions develop when the ratio of concentrate to roughage is decreased and when the transition period from a roughage to a finishing ration is lengthened. Increased roughage in the ration and multiple daily feedings increase the time of mastication and saliva flow; this increases buffer to the rumen and provides a continuous and uniform fermentation that reduces intraruminal acidity, which in turn lowers the number of ruminal lesions and, indirectly, the number of liver abscesses.

MALASSIMILATION SYNDROMES IN LARGE ANIMALS

Malassimilation is a decreased ability of the GI tract to incorporate nutrients into the body, either due to maldigestion or malabsorption. Maldigestion is the failure of adequate degradation of dietary constituents within the GI tract, which is required to facilitate absorption due to defects in pancreatic exocrine function, bile acid content, or brush border enzymes.

Malabsorption is the failure of passage of nutrients from the intestinal lumen into the bloodstream. Some disease processes involve both maldigestion and malabsorption, such as is seen in young animals with lactase deficiency. Maldigestion alone is an infrequent cause of malassimilation in large animals. In horses, diseases causing malabsorption are much more common than diseases causing maldigestion. In cattle, small ruminants, and camelids, the forestomach bacteria and protozoa contribute to nutrient degradation, which makes maldigestion a very rare condition.

Etiology and Pathogenesis: Maldigestion syndromes are uncommon and poorly

understood in large animals. They may be due to alterations in gastric function or activity of rumen microflora, abnormal bacterial proliferation in the small intestine, or a decrease or lack of small-intestinal brush border enzyme activity (eg, lactase deficiency). Less likely causes include drug-induced alteration in secretion or excretion of bile salts, or deficiency or inactivation of pancreatic lipase. Changes in bile salt concentration may not impair digestion in adult herbivores but may exacerbate diarrhea in milk-fed neonates. Surgical resection or bypass of the distal small intestine may facilitate bacterial overgrowth with associated bile salt abnormalities.

Lactose is a disaccharide composed of glucose and galactose. The enzyme lactase, which catalyzes the degradation of lactose into its components, is localized in the small-intestinal brush border of foals and calves. The degradation is necessary to facilitate absorption. Primary lactase deficiency is inherited as an autosomal recessive trait in people, but its occurrence

and mode of inheritance in large animals is poorly documented. Acquired or secondary lactase deficiency seems to be more common in large animals. It is seen in foals, calves, and crias as a result of intestinal mucosal changes induced by viral, protozoal, and bacterial enteritis. Sloughing of the small-intestinal epithelial cells, loss of villous tips, and loss of some or all of the crypt cells result in some degree of lactase deficiency because of loss of lactase-secreting epithelial cells. Morphologic changes may include partial villous atrophy, crypt hyperplasia, and infiltration of the lamina propria. Osmotic diarrhea in lactase-deficient foals and calves occurs due to increased undigested/unabsorbed nutrients entering the caudal intestinal parts, subsequently increasing bacterial fermentation, concentration of osmotically active particles, and retention of water and electrolytes in the intestine.

A number of diseases may induce a malabsorption syndrome by altering the normal absorptive mechanisms of the small intestine. Malabsorption is commonly seen in animals with GI disease. It may arise from structural or functional disorders of the small intestine or have a multifactorial etiopathogenesis. Malabsorption is often seen concurrently with enteric protein loss. Either may cause loss of nutrients in the feces and subsequent weight loss. Malabsorption is not synonymous with diarrhea in any species, although diarrhea may be a common clinical feature. Function of the large intestine may be secondarily altered because of changes in the small intestine. Transient diarrhea may occur as abnormal quantities of carbohydrates, protein, fatty acids, and bile acids enter the large intestine in the ileal effluent. These substances can directly or indirectly enhance intestinal secretion or decrease absorption rates. Malabsorption of nutrients may result from insufficient absorptive surface area, an intrinsic defect in the mucosal or submucosal morphology of the intestinal wall, or obstruction of blood and lymphatic vessels. Rotavirus infection in younger animals may cause destruction of intestinal villous epithelial cells, which results in maldigestion due to decreased activity of brush border disaccharidase enzymes and in malabsorption due to decreased absorptive surface area. Coronavirus and cryptosporidia may have similar effects. A decreased absorptive surface area can also result from

small-intestinal resection (short-bowel syndrome) or from villous atrophy due to granulomatous enteritis. Local infiltrative or inflammatory disease, edema, or lymphatic obstruction (granulomatous enteritis, lymphosarcoma) secondary to local or systemic causes may interfere with the ability of the intestinal wall to absorb nutrients. Inefficient absorption also may develop due to increased mucosal permeability caused by cellular damage. Metabolic abnormalities may alter the epithelial cells and decrease the available energy for active transport and maintenance of the carrier proteins or brush border enzymes. Congenital deficiencies of enzymes normally present on the microvilli are not well recognized in large, domestic animals. However, neonates and ruminants have low levels of maltase, and ruminants especially lack sucrase. In most mammalian species, lactase activity declines with age.

In **horses**, malabsorption is commonly caused by the following: 1) inflammatory or infiltrative disorders—diffuse lymphosarcoma of the small intestine (alimentary lymphoma); enteritis due to eosinophilic, lymphocytic-plasmacytic, or basophilic infiltrate; multisystemic eosinophilic epitheliotropic enterocolitis; granulomatous enteritis (inflammatory bowel disease); *Lawsonia intracellularis* (weanling foals, yearlings); intestinal ischemia and damage due to migration of *Strongylus vulgaris* larvae, small strongyles, or *Strongyloides westeri* (foals) infection; cryptosporidia; postinfection inflammation; amyloid-associated gastroenteropathy; multiple abscessation in the bowel; tuberculosis; histoplasmosis; intestinal *Rhodococcus equi* infection; invasive enterocolitis (*Salmonella* spp); 2) biochemical or genetic abnormalities—congenital or acquired lactase deficiency (lactose intolerance), dietary-induced enteropathy, monosaccharide transport defect, pancreatic exocrine insufficiencies; 3) diseases causing inadequate absorptive area—villous damage or atrophy due to viral infection (rotavirus, coronavirus) or bacterial enteritides in foals, cryptosporidiosis, intestinal resection; 4) cardiovascular disorders—congestive heart failure, intestinal ischemia; 5) lymphatic obstruction—lymphosarcoma, mesenteric lymphadenopathy, intestinal lymphangiectasia, abscessation, thoracic duct obstruction; and 6) miscellaneous—drug-induced, heavy metal toxicosis, zinc deficiency.

In **cattle**, malabsorption syndromes are less frequently documented but likely are seen most often in calves with diarrhea.

Diseases that cause malabsorption syndromes in ruminants include diarrhea caused by viruses, bacteria, or protozoa in calves and young stock. These inflammatory changes often result in maldigestion and malabsorption. Another major group of cattle suffering from malabsorption syndrome is older cattle with *Mycobacterium avium* subsp *paratuberculosis* infection (Johne's disease). Rare underlying reasons for malabsorption in ruminants are local or generalized ischemia, protein malnutrition, congestive heart failure, lymphatic obstruction, parasitism (eg, trichostrongylosis of sheep and cattle), or tuberculosis. Oral antibiotics may cause an imbalance in GI tract flora and interfere with digestion and intestinal absorption of nutrients. Treatment with high doses of ampicillin, neomycin, or tetracycline significantly decreases and delays glucose absorption during oral glucose tolerance tests in calves.

New World camelids can be affected by most conditions that cause malabsorption syndrome in ruminants. Virus-caused diarrhea (coronavirus) is particularly a problem in young crias. Intestinal protozoa infection (eg, *Eimeria macusaniensis*) may result in weight loss and hypoproteinemia due to malabsorption during either the prepatent or patent phase of infection. Severe debilitation caused by coccidiosis is typically seen in young animals; however, chronic malabsorption caused by chronic enteritis can also be found in adult llamas and alpacas, which typically shed high numbers of the pathogen.

In **swine**, malabsorption is poorly documented; however, proliferative enteropathy (*L. intracellularis*) can result in malabsorption. In piglets, an amylase deficiency may result in starch malabsorption during the immediate postweaning period. Diarrhea of other origin (eg, *Escherichia coli*) may cause malabsorption syndrome in piglets.

Clinical Findings: Clinical signs of malassimilation syndrome are variable, depending on the underlying disease condition and the presence or absence of concurrent protein-losing enteropathy. Malassimilation syndromes frequently result in a negative energy balance, and subsequently in weight loss, muscle wasting, and possibly low serum protein

concentrations. Therefore, chronic weight loss or reduced growth rate is a typical clinical sign.

Appetite of affected animals may be normal, increased, or decreased and is, therefore, not very helpful as a diagnostic parameter. Polyphagia may be seen due to insufficient nutrient absorption to stimulate the satiety centers. In small-intestinal malabsorption, decreased feed intake or anorexia is present more commonly, because the primary disease process causes loss of appetite.

Feces are frequently normal in consistency and volume. Diarrhea may be present but is not a consistent feature. In adult animals, small-intestinal disease must be rather extensive before diarrhea develops, because the colon can compensate and absorb the increased fluid load. This is especially the case in llamas and alpacas. In adult horses and ruminants, diarrhea indicates involvement of the large intestine. In young animals in which colonic function is not yet fully developed, diarrhea is seen with small-intestinal and large-intestinal disease.

Clinical signs of malassimilation may also include exercise intolerance, lethargic attitude, and variable thirst. Vital signs are usually normal until late in the disease. Pyrexia may be seen with inflammatory and neoplastic conditions. Abdominal pain may result from bowel inflammation, mesenteric or mural abscesses or adhesions, or partial obstruction. Ascites, dependent edema, and weakness may develop later in the disease process, especially if enteric protein loss is present. Skin and ocular lesions, vasculitis, arthritis, hepatitis, and renal disease may indicate immunologic reactions, particularly with inflammatory bowel disease. Skin lesions seen with malabsorption-related dermatosis include a thin hair coat, patchy alopecia, and focal areas of scaling and crusting that are often symmetrically distributed.

Foals and calves with lactose intolerance commonly show diarrhea, poor growth rate, and an unthrifty appearance. Some may experience flatulence, mild abdominal discomfort, or bloating after intake of milk. In young animals with acquired lactase deficiency, clinical signs (eg, diarrhea, dehydration, weight loss) and clinicopathologic alterations (eg, acidosis, hypoglycemia, and electrolyte abnormalities) are indistinguishable from those of the primary enteropathy. The condition of the animal may improve quickly, and diarrhea may resolve when milk is withdrawn.

Lesions: The carcass is thin to emaciated, depending on the duration and severity of

the malassimilation disease. Specific lesions depend on the primary underlying disease process. Overt signs of malabsorption do not always correlate with gross and histopathologic changes, emphasizing the importance of functional disorders.

Diagnosis: Small-intestinal malabsorption cannot be determined by clinical examination or by routine laboratory data. However, clinical examination may lead to a presumptive diagnosis after more common causes of weight loss have been excluded. Determination of the primary underlying pathologic process is necessary to establish an appropriate treatment regimen and prognosis.

A complete history should focus on duration of condition, precipitating factors, nutritional history, deworming and routine health care program, previous or concurrent diseases, as well as the number, age, and proximity of other affected animals. A thorough physical examination is performed to correlate physical findings with clinical signs and history. In adult horses and cattle, rectal palpation is performed to determine the presence of intra-abdominal masses, enlarged lymph nodes, adhesions, abnormal positioning or thickening of bowel segments, or abnormalities in the cranial mesenteric artery. The kidneys, bladder, and related structures should also be evaluated.

A CBC and serum biochemical parameters (eg, total protein, albumin, fibrinogen, glucose, cholesterol, bilirubin, ketones, fatty acids, CK, AST, glutamate lactate dehydrogenase) help determine general health status of the animal; presence of inflammation or an infectious process; involvement of body systems; and metabolic, electrolyte, and serum protein status. Urinalysis, abdominocentesis, and fecal examination for parasite ova, larvae, protozoa, and occult blood should also be performed to exclude more common causes of weight loss. Additionally, urinalysis should be performed to assess whether glucose or protein is being excreted via urine, which could be a further cause for chronic weight loss.

Evaluation of plasma protein electrophoresis, fecal pH, bacteriologic culture, and immunologic studies may be indicated. Intracolonic fermentation of malabsorbed carbohydrates will often reduce the fecal pH in foals and calves. Protein-losing enteropathy can be diagnosed presumptively by excluding other causes of protein

loss, such as renal disease or loss into a third space (peritoneum, pleural space), and by excluding the possibility of decreased albumin production due to another condition such as liver disease. Standard and contrast radiography of the bowel may be feasible in foals and small ponies, calves, and New World camelids. Abdominal ultrasonography is a useful diagnostic tool to determine bowel-wall thickness and intestinal motility, as well as the presence of excess fluid in the abdominal cavity, masses, adhesions, abnormal positioning of bowel in the abdominal cavity, and vascular lesions in the cranial mesenteric artery.

When malassimilation is suspected, a carbohydrate absorption test may be performed to assess small-intestinal function. In horses, a gastroscopy to diagnose lesions in the stomach (eg, granulomas, tumor, ulcers) and duodenum or retention of ingesta should be accomplished before absorption tests are performed. For absorption tests, the intestinal disorder must be diffuse and/or must affect the delivery to and transit through the small intestine to be diagnostic. An abnormal or flattened absorption curve is suggestive of small-intestinal dysfunction. However, a flattened absorption curve can also be caused by other conditions. Although absorption tests may indicate the presence of malassimilation, an etiologic diagnosis requires a biopsy of intestinal mucosa and possibly lymph node. In some cases, rectal biopsy may reveal focal or diffuse inflammatory infiltration. Bacteriologic culture of the feces, biopsy samples, and fecal examination for leukocytes and epithelial cells may confirm the presence of salmonellae or other invasive organisms. In some cases, laparoscopy or exploratory celiotomy is required to obtain the intestinal or lymph node biopsies. Surgery may not be advisable in a debilitated animal, because wound healing is poor and dehiscence is a potential problem. If undertaken, intestinal and lymph node biopsies should be obtained for culture, histopathology, enzymology, and immunology. Because of the risk and cost of obtaining appropriate tissue samples, malassimilation syndrome is often presumptively diagnosed with the aid of absorption tests.

Clinically applicable absorption tests include D-glucose and D-xylose. These tests may help assess small-intestinal function in preruminant calves, foals, crias, and mature horses. Indications for an oral D-xylose absorption test in foals, calves, and possibly

crias include persistent diarrhea not attributable to infectious agents, poor growth despite normal intake, and other signs of maldigestion (repeated episodes of gas colic, bloating, ileus). In monogastric animals, the test solution is administered into the stomach. In ruminants and New World camelids, the forestomachs must be bypassed (esophageal groove, abomasocentesis), because otherwise the sugars are metabolized by the forestomach flora; however, oral carbohydrate tolerance studies are not frequently used in ruminants. The D-glucose absorption test has the advantages of being easy and inexpensive, and methods to determine blood glucose concentrations are available in most clinical laboratories. The main disadvantage is that results are not only a function of intestinal absorption, but also are strongly influenced by the intensive cellular uptake and metabolism of glucose after it has been absorbed. The D-xylose absorption test more directly measures intestinal absorptive capacity and is not influenced by endogenous factors and intestinal enzymatic activity, respectively. Disadvantages are that D-xylose is more expensive, and availability of commercial laboratories that perform plasma xylose determinations is limited. However, D-xylose concentrations can be measured using classic photometric techniques, which do not require special equipment and can be performed in a clinical laboratory.

Glucose or galactose may inhibit the absorption of D-xylose; therefore, fasting is necessary before the test is performed in horses and preruminant calves. The protocols of both tests require prolonged fasting, which may be deleterious to sick young foals and calves. The results of both tests are also affected by gastric emptying rate (D-xylose has also been used to estimate abomasal emptying rate in cattle), small-intestinal transit time, diet, and length of fasting period before testing. The shape of the absorption curve is influenced by renal clearance, hypoxia, anemia, systemic and intestinal bacterial infections, and IgG concentrations in foals. The age of the animals also affects absorption and digestion of glucose, lactose, and D-xylose. Therefore, the control animals must be within a few days of age of the affected animal if reference ranges are not available for its age group.

A delayed peak in the absorption curve of both the D-glucose and D-xylose test may result from delayed gastric emptying resulting from hypertonicity of the glucose or xylose solution, excitement, pain,

retained gastric contents, changes in GI transit time and motility, or partial obstruction. Further sedation of the animal decreases GI motility and secondarily the absorption. A flat absorption curve may be also seen in animals with normal absorptive capacity due to a transient decrease in intestinal blood flow or to bacteria in the lumen of the small intestine metabolizing the test sugar. The test substance rapidly equilibrates with many body fluids (eg, ascites), which lowers the blood concentration of xylose and may result in a flat curve.

D-Xylose Absorption Test: D-xylose is a pentose also known as wood sugar; only trace amounts are found in feedstuffs of plant origin. The D-xylose absorption test measures absorptive capacity of the small-intestinal mucosa because functional enterocytes actively transport D-xylose across the mucosa and into the bloodstream. Subnormal absorption supports a diagnosis of malabsorption. Age and diet also affect D-xylose absorption in healthy horses. Foals <3 mo old have a higher peak concentration of D-xylose after administration than adults. Adult horses maintained on a high-roughage, low-energy diet have a higher peak concentration of D-xylose after administration than those fed a high-energy diet. Food deprivation can alter D-xylose absorption in horses without overt GI tract disease, which must be considered when interpreting results in horses that are anorectic regardless of cause.

D-Xylose (0.5–1 g/kg in a 10% solution) is administered via nasogastric tube to a horse that has been fasted overnight (18–24 hr). Heparinized venous blood samples are collected before D-xylose administration (time 0) and at 30-min intervals afterward for 4 hr (± 6 hr sample). Expected peak values (20–25 mg/dL) should occur between 60 and 120 min after dosing. The normal curve should have a bell shape or inverted V shape with a definable peak plasma xylose concentration 1–2 hr after administration. Peak absolute plasma values should be ≥ 15 mg/dL above baseline values in healthy horses. In adult cattle the D-xylose (0.5 g/kg in a 50% solution) must be administered by abomasocentesis to bypass the rumen. Similar to that in horses, the curve is almost bell shaped in high-yielding dairy cattle; peak values of 1.1–1.3 mmol/L (16–20 mg/dL) occur ~90 min after the solution is administered.

D-Glucose Absorption Test: Glucose absorption curves are steeper in pasture-fed horses than in those fed a higher

energy ration. Lower peak values are seen in horses on a high-concentrate ration. The length of the pretest fast influences the absorption curve. Prolonged fasting may delay or decrease peak glucose concentration, thus giving a false-positive result. In two studies, >90% of adult horses with evidence of "total" glucose malabsorption had severe infiltrative lesions of the small intestine. The majority of horses (18/25) classified with "partial" glucose malabsorption also had obvious pathologic abnormalities of the small intestine.

Performance of the D-glucose absorption test is similar to that of the D-xylose absorption test except samples are collected into sodium fluoride tubes. In healthy horses, blood glucose concentrations should peak 90–120 min after administration. This peak should be >85% above the resting glucose level. Reportedly complete malabsorption is defined as a peak <15% above resting concentrations; partial malabsorption is defined as a peak 15%–85% above resting levels. One of the major disadvantages to the oral glucose absorption test is that when using the conventional protocol sampling is over a 6-hr period. One reported modified protocol requires only two test samples at 0 and 120 min after administration. This modification reportedly did not affect the reliability of the test result.

Oral Lactose Tolerance Test: Diagnosis of acquired lactase deficiency is usually presumptive based on history, clinical signs, and confirmation of presence of associated pathogens. Definitive diagnosis can be achieved with an oral lactose tolerance test. Lactose is hydrolyzed within the brush border of the small-intestinal enterocytes by lactase to constituent D-glucose and galactose before these monosaccharides can be absorbed. Oral lactose tolerance testing is directed specifically at assessing whether lactase activity is present. Adult horses (>3 yr old) are lactose intolerant, and the test is unsuitable for adult ruminants and adult New World camelids. The oral lactose tolerance test is of value in evaluating young foals and preruminant calves with diarrhea or poor growth. Lactose intolerance has been documented in foals, calves, and kids.

An oral lactose tolerance test does not distinguish maldigestion from malabsorption and requires fasting for several hours. Feeding enzymatically treated milk (lactose-free milk) to animals suspected of being lactose intolerant may be tried before subjecting animals to the lengthy

fast (12–18 hr) required before this test is performed. Before performing an oral lactose intolerance test, grain and hay should be withheld for 18 hr. The calf or foal should be prevented from nursing (muzzled) for ≥4 hr before administering D-lactose at 1 g/kg as a 20% solution via nasogastric tube; the muzzle should be kept in place for the duration of the test. Blood samples are collected into tubes containing fluoride oxalate for determination of blood glucose concentrations at 30 min, and immediately before and at 30-min intervals for 3–4 hr after dosing. Blood glucose concentration should be double that of the resting values within 60–90 min of lactose administration. Peak glucose concentrations should be ≥35 mg/dL higher than the baseline in healthy foals. Abnormal results suggestive of lactose intolerance include a delayed, prolonged, or lack of increase in blood glucose concentration from baseline.

Lack of an appropriate increase in blood glucose concentration after lactose administration may be due to maldigestion or malabsorption. Therefore, if the lactose tolerance test is abnormal, a D-glucose or D-xylose absorption test should be performed to determine whether malabsorption or maldigestion alone is the problem. Casein hypersensitivity is distinguished from lactose intolerance by assessing the animal's response to enzymatically treated and untreated milk. Definitive confirmation of lactase deficiency is through direct measurement of mucosal lactase activity in the intestinal tissue. However, this is rarely undertaken in the clinical setting, because a surgical biopsy of the mucosa is required.

A hydrogen breath test has also been described for detection of carbohydrate malabsorption in horses. In a clinical study, diseased horses showed higher fasting breath hydrogen levels than did healthy horses. However, because of the expensive laboratory procedures, the test is not widely used.

Treatment: The etiology of the primary underlying disease process must be determined before specific therapy for malassimilation syndrome can be initiated. Specific therapy for most causes of malassimilation is not available, except for lesions due to parasite damage. Anticoccidial and larvicidal dewormings may improve the condition; however, a complete healing and return to full absorption capacity is not always achievable depending on the damage. Anti-inflammatory agents (eg, NSAIDs, corticosteroids) may also help

decrease the inflammatory response within the affected bowel. Supportive care and facilitation of nutrient absorption from more caudal parts of the intestine must be encouraged until the intestinal epithelium recovers and new villous cells are produced. Maturation and healing of the intestinal absorptive surfaces may take weeks to months in severe cases.

Calves and foals with acquired lactase deficiency after diarrheal disease (viral, bacterial, protozoal) often respond well to supportive care (correction of acid-base, electrolyte, and glucose abnormalities) and feeding of enzymatically treated milk until the small-intestinal mucosa has regenerated. Foals and calves should be fed small amounts of high-quality roughage or grain (if they are able to tolerate it) to help meet their energy needs, although enteral feeding should be continued whenever possible. Young foals and calves that do not tolerate feedings of milk or enzymatically treated milk may benefit from short-term (<24 hr) withdrawal of milk. These animals need alternative sources of energy and nutrients such as short-term feeding (≤ 24 hr) of glucose-containing electrolyte solutions or, in more severe cases, partial or total parenteral nutrition. Dietary change to a soy-based, non-lactose-containing milk replacer and early weaning are advised for animals with nonresponsive lactose intolerance.

Treatment of inflammatory bowel disease in horses has been attempted but is often unsuccessful even with aggressive corticosteroid administration. Sulfasalazine and isoniazid have been recommended, but their usefulness is unproved. Similarly, the usefulness of dimethyl sulfoxide in the treatment of intestinal amyloidosis is unknown. Animals with anaerobic or aerobic bacterial overgrowth may respond to antimicrobial administration. Adequate penetration of antimicrobials into inflammatory bowel lesions (*Rhodococcus equi* in foals) is doubtful. Successful treatment of *Lausonia intracellularis* in foals has been achieved with long-term administration of antimicrobials (erythromycin, azithromycin, clarithromycin, chloramphenicol, oxytetracycline, doxycycline) and aggressive supportive care (fluids, plasma) as dictated by the animal's clinical condition. Any treatment attempt of cattle with clinical signs of Johne's disease have proved to be unsuccessful; slaughter or euthanasia is recommended. *Eimeria macusaniensis*

infections in affected camelids may successfully be treated if diagnosed early. Treatment currently involves administration of amprolium, sulfonamides, ponazuril, or toltrazuril with appropriate supportive care.

Horses with malabsorption due to a disease process or after small-bowel resection must be fed a diet that optimizes digestion of feeds in the large intestine. The diet should provide easily absorbed protein, carbohydrates, fat, and water-soluble vitamins and maintain mineral balance. Increased concentrate-to-forage ratios decrease digestion of feeds in the large intestine and should be avoided. Horses benefit from a fiber-based diet. To enhance digestion in the large intestine, easily fermentable roughages (eg, alfalfa) should be fed. High-quality fiber, metabolized in the cecum and colon to volatile fatty acids, may partially compensate for small-intestinal losses. In young animals, the diet may be supplemented with milk protein if lactase deficiency is not present. Fat may be added to the diet to enhance caloric intake. Calcium, magnesium, phosphate, zinc, copper, and iron may need to be supplemented, because they are absorbed in horses in the small intestine only. Water-soluble (especially vitamin B₁₂) and fat-soluble vitamins should be supplemented parenterally as needed. Excessive supplementation, which could lead to toxicosis, should be avoided.

Horses that will not eat may have to be force-fed via nasogastric tube. The horse should be fed small, frequent meals to take advantage of the limited remaining absorptive ability of the small intestine without overloading it. Preruminant calves that are repeatedly tube-fed may develop ruminal acidosis due to deposition of fermentable feed material into the rumen (rumen drinker) rather than the abomasum. Partial or total parenteral nutrition may be necessary for animals that refuse to eat or that cannot tolerate force-feeding. However, total parenteral nutrition is expensive and difficult to continue on a long-term basis in horses or even impossible in ruminants.

Prognosis: Efforts should be made to determine an etiologic diagnosis once malassimilation has been confirmed so that an accurate prognosis can be given and appropriate therapy prescribed. Most conditions causing malassimilation in adult large animals warrant a poor prognosis, and treatment is commonly unsuccessful.

However, parasitic infection of the bowel or its blood supply can respond to anthelmintic therapy. Occasionally, a non-neoplastic infiltration of the bowel may respond to corticosteroids, but the response may be transient in some cases. Calves, foals, and

kids with lactase deficiency may respond well to supportive care and dietary management. Prognosis for horses with malabsorption due to inflammatory bowel disease is poor; most reported cases have been fatal.

ABDOMINAL FAT NECROSIS

Hard masses of necrotic fat are occasionally identified in the peritoneal cavity of mature cattle, especially the Channel Island breeds, Japanese Black cattle, and beef cattle grazing fescue for long periods. The disease has also been seen in goats and some species of deer maintained on pastures consisting primarily of tall fescue. The masses are commonly mistaken for a developing fetus on palpation per rectum because they feel like "floating corks" similar to cotyledons. The masses of necrotic fat usually do not cause clinical signs but in advanced cases can create an extraluminal obstruction that results in episodes of moderate abdominal pain, distention of intestine proximal to the fat, and the passage of small amounts of feces.

The composition of the deposits in cattle with fat necrosis is identical to that of fat in healthy cows. The abnormal fat deposition is confined to abdominal fat and is consistent with current understanding that abdominal fat is controlled in a different manner than fat deposits elsewhere in the body. Fat necrosis has historically been termed lipomatosis, but this term is now considered inappropriate because the masses are not neoplastic or hyperplastic.

The etiology is unknown, but one proposed cause is consumption of feeds containing high concentrations of long-chain, saturated fatty acids. Fat necrosis is most commonly seen in beef cattle ≥ 2 yr old after prolonged grazing of tall fescue infected with the endophyte *Neotyphodium (Acremonium) coenophialum* (see also FESCUE POISONING, p 3016); fat necrosis is associated with endophyte infection rates of $\geq 65\%$. Fat necrosis is seen throughout the southeastern USA where tall fescue is the primary pasture plant for grazing.

Hard masses of necrotic fat form in the omentum, mesentery, and perirenal fat. The masses may cause clinical disease when

they compress the abomasum, small intestine, and spiral colon; obstruct the birth canal; or more rarely compress the ureters. Palpation per rectum is useful in diagnosis and in determining prevalence in a cattle herd. Advanced cases in aged dairy cows may be detected by abdominal ballottement with the identification of large firm masses in the abdomen. Ultrasonographic examination of the abdomen reveals the presence of hyperechoic masses of variable size in the omentum, with localized masses appearing to float in an excess of peritoneal fluid. Hyperechoic masses adjacent to intestine may be associated with luminal constriction. A presumptive diagnosis of abdominal fat necrosis can be made using ultrasound-guided biopsy of the echogenic masses or by direct biopsy during right flank exploratory laparotomy. Less commonly, isolated fat masses may be found freely floating in the peritoneal fluid at surgery. The size of the masses usually slowly increases, but spontaneous resolution can occur. Removal of cattle from fescue pastures or dilution of fescue intake by supplying legume or other grass pasture can promote the slow reduction in the size of masses. Isoprothiolone (50 mg/kg/day, PO, for 8 wk) effectively decreases the size of fat necrosis lesions in Japanese Black cattle.

In affected deer herds, 90% of the females may be affected with fat necrosis. Clinical signs include slow development of anorexia, depression, and uremia associated with large masses of necrotic abdominal fat constricting the ureters, causing hydrourter and hydronephrosis.

A second form of abdominal fat necrosis in domestic animals, less well defined, appears to be related to pancreatitis. Although not associated with a clinical syndrome, the lesions (discrete or confluent masses of necrotic adipose tissue) are

usually confined to peripancreatic fat. However, fat necrosis lesions may also be found throughout the abdomen.

A third form, a focal necrosis of abdominal and retroperitoneal fat (steatitis or yellow-fat disease) is seen

most often in sheep but also in pigs, horses, cats, and other species. Little information is available about the condition in these species, but abdominal radiography or ultrasonography may help identify focal necrosis in cats.

DISEASES OF THE MOUTH IN SMALL ANIMALS

For a discussion of developmental diseases of the mouth, *see* p 162. For EOSINOPHILIC GRANULOMA COMPLEX, *see* p 971.

The primary function of the mouth is to introduce food into the digestive tract. Additional functions include communication and social interaction, grooming, protection, heat regulation (particularly in dogs), and grasping objects. The latter is very important for performance animals (eg, retrievers, military and police dogs). Similar to other areas of the alimentary tract, the mouth in the normal, healthy state supports a large and diverse population of bacteria that lives primarily in biofilm communities. Unlike other areas of the body, the mouth also contains nonvital surfaces (enamel of teeth) that have neither local immune system defenses nor the ability to regenerate through cellular replacement. The oral mucosal tissues have an excellent vascular supply, and the tightly adherent gingiva protects the underlying alveolar bone from trauma, thermal injury, and bacterial invasion.

Food prehension requires a complex interaction of the muscles of mastication, the teeth, the tongue, and the pharyngeal muscles. When any of these become compromised through disease or trauma, malnutrition and dehydration may result.

A complete oral examination should be included in every physical examination, because oral diseases are most effectively treated when diagnosed early. Unfortunately, many problems remain hidden in the mouth until they have progressed to an advanced stage.

ORAL INFLAMMATORY AND ULCERATIVE DISEASE

Inflammation of the oral tissues can be either primary or secondary. Inflammation

in the oral cavity may affect the gingiva (gingivitis), nongingival tissues of the periodontium (periodontitis), alveolar mucosa (alveolar mucositis), sublingual mucosa (sublingual mucositis), lip and cheek mucosa (labial and buccal mucositis), lip (cheilitis), oral mucosa (stomatitis), mucosa of the dorsal or ventral tongue surface (glossitis), mucosa of the caudal oral cavity (caudal mucositis), mucosa forming the lateral walls of the pharynx (faucitis), mucosa of the palate (palatitis), palatine tonsil (tonsillitis), or mucosa of the pharynx (pharyngitis). The nature and severity of the lesions vary greatly depending on the etiology and duration of the disease. Contact mucositis and contact mucosal ulceration represent lesions in susceptible animals that are secondary to mucosal contact, with a tooth surface bearing the responsible irritant, allergen, or antigen. They have also been called "contact ulcers" and "kissing ulcers." Stomatitis is inflammation of the mucous lining of any of the structures in the mouth; in clinical use, the term should be reserved to describe widespread oral inflammation (beyond gingivitis and periodontitis) that may also extend into submucosal tissues (eg, marked caudal mucositis extending into submucosal tissues may be termed caudal stomatitis).

Periodontal disease, including gingivitis and periodontitis, is the most common oral problem in small animals. Gingivitis is a gingival inflammatory response to the presence of bacterial plaque on an adjacent tooth surface. Periodontitis is inflammation of nongingival tissues of the periodontium (namely periodontal ligament and alveolar bone); it results from the combination of bacterial periodontopathogens and the host's immune response that together destroy the tooth-supporting tissues. (*See also* PERIODONTAL DISEASE, p 178.)

Periapical disease (granuloma, abscess, or cyst) is usually caused by endodontic disease (spread of infection and inflammation from within the tooth through the apical foramina into the periapical tissues). Clinically, a sinus tract may develop that manifests as a circular raised area of inflamed granulation tissue with a central draining fistula that opens near the mucogingival junction. The tract can be followed to the primary periodontal or periapical lesion, and the etiology resolved. (See also ENDODONTIC DISEASE, p 180.) A parulis is a true periodontal abscess (eg, an encapsulated mucopurulent lesion within a periodontal pocket).

Other causes of oral inflammatory conditions include immunopathy (eg, autoimmune disease, immune deficiency), chemical agents, infectious disease, trauma, metabolic disease, developmental anomalies or conformational anatomy that predisposes to irritation or inflammation, burns, radiation therapy, or neoplasia. Infectious agents that have been associated with oral inflammation, glossitis, stomatitis, and oral ulcerations include feline herpesvirus, feline calicivirus, feline leukemia virus, feline immunodeficiency virus, canine distemper virus, *Bartonella henselae*, and certain *Leptospira* serovars. Traumatic stomatitis may be seen after oral exposure to plant material (embedded plant awns) or fiberglass insulation. When chewed, plants of the species *Dieffenbachia* may also cause oral inflammation and ulcers. Contact with processionary caterpillars may also cause severe glossitis. Thallium is the major heavy metal responsible for oral lesions; incidence of this toxicity is low. Uremia can cause stomatitis and oral ulcers. Recurrent oral ulcerations are also seen in gray Collies with cyclic hematopoiesis.

Signs vary widely with the cause and extent of inflammation. Anorexia may be seen, especially in cats. Halitosis and drooling are common with caudal stomatitis or glossitis, and saliva may be blood tinged. The animal may paw at its mouth and resent any attempt to examine the oral cavity because of pain. Regional lymph nodes may be enlarged.

Feline Stomatitis

(Gingivostomatitis, Caudal stomatitis, Lymphocytic-plasmacytic stomatitis)

Feline stomatitis (FS) is a relatively uncommon (3% of feline oral problems) but serious condition. Affected cats present with progressively worsening inflammation

of oral mucosal tissues (particularly the gingiva, alveolar mucosa, labial and buccal mucosa, sublingual mucosa, and mucosa of the caudal oral cavity) and increasing levels of discomfort. More significantly, the mucosa of the caudal oral cavity and the area at and lateral to the palatoglossal folds are often severely ulcerated, friable, inflamed, and proliferative. Severe ulceroproliferative inflammation that involves this area bilaterally in the back of the mouth is pathognomonic for FS. The cause is unproved, but it is suspected to result from an inappropriate inflammatory response in affected cats to one or more antigens. A high percentage of affected cats (100% in some studies) are chronic carriers of feline calicivirus. FS may be caused by the sum of multiple sensitivities in an individual, with antigen on the tooth surfaces, including the root surfaces and periodontal ligament, exceeding a threshold.

The most immediate sign is severe pain when opening the mouth. Cats vocalize and jump when they yawn or open their mouth to eat. Halitosis, pyalism, and dysphagia may be seen. Cats often show an "approach-avoidance" behavior as they approach their food in hunger, then hiss and run off in anticipation of discomfort. If the condition is severe and of long duration, weight loss may be evident. The disease is slowly progressive and may not be recognized until lesions have become severe. Mandibular lymphadenopathy is sometimes present. Pain often prevents adequate examination of the oral cavity without sedation or anesthesia.

Diagnosis: Diagnosis is made by visual identification of bilateral inflammation of the mucosa of the caudal oral cavity and the tissues at or lateral to the palatoglossal folds during oral examination. In advanced cases, the cat will strongly object to opening the mouth. Additional tests include virus isolation (eg, calicivirus and herpesvirus), retroviral tests, and evaluation for systemic disease (eg, renal failure). Although a definitive association with *Bartonella* infection has not been shown, testing has been recommended. In atypical cases (unilateral involvement, usually proliferative focal lesion), biopsy and histopathologic evaluation is required to exclude oral neoplasia or other specific oral disorders. Most biopsy samples collected from chronic inflammatory or ulcerated lesions reveal a predominance of lymphocytes and plasma cells, which indicate the chronic inflammatory nature of the lesion without elucidating the primary etiology.

Treatment: Partial-mouth extraction (removal of all premolars and molars) or full-mouth extraction (removal of all teeth) and debridement of the associated soft and hard tissues is the only treatment to provide lasting improvement and aid in overall longterm control. Partial- or full-mouth extractions provide significant improvement in 60%–80% of affected cats when done early in the disease course and when no root tips or fragments are left behind. Chronically affected cats treated medically for many months have a poorer prognosis after surgery. Dental radiographs of areas with missing teeth are required to check for retained roots. Any retained root fragments must be removed, because they will prevent improvement. Postoperatively, medical therapy focuses on controlling inflammation, infection, and pain. Oral administration of corticosteroids such as prednisolone is less effective than SC or IM injection of methylprednisolone. An alternative is transdermal administration of prednisolone. In refractory cases, use of interferon omega may be considered, injected intralesionally before the start of oral administration. Commonly used antibiotics include amoxicillin-clavulanic acid or clindamycin, but the response to treatment may be lacking or only transient. Culturing the lesions and performing susceptibility tests are rarely indicated, even in chronic or recurrent infections. Nutritional support is required in chronic cases with severe weight loss and dehydration. Pain control with sublingual buprenorphine or a transdermal fentanyl patch should also be considered, along with dietary changes (nonallergenic, soft palatable foods) and administration of topical antiseptics (eg, dilute chlorhexidine or zinc ascorbate). Placement of a feeding tube should be considered in debilitated cats that do not respond to therapy.

Many other treatments for FS have been reported, including good home oral hygiene, periodontal therapy, frequent dental cleanings, cyclosporine therapy, laser therapy, and bovine lactoferrin. Perhaps with the exception of cyclosporine, none of these provide longterm resolution. Corticosteroid administration alone usually results in significant and immediate clinical improvement from modulation of the excessive inflammatory response, but it is not recommended except as a last resort. Without surgery (ie, partial- or full-mouth extractions), repeated use of corticosteroids is frequently required. This treatment becomes progressively less effective and eventually completely ineffective. In

addition, cats that have received repeated corticosteroid treatments have a poorer prognosis once the teeth are extracted. Partial- or full-mouth extractions often result in significant improvement or complete resolution of the inflammation if performed early in the course of the disease and before multiple corticosteroid treatments.

Canine Stomatitis

Characteristics of canine stomatitis that often manifest as contact mucositis and contact mucosal ulceration (also called chronic ulcerative paradental syndrome or CUPS) include severe gingivitis, multiple sites of gingival recession and dehiscence, and large areas of ulcerated labial and buccal mucosa adjacent to the surfaces of large teeth. The problem commonly affects Greyhounds, and it has also been seen in Maltese, Miniature Schnauzers, Labrador Retrievers, and other breeds.

Diagnosis: Diagnosis of canine stomatitis is by clinical observation of the typical oral lesions after excluding other etiologies such as uremic stomatitis, caustic stomatitis, or specific infectious agents. The characteristic lesion is the contact ulcer that develops where the lip or cheek mucosa contacts the tooth surface, most commonly on the inner surface of the upper lip adjacent to the upper canine and carnassial teeth. These lesions have also been termed “kissing ulcers” or “kissing lesions,” because they are found where the lips “kiss” the teeth. An immune profile should be done, and a biopsy considered for histopathology.

Treatment: The underlying pathology of canine stomatitis is an immunopathy that results in an excessive local inflammatory response to the antigens in dental plaque. Eliminating, or at least minimizing, plaque through professional dental cleaning and meticulous home oral hygiene (twice daily tooth brushing) may resolve the problem. However, even slight residual plaque on the tooth surfaces will perpetuate the inflammation and ulcerations. Supplemental antimicrobial measures with topical chlorhexidine gluconate rinses or gels and possibly oral antibiotic treatment with metronidazole should also be used. In severe cases, topical anti-inflammatory preparations to modulate the inflammatory response may provide comfort. Discomfort caused by the ulcers complicates efforts to brush the teeth and administer oral medications. In cases in which discomfort is

severe and the owners are unable or unwilling to brush the teeth, extraction of all teeth associated with ulcers may be necessary to remove the contact surfaces on which plaque accumulates. Although this may help control the lesions, it is not curative, because plaque forms on mucosal surfaces in the mouth, including the tongue. In some cases with complete extractions, dogs continue to develop lesions due to a hyperimmune response to the plaque.

Lip Fold Dermatitis and Cheilitis

Lip fold dermatitis is a chronic, moist dermatitis seen most commonly in breeds that have pendulous lips and lower lateral lip folds (eg, spaniels, English Bulldogs, Saint Bernards) that have prolonged contact with saliva. The lesions may be exacerbated when poor oral hygiene results in increased salivary bacterial levels. The lower lip folds can become very malodorous, inflamed, uncomfortable, and swollen.

Lip wounds, resulting from fights or chewing on sharp objects, are common and vary widely in severity. Thorns, grass awns, plant burrs, and fishhooks may embed in the lips and cause marked irritation or severe wounds. Irritants such as plastic or plant material can produce inflammation of the lips. Lip infections may develop secondary to wounds or foreign bodies or can be associated with inflammation of adjacent areas. Direct extension of severe periodontal disease or stomatitis can produce cheilitis. Licking areas of bacterial dermatitis or infected wounds can spread the infection to the lips and lip folds. Other causes of inflammation of the lips include parasitic infections, autoimmune skin diseases, and neoplasia.

Clinical Findings and Diagnosis: Inflammation of the lips and lip folds can be acute or chronic. Animals with cheilitis may paw, scratch, or rub at their mouth or lip; have a foul odor on the breath; and occasionally salivate excessively or be anorectic. With chronic infection of the lip margins or folds, the hair in these areas is discolored, moist, and matted with a thick, yellowish or brown, malodorous discharge overlying hyperemic and sometimes ulcerated skin.

Cheilitis due to extension of infection from the mouth or another area of the body usually is detected easily because of the primary lesion.

Treatment: Medical management of lip fold dermatitis includes clipping the hair,

cleaning the folds 1–2 times/day with benzoyl peroxide or a mild skin cleanser, and keeping the area dry. Topical diaper rash cream applied daily may be helpful. Surgical correction (cheiloplasty) of deep lip folds is a more longlasting remedy.

Cheilitis that is unrelated to lip folds usually resolves with minimal cleansing, appropriate antibiotics if a bacterial infection is present, and specific treatment of primary etiologies (eg, autoimmune skin disease). Wounds of the lips should be cleaned and sutured if necessary. Treatment of periodontal disease or stomatitis is necessary to prevent recurrence.

Infectious cheilitis that has spread from a lesion elsewhere usually improves with treatment of the primary lesion, but local treatment also is necessary. With severe infection, hair should be clipped from the lesion and the area gently cleaned and dried. Antibiotics are indicated if the infection is severe or systemic.

Mycotic Stomatitis

Mycotic stomatitis caused by overgrowth of the opportunistic yeast *Candida albicans* is an uncommon cause of stomatitis in dogs and cats. It is characterized by stomatitis, halitosis, pytalism, anorexia, oral ulceration, and bleeding from the oral tissues. It is usually thought to be associated with other oral diseases, longterm antibiotic therapy, or immunosuppression. Diagnosis is confirmed by culture of the organism from the lesion or by histologic evidence of tissue invasion.

Any existing underlying local or systemic diseases affecting the oral cavity should be treated. Ketoconazole or a related benzimidazole should be administered until the lesions resolve, after which antibiotic therapy should be discontinued. An adequate level of nutrition should be maintained. The prognosis is guarded if predisposing diseases cannot be adequately treated or controlled.

Acute Necrotizing Ulcerative Gingivitis

(Necrotizing ulcerative gingivostomatitis, Ulceromembranous stomatitis, Necrotizing ulcerative stomatitis, Vincent stomatitis, Trench mouth)

Acute necrotizing ulcerative gingivitis (ANUG) is a relatively uncommon disease of dogs characterized by severe gingivitis, ulceration, and necrosis of the oral mucosa. *Fusobacterium* spp and spirochete organisms (*Borrelia vincenti*), normal

inhabitants of the mouth, have been suggested as a cause of this disease after some predisposing factor increases their numbers or decreases the local resistance of the oral mucosa. The role, if any, of these organisms in causing disease is unknown. In people, *Bacteroides melaninogenicus intermedius* may play a more important role. Other potential factors are stress, excess glucocorticoid administration in susceptible dogs, and poor nutrition.

The disease appears first as reddening and swelling of the gingival margins and interdental papillae, which are painful, bleed easily, and may progress to gingival recession. Extension to other areas of the oral mucosa is common, resulting in ulcerated, necrotic mucous membranes and exposed bone in severe cases, leading to osteomyelitis and osteonecrosis. Halitosis is severe, and the animal may be anorectic because of pain. Pytalism sometimes occurs, and the saliva may be blood tinged. Differential diagnoses include severe periodontal disease, autoimmune skin disease, uremia, neoplasia, and other systemic disease associated with oral lesions.

Diagnosis is made by exclusion of other etiologies.

Treatment of periodontal disease, partial- or full-mouth extractions, debridement of lesions, oral hygiene, antibiotics (amoxicillin-clavulanate, ampicillin, clindamycin, metronidazole, tetracyclines), and oral antiseptics (dilute chlorhexidine solution or gel) are indicated.

Glossitis

Glossitis, an acute or chronic inflammation of the tongue, may be due to infectious (calicivirus, herpesvirus, rhinotracheitis virus, leptospirosis), physical (irritation from excess calculus and periodontal disease, foreign bodies that penetrate or become lodged under the tongue, traumatic wounds), or chemical agents; metabolic disease (uremia, hypoparathyroidism, diabetes); or other causes such as electric or thermal burns and insect stings. Foreign body glossitis is especially a problem in longhaired dogs that attempt to remove plant burrs from their coats.

Drooling and a reluctance to eat are common signs, but the cause may go undiscovered unless the mouth is carefully examined. Periodontitis may result in reddening, swelling, and occasionally ulceration of the lateral edges and the tip of the tongue. A thread, string, or other linear foreign body may get caught under the

tongue. There may be no inflammation of the dorsal surface of the tongue, but the ventral surface is painful, shows acute or chronic irritation, and frequently is lacerated by the foreign body. Porcupine quills, plant material, and other foreign materials may become embedded so deeply they are not palpable. Insect stings cause acute swelling of the tongue.

In chronic cases of ulcerative glossitis, a thick, brown, foul-smelling discharge (occasionally with bleeding) may be present. Frequently, the animal is reluctant to allow oral examination.

Fissured, or plicated, tongue (lingua dissecta) describes a textural variation of the dorsum of the tongue with deep central or lateral longitudinal grooves. The fissure deepens with age and is therefore thought to be acquired from some extrinsic factor. However, it may also represent a developmental anomaly. The groove often becomes deeply filled with hairs that act as a local irritant, causing inflammation and discomfort.

Any foreign bodies or hairs should be removed, and broken or diseased teeth removed or treated. Bacterial infectious glossitis should be treated with an appropriate systemic antibiotic. Debridement and dilute chlorhexidine mouthwashes are beneficial in some cases. Lingual curettage is sometimes required if foreign material is embedded in the tongue. A soft diet and parenteral fluids are administered as needed. If the animal is debilitated and unable to eat well for a prolonged period, a feeding tube to allow for nutritional support should be considered. Acute glossitis due to insect stings may require emergency treatment.

If the glossitis is secondary to another condition, the primary disease should be treated. Tongue tissues heal rapidly after irritation and infection have been eliminated.

SOFT-TISSUE TRAUMA

Chewing Lesions

A proliferative, verrucous lesion along the bite-plane of the cheek or sublingual region may result from self-trauma when the tissue becomes entrapped between the teeth during chewing. Surgical removal of the excess tissue prevents further trauma.

Mouth Burns

Thermal, chemical, or electric burns involving the mouth are not uncommon.

The animal should be evaluated and treated for systemic involvement, which may be life-threatening (neurogenic pulmonary edema). The tongue, lips, cheeks, labial and buccal mucosa, and palate are frequently involved with electric burns. The injuries may be mild with only temporary discomfort, or they may be destructive with loss of tissue, scar formation, and subsequent deformity or tissue deficits. Chewing on an electric cord is most frequently a problem in kittens, puppies, and pet rabbits. These animals often have a linear scar across the dorsum of the tongue, outlining the path of the electric cord. One or both lip commissures may have a scar or wound, and the adjacent carnassial teeth may be discolored and eventually require endodontic treatment.

The owner may have observed the incident, but more commonly it occurs in the owner's absence. The animal hesitates to eat or drink, drools, and resents handling of its mouth or face. If tissue destruction is marked, ulcerative or gangrenous stomatitis can develop, with secondary bacterial infections. If recent contact with a corrosive alkaline chemical has occurred, the mouth should be flushed with mild solutions of vinegar or citrus juice; if the chemical was acidic, a solution of sodium bicarbonate should be used. Copious flushing of the mouth with water helps remove some of the chemical substances. More commonly, the animal is seen too long after the exposure for neutralization to be effective. The hair should be clipped and/or washed if it is suspected to be a continued source of a chemical that caused the caustic mucosal lesions.

Animals that have inflamed oral mucosa without tissue defects require no specific supportive treatment other than a soft or liquid diet until the lesion has healed. If tissue damage is extensive, treatment includes lavage with dilute chlorhexidine solution and conservative tissue debridement. The risk of secondary infection should be minimized with systemic antibiotic therapy for several days.

PAPILLOMAS

Papillomas are benign growths caused by the canine papillomavirus (see p 952). The oral mucosa and commissures of the lip are most frequently involved, but the growths (usually multiple but sometimes single) can involve the palate and oropharynx. Papillomas are most common in young dogs and appear suddenly, with rapid growth and spread. Signs are seen when the growths

interfere with prehension, mastication, or swallowing. Occasionally, if the growths are numerous, the dog may bite them when chewing, causing them to bleed and become infected. They may regress spontaneously within a few weeks to months, and removal is generally not necessary. If necessary, the exophytic lesion can be debulked with electro- or radiosurgery or by sharp resection. Surgical removal of one or more of the papillomas may initiate regression. The use of commercial or autogenous vaccines should be considered in very severe cases in which the dog cannot swallow or breathe normally. The self-limiting character of the disease makes evaluation of any treatment difficult. Severe oral papillomatosis may be seen in immunocompromised dogs with lymphoma.

Other wart-like lesions are benign exophytic proliferations of squamous epithelium. They are clinically indistinguishable from virus-induced papillomas but are generally slow growing and solitary. They most commonly remain benign, and surgical removal is curative.

ORAL TUMORS

Benign Oral Tumors

Peripheral odontogenic fibromas (previously called fibromatous epulis or ossifying epulis) are the most common benign oral tumors. These firm masses involve the gingival tissue adjacent to a tooth. They affect dogs of any age but are most common in dogs >6 yr old. Some develop centers of ossification, visible as distinct alveolar bone proliferation extending into the soft-tissue mass. They are generally solitary, although multiple lesions may be present. The tumors do not metastasize but may become quite extensive. They arise from the periodontal ligament of the affected tooth, and complete surgical removal must include tissues up to and including the periodontal ligament. This usually necessitates conservative resection of the neoplastic lesion, extraction of the affected tooth or teeth, and curettage of the extraction sites (ie, removal of remaining periodontal ligament). Complete excision is curative.

The canine acanthomatous ameloblastoma (previously called acanthomatous epulis) is much more locally aggressive, quickly invading the local tissues including bone. This tumor does not metastasize, but because of its locally aggressive nature, surgical excision should include a 1-cm margin of clinically normal tissue (including

bony margins) to prevent recurrence. Radiation therapy may minimize disfigurement when treating large tumors. Adequate surgical removal is curative.

Malignant Oral Tumors

In dogs, the three most common malignant oral tumors are malignant melanoma, squamous cell carcinoma, and fibrosarcoma. The incidence of malignant oral tumors is higher in dogs >8 yr old.

Squamous cell carcinomas are by far the most common malignant oral neoplasms in cats; they commonly involve the gingiva and tongue and are locally highly invasive. Fibrosarcomas are the next most common. In cats, these tumors are locally invasive and, if extensive, carry a poor prognosis.

Clinical Findings: Signs of malignant oral tumors vary depending on the location and extent of the neoplasm. Halitosis, reluctance to eat, and hypersalivation are common. If the oropharynx is involved, dysphagia may be present. The tumors frequently ulcerate and bleed. The face may become swollen as the tumor enlarges and invades surrounding tissue. Regional lymph nodes often become swollen before oral and pharyngeal tumors are seen.

Oral mast cell tumor in a dog. Courtesy of Dr. Ben Colmery III.

Diagnosis: Because of the varied behavior of oral and maxillofacial tumors, presurgical characterization is valuable to plan the extent of the required surgery. Biopsy is the most reliable method to obtain a definitive diagnosis; however, a cytologic diagnosis from impression smears of a fine-needle aspirate is possible in many cases.

Therefore, a histologic diagnosis is typically necessary to plan for accurate treatment. Malignant melanomas are variable in appearance, pigmented or nonpigmented, and should be considered in the diagnosis of any oral tumor. Squamous cell carcinomas commonly involve the gingiva or palatine tonsils (unilateral), and lymphosarcoma should be a differential diagnosis for bilaterally enlarged tonsils. Lymph nodes and the lungs should be evaluated for regional and distant metastasis.

Treatment: Malignant melanomas are highly invasive and metastasize readily; consequently, the prognosis is guarded to poor. Surgical resection can extend survival and may be curative, particularly with masses in the rostral areas of the mouth. However, local recurrence is common. Immunotherapy is available as an adjunct treatment to radical surgery and chemotherapy. Nontonsillar squamous cell carcinomas are locally invasive with a low rate of metastasis, and the prognosis in dogs is good with aggressive and complete surgical resection, radiation therapy, or both. Tonsillar squamous cell carcinomas are aggressive and have a poor prognosis. Fibrosarcomas have a guarded prognosis because of their locally aggressive nature. Recurrence of tumor growth after resection is common.

In cats, squamous cell carcinoma has a poor prognosis unless the entire tumor can be removed, and longterm survival is usually seen only if diagnosed and treated early.

SALIVARY DISORDERS

Ptyalism

Ptyalism is drooling of saliva. This may be caused by hypersialosis (hypersecretion of saliva) or pseudoptyalism (secondary to conformational abnormalities or swallowing disorders in animals producing a normal quantity of saliva). Both are discussed together as ptyalism.

Ptyalism may result from the following: 1) drugs, toxins, or poisons, eg, organophosphates; 2) local irritation or inflammation associated with stomatitis, glossitis

(especially in cats), oral foreign bodies, neoplasms, injuries, or other mucosal defects; 3) infectious diseases (eg, rabies), the nervous form of distemper, or other convulsive disorders; 4) motion sickness, fear, nervousness, or excitement; 5) reluctance to swallow or interference with swallowing (from irritation of the esophagus, esophageal obstruction by regional pathology, or from stimulation of GI receptors caused by gastritis or enteritis); 6) sublingual lesions (eg, linear foreign body, tumor); 7) tonsillitis; 8) administration of medicine (particularly in cats); 9) conformational defects (eg, heavy, pendulous lower lips); 10) metabolic disorders (eg, hepatic encephalopathy [especially in cats]) or uremia; 11) abscess or other inflammatory blockage or condition of the salivary gland.

The possibility of rabies should be eliminated before oral examination. The underlying cause, local or systemic, should be determined and treated. Acute moist dermatitis of the lips and face may develop if the skin is not kept as dry as possible. Cleansing with a dilute chlorhexidine solution or benzoyl peroxide may be helpful.

Salivary Mucocele

A salivary mucocele (or sialocele) is an accumulation of saliva in the submucosal or subcutaneous tissues after damage to the salivary duct or gland capsule. This is the most common salivary gland disorder of dogs. Although any of the salivary glands may be affected, the ducts of the sublingual and mandibular glands are involved most commonly. Saliva often collects in the intermandibular or cranial cervical area (cervical mucocele). It can also collect in the sublingual tissues on the floor of the mouth (sublingual mucocele or ranula). A less common site is in the pharyngeal wall (pharyngeal mucocele) or lower eyelid (zygomatic mucocele).

The cause may be traumatic or inflammatory blockage or rupture of the duct or capsule (with damage of parenchyma) of the sublingual, mandibular, parotid, or zygomatic salivary gland. Usually, the exact cause is not determined, but a developmental predisposition in dogs has been suggested.

Signs depend on the site of saliva accumulation. In the acute phase of saliva accumulation, the inflammatory response results in the area being swollen and painful. Frequently, this stage is not seen by the owner, and the first noticed sign may be a nonpainful, slowly enlarging, fluctuant

mass, frequently in the cervical region. A ranula may not be seen until it is traumatized and bleeds. A pharyngeal mucocele can obstruct the airways and result in moderate to severe respiratory distress. A zygomatic mucocele may result in exophthalmos or enophthalmos, depending on its size and location.

A mucocele is detectable as a soft, fluctuant, painless mass that must be differentiated from abscesses, tumors, and other retention cysts of the neck. Pain or fever may be present if the mucocele becomes infected. A salivary mucocele usually can be diagnosed by palpation and aspiration of light brown or blood-tinged, viscous saliva. Usually, careful palpation with the animal in dorsal recumbency can determine the affected side; if not, sialography may be helpful.

Surgery is recommended to remove the damaged salivary gland and duct. Periodic drainage if surgery is not an option is usually only a temporary measure and has the potential for iatrogenic infection. Marsupialization is often ineffective. Gland-duct removal has been recommended for curative treatment of salivary mucoceles.

Salivary Fistula

Salivary fistula is an uncommon problem that can result from trauma to the mandibular, zygomatic, or sublingual salivary glands. Wounds of the parotid gland are most likely to develop a fistula. Parotid duct injury may be the result of a traumatic wound (eg, bite wound), abscess drainage, or prior surgery in the area with iatrogenic rupture. The constant flow of saliva prevents healing, and a fistula develops.

History of injury in the gland area, location of the fistula, and nature of the discharge are characteristic. A salivary fistula must be differentiated from a draining sinus (due to a penetrating foreign body or endodontic disease of a mandibular tooth) in the neck or from sinuses arising from congenital defects. Surgical ligation of the duct usually results in resolution, but excision of the associated gland may also be necessary.

Salivary Gland Tumors

Salivary gland tumors are rare in dogs and cats, although cats are affected twice as frequently as dogs. Most are seen in dogs and cats >10 yr old. There is no clear breed or sex predilection, although Poodles and Spaniel breeds may be predisposed. Most salivary gland tumors are malignant, with carcinomas and adenocarcinomas the most

common. Local infiltration and metastasis to regional lymph nodes and lungs are common, as is local recurrence after surgical excision. Radiotherapy, with or without surgery, offers the best prognosis.

Sialadenitis

Sialadenitis, or inflammation of the salivary gland, is rarely a clinical problem in dogs and cats. However, it is frequently an incidental finding on histopathology at necropsy.

The cause may be trauma from penetrating wounds or systemic infection affecting the salivary gland or surrounding tissue. Sialadenitis as a component of systemic disease has been reported with rabies, distemper, and the parainfluenza virus that causes mumps in people.

Signs include fever, depression, and painful, swollen salivary glands. Rupture of an abscessed gland discharges pus into the surrounding tissue or the mouth. Rupture through the skin may cause a salivary fistula to form. Swelling of the parotid gland is most prominent below the ear, swelling of the mandibular gland at the angle of the jaw, and swelling of the zygomatic gland just caudal to the eye. Zygomatic gland involvement may result in retrobulbar swelling, divergent strabismus of the affected eye, exophthalmos, excess tearing, and reluctance to open the mouth or eat. Abscesses of the zygomatic and parotid glands are acutely painful; the animal may hold its head rigidly and resent any manipulation involving the head or neck.

Radiographs and laboratory tests are usually not helpful, although evaluation of fluid in an abscess can lead to a diagnosis. Histopathology of salivary gland tissue can reveal acute or chronic inflammatory changes or necrosis.

Mild sialadenitis requires no treatment, and recovery is usually rapid and complete. A developed abscess should be drained through the overlying skin or, if involving the zygomatic gland, behind the last upper molar on the affected side. Systemic antibiotics should be administered.

Lack of resolution or recurrence necessitates cytology of aspirated material, biopsy, or surgical removal of the affected gland.

Sialadenosis in Dogs

Sialadenosis is a non-inflammatory, non-neoplastic, usually bilateral enlargement of the mandibular salivary glands, associated with regional swelling (dependent on location) and exophthalmos but no

apparent pain. The dog may retch and gulp, which is elicited by mild excitement and occurs several times a day. There may be weight loss, reluctance to exercise, snorting, lip smacking, nasal discharge, hypersalivation, inappetence, and depression. Histologically, there are no obvious abnormalities. Excessive saliva production may be associated with increased parasympathetic activity or changes in sympathetic innervation. Phenobarbital administration usually results in lasting improvement, providing support for a neurogenic pathogenesis.

Necrotizing Sialometaplasia in Dogs

Necrotizing sialometaplasia has also been termed salivary gland necrosis or infarction. There is squamous metaplasia of the salivary gland ducts and lobules, with ischemic necrosis of the salivary gland lobules. It can be seen in dogs (mostly small breeds such as terriers) of all ages, most often 3–8 yr old. Affected dogs usually are depressed, nauseous, and anorectic. Clinical signs include salivary gland enlargement that may be painful on palpation, weight loss, ptialism, retching, gagging, regurgitation, and vomiting. Other signs include persistent swallowing, lip smacking, coughing, tachypnea, dyspnea, and abdominal respiration. Examination of samples from fine-needle aspirates or biopsies often reveal no abnormalities. Diagnosis requires excluding other causes of enlargement. Surgical removal of the affected salivary gland produces minimal if any improvement. Pain management, antibiotics (based on culture and sensitivity of the fluid/tissue aspirate), NSAIDs, antiinflammatory doses of glucocorticoids, and control of internal parasites have resulted in favorable responses in some cases. Phenobarbital administration (1–2 mg/kg, PO, bid, or higher initial doses) has resulted in dramatic improvement in several cases, providing more support for a neurogenic pathogenesis.

Xerostomia

Hypoptialism is a decreased secretion of saliva that can result in a dry mouth (xerostomia). It can cause significant discomfort and difficulty during eating. It is uncommon in dogs and cats but is very common in people who have undergone radiation therapy for tumors of the head and neck that resulted in collateral radiation injury to the salivary glands. As radiation treatment is used more commonly in

veterinary medicine, xerostomia may become more frequent in animals. Decreased salivary secretion may also result from use of certain drugs (eg, atropine), extreme dehydration, pyrexia, or anesthesia. It is seen in some dogs with keratoconjunctivitis sicca and can be immune-mediated. Occasionally, it is due to disease of the

salivary gland. Determination and treatment of the underlying cause is of primary importance. Physiologically balanced mouthwashes relieve the discomfort that results from xerostomia. Fluids should be administered if the animal is dehydrated. Immunosuppressive therapy is indicated if immune-mediated disease is suspected.

DISEASES OF THE ESOPHAGUS IN SMALL ANIMALS

CRICOPHARYNGEAL ACHALASIA

Cricopharyngeal achalasia is characterized by inadequate relaxation of the cricopharyngeal muscle, which leads to a relative inability to swallow food or liquids. It is seen primarily as a congenital defect but is occasionally seen in adult dogs. The cause is generally unknown, but in adult animals it may be associated with acquired neuromuscular disorders. Repeated attempts to swallow are followed by gagging and regurgitation. Aspiration pneumonia is a common complication. An accurate diagnosis requires fluoroscopic evaluation of swallowing after oral administration of contrast material alone and mixed with food. Abnormal function (lack of relaxation) of the cricopharyngeal muscle results in retention of barium in the posterior pharynx.

Treatment consists of cricopharyngeal myotomy or cricopharyngeal and thyropharyngeal myectomy, which usually results in normal swallowing immediately after surgery. The success rate of surgery approaches 65%. Dogs with acquired

neuromuscular disorders are less likely to respond to surgery but may respond to treatment of the underlying disease. Aspiration pneumonia should be treated aggressively if present.

DILATATION OF THE ESOPHAGUS

(Megaeosophagus)

Megaeosophagus may be due to a congenital defect or may be an adult-onset, acquired disorder. Congenital defects that may result in megaeosophagus include vascular ring anomalies, esophageal diverticula, congenital myasthenia gravis, and an idiopathic form. (See also CONGENITAL AND INHERITED ANOMALIES OF THE ESOPHAGUS, p 166.) Adult-onset megaeosophagus may be primary (idiopathic) or secondary to systemic disease. Secondary megaeosophagus may be due to myasthenia gravis, systemic lupus erythematosus, polymyositis, hypoadrenocorticism, heavy metal (lead) toxicity, thallium toxicity, glycogen storage disease, neurotoxin-induced cholinesterase inhibition, dysautonomia, CNS disorders including neoplasia, and possibly hypothyroidism. Esophageal dilatation may also develop cranial to an esophageal lesion such as an esophageal stricture, foreign body, neoplasia, or extraesophageal compression.

The cardinal sign is regurgitation. A puppy with congenital megaeosophagus characteristically begins to regurgitate at weaning when it starts to eat solid food. Affected pups are generally unthrifty and smaller than their littermates. Pressure applied to the abdomen may cause ballooning of the esophagus at the thoracic inlet. Aspiration pneumonia is a complication with associated signs of cough, fever, and sometimes nasal discharge. Adult

Esophagram demonstrating dilatation of the esophagus (megaeosophagus), lateral projection. Courtesy of Dr. Ronald Green.

animals that develop megaesophagus also start to regurgitate and ultimately lose weight. Respiratory signs may predominate, with little or no apparent regurgitation. Thoracic radiographs reveal air, fluid, or food in a dilated esophagus. The esophagus is usually uniformly dilated. A large ventral deviation may be present cranial to the heart. Megaesophagus secondary to a stricture, foreign body, neoplasia, or vascular ring anomaly is visualized as a dilatation of the esophagus cranial to the defect only. Strictures, foreign bodies, or vascular ring anomalies can be excluded with an esophagram and/or esophagoscopy.

In adult dogs, associated diseases (eg, myasthenia gravis) should be excluded or, if found, treated. Surgery is indicated for a vascular ring anomaly. Surgery may not successfully resolve the clinical signs in longstanding cases with severe esophageal dilatation cranial to the anomaly. Medical management is indicated for congenital or acquired idiopathic megaesophagus. Congenital megaesophagus may resolve as the animal ages, usually by 6 mo of age. The consistency of the diet that best prevents regurgitation varies from dog to dog; a soft gruel works for some, while dry food works for others. Another possibility is canned food formed into a meatball shape. Frequent, small meals work best for most dogs. Feeding from an elevated position with the forelimbs higher than the hindlimbs and holding that position for at least 10–15 min after eating allows gravity to assist food passage into the stomach. Neither surgery nor medications improve esophageal function. Ultimately, most animals succumb to aspiration pneumonia.

ESOPHAGEAL DYSMOTILITY

Young dogs may have a disorder of esophageal dysmotility without overt megaesophagus. Clinical signs can be similar to those of megaesophagus, although some dogs without clinical signs have abnormal motility during an esophagram. In one study in more than half the cases, the condition improved or resolved with age. Terrier breeds were overrepresented. Cats can also have esophageal dysfunction, which can be idiopathic; congenital; or secondary to myasthenia gravis, mediastinal masses, vascular ring anomalies, dysautonomia, and strictures. Many cats improve with medical management such as the use of sucralfate, H₂-blockers, and metoclopramide.

ESOPHAGEAL STRICTURES

(Esophageal stenosis)

Esophageal stricture is a pathologic narrowing of the lumen that may develop after anesthesia, trauma (eg, foreign body), ingestion of caustic substances, exposure to certain drugs (such as doxycycline or clindamycin), esophagitis, gastroesophageal reflux, or tumor invasion. Most strictures develop in the thoracic portion of the esophagus. Esophageal tumors are rare, but esophageal sarcomas may be associated with *Spirocerca lupi* infection (see p 412), requiring consideration in areas where this parasite is prevalent. Esophageal compression by vascular ring anomalies or extramural tumors may mimic the signs of strictures.

Clinical signs are similar to those associated with foreign bodies and include regurgitation, ptyalism, dysphagia, and pain. An esophagram under fluoroscopy is the preferred tool for diagnosis, because it allows visualization of the number, length, location, and severity of strictures. Esophagoscopy can also be diagnostic but does not allow visualization beyond the stricture unless esophageal balloon dilation is also performed.

Treatment with balloon catheter dilation has been the most successful. Bougienage is another, less available, technique. It theoretically causes more shear stress on the esophagus but has not been shown to have a significantly different complication rate than balloon dilation. Some cases can require multiple dilation procedures. Esophageal stents have been used in strictures that have been refractory to dilation procedures. However, this method has been limited by a high rate of complications, including stent migration, stent shortening, stent breakage, recurrence of stricture, infection, megaesophagus, overgrowth of tissue into the stent, ptyalism, apparent nausea, gagging, vomiting, regurgitation, and tracheal-esophageal fistula. Surgical resection of a single stricture is another option; however, it is less successful. These treatments are likely to induce some degree of esophagitis, which must be treated to decrease the chance of stricture reformation. The use of corticosteroids, either systemically or intralesionally, to help prevent stricture reformation is controversial. No data exist regarding the success of this adjunct therapy for esophageal strictures in dogs and cats,

but intralesional use has been helpful in reducing recurrence in people.

ESOPHAGITIS

Inflammation of the esophagus is usually caused by foreign bodies, gastroesophageal reflux, and occasionally certain drugs (eg, doxycycline). Gastroesophageal reflux is usually associated with anesthesia, drugs that decrease lower esophageal sphincter tone (eg, atropine, acepromazine), and acute or chronic vomiting. Other causes of esophagitis include ingestion of an irritating or caustic substance, neoplasia, and *Spirocerca lupi* infection (see p 412). Feeding tubes that traverse the gastroesophageal junction may result in gastroesophageal reflux. Calicivirus in cats may also cause esophagitis.

Regurgitation is the classic sign of esophagitis; others include ptyalism, repeated swallowing attempts, pain, depression, anorexia, dysphagia, and extension of the head and neck. Mild esophagitis may have no associated clinical signs.

Endoscopy is the diagnostic tool of choice. It allows visualization of any associated problems (eg, foreign body) and direct assessment of esophageal damage. Plain radiographs are of little or no benefit in the diagnosis of esophagitis. An esophagram under fluoroscopy demonstrates any associated esophageal motility defects secondary to the esophagitis and may demonstrate esophageal wall defects if severe.

Mild esophagitis may require no treatment. If clinical signs are present, medical therapy should be instituted. Esophagitis secondary to gastroesophageal reflux is treated by decreasing gastric acidity, increasing lower esophageal sphincter tone, increasing the rate of gastric emptying, and providing pain control. In most cases, H_2 -receptor antagonists (eg, ranitidine, famotidine) are sufficient to decrease gastric acid production; however, in severe cases of esophagitis, a proton pump inhibitor (eg, omeprazole) is preferred. Cisapride and metoclopramide increase lower esophageal tone and the rate of gastric emptying. Cisapride is more potent than metoclopramide. A sucralfate slurry may also be administered orally for esophageal cytoprotection. Soft food, low in fat and fiber, should be fed in small, frequent meals. Systemic analgesics may be used for pain relief.

If esophagitis is severe, a gastrostomy tube may be used to completely rest the

esophagus. The administration of corticosteroids to prevent esophageal stricture formation is controversial. Broad-spectrum antibiotics should be used for concurrent aspiration pneumonia and may be useful in severe esophagitis as an attempt to prevent bacterial invasion and infection.

ESOPHAGEAL FOREIGN BODIES

Esophageal foreign bodies are more common in dogs than cats. Bones are the most common foreign body, but needles, fishhooks, wood, rawhide, and dental chew treats may also become lodged in the esophagus. Objects usually lodge in the areas of the esophagus with the least distensibility: the thoracic inlet, over the heart base, or the caudal esophagus just cranial to the diaphragm. Occasionally, an object may lodge in other locations such as the upper esophageal sphincter.

Ptyalism, gagging, dysphagia, regurgitation, and repeated attempts to swallow are signs of an esophageal foreign body. Often, the owner may see the animal eat the foreign body. The signs depend on the location of the foreign body and on the degree and duration of obstruction. A partial obstruction may allow fluids but not food to pass. With a chronic obstruction, anorexia, weight loss, and lethargy are common.

Perforation of the cervical esophagus may result in local abscessation or subcutaneous emphysema; perforation of the thoracic esophagus may result in pleuritis, mediastinitis, pyothorax, pneumothorax, bronchoesophageal fistula formation, or fatal aortic esophageal fistula formation. Esophagitis, mucosal laceration, esophageal stricture, and esophageal diverticulum formation are also potential complications. Esophageal stricture formation is the most common complication associated with an esophageal foreign body. Aspiration pneumonia may also be seen secondary to the regurgitation.

Many esophageal foreign bodies are radiopaque and can be seen on plain radiographs. A contrast esophagram or esophagoscopy is often required to identify radiolucent foreign bodies. If a perforation is suspected, an iodinated contrast medium should be used instead of barium suspensions. Esophagoscopy permits evaluation of both the foreign body and the esophageal wall and often allows therapeutic intervention.

Esophageal foreign bodies, once diagnosed, should be removed immediately. Most often, a foreign body can be removed

per os with a flexible endoscope and forceps. A rigid endoscope can also be used if a flexible scope is not available, but care must be taken when manipulating the scope in the esophagus to prevent lacerations or perforations. If the foreign body is smooth, a Foley catheter can be inserted distal to the foreign body, inflated, then removed orally, bringing the foreign body with it. A large endotracheal tube can be placed over the endoscope to remove sharp foreign bodies such as fish hooks, which can be drawn up into the endotracheal tube and removed without damaging the esophagus on the way out. If a foreign body cannot be removed per os, it may be pushed into the stomach where it can either be digested (eg, bones), passed, or removed via a gastrotomy. Surgery is indicated if a perforation has occurred or the foreign body cannot be removed via endoscopy; in one study, the recovery rate was 93% after surgery. However, there is potential for stricture formation and complications secondary to the poor wound-healing ability of the esophagus. Esophagitis, if present, should be treated appropriately (*see above*).

ESOPHAGEAL DIVERTICULA

Diverticula are pouch-like dilatations of the esophageal wall and may be congenital or acquired. They are rare in dogs and cats. Acquired diverticula are of two types: pulsion or traction. **Pulsion diverticula** are caused by increased intraluminal pressure or deep esophageal inflammation, which can lead to mucosal herniation. Predisposing conditions include esophagitis, esophageal stricture, foreign bodies, vascular ring anomalies, megaesophagus, and hiatal hernia. This type of diverticulum involves the esophageal epithelium and connective tissue. **Traction diverticula** result from inflammation in the chest cavity in close proximity to the esophagus. Fibrous tissue is

produced, which then contracts, pulling the esophageal wall outward. This diverticulum involves all layers of the esophagus.

Small diverticula may be subclinical. Large diverticula allow food to become trapped in the pouch, leading to postprandial dyspnea, regurgitation, and anorexia. Survey radiographs may show the diverticulum if it is full of ingesta or air, but contrast radiographs are best to demonstrate the pouch. Endoscopy will also allow visualization and can identify ulceration and scarring.

Small diverticula may be treated with a bland, soft diet fed with the animal in an upright position. Large diverticula require surgical excision and reconstruction of the esophageal wall. The prognosis after surgery is fair to good.

BRONCHOESOPHAGEAL FISTULA

Bronchoesophageal fistulas are rarely seen in dogs and cats. They most commonly develop secondary to foreign body penetration of the esophagus. Fistulas may develop between the esophagus and any part of the respiratory tree. A congenital form has been described, and Cairn Terriers may be predisposed. The most common clinical sign is coughing after eating or drinking. Regurgitation may also be seen, and anorexia, fever, and lethargy may be related to pneumonia.

Survey radiographs may reveal a radiopaque foreign body and pneumonia. Contrast esophagograms will show the communication between the esophagus and airways. Use of a small amount of barium is recommended—iodinated contrast agents are hyperosmolar and can cause pulmonary edema.

Surgical correction consisting of a lung lobectomy and repair of the defect in the esophagus is required. The prognosis after surgery is good.

DISEASES OF THE STOMACH AND INTESTINES IN SMALL ANIMALS

CANINE PARVOVIRUS

Etiology and Pathophysiology:

Canine parvovirus (CPV) is a highly contagious and relatively common cause of

acute, infectious GI illness in young dogs. Although its exact origin is unknown, it is believed to have arisen from feline panleukopenia virus or a related parvovirus of nondomestic animals. It is a nonenveloped, single-stranded DNA virus, resistant

to many common detergents and disinfectants, as well as to changes in temperature and pH. Infectious CPV can persist indoors at room temperature for at least 2 mo; outdoors, if protected from sunlight and desiccation, it can persist for many months and possibly years. In North America, clinical disease is largely attributed to CPV-2b; however, infection with a newer and equally virulent strain, CPV-2c, is increasingly common, having been identified in at least 15 states. To date, no association has been identified between CPV strain and severity of clinical disease.

Young (6 wk to 6 mo), unvaccinated or incompletely vaccinated dogs are most susceptible. Rottweilers, Doberman Pinschers, American Pit Bull Terriers, English Springer Spaniels, and German Shepherds have been described to be at increased risk of disease. Assuming sufficient colostrum ingestion, puppies born to a dam with CPV antibodies are protected from infection for the first few weeks of life; however, susceptibility to infection increases as maternally acquired antibody wanes. Stress (eg, from weaning, overcrowding, malnutrition, etc), concurrent intestinal parasitism, or enteric pathogen infection (eg, *Clostridium* spp, *Campylobacter* spp, *Salmonella* spp, *Giardia* spp, coronavirus) have been associated with more severe clinical illness. Among dogs >6 mo old, intact male dogs are more likely than intact female dogs to develop CPV enteritis.

Virus is shed in the feces of infected dogs within 4–5 days of exposure (often before clinical signs develop), throughout the period of illness, and for ~10 days after clinical recovery. Infection is acquired through direct oral or nasal contact with virus-containing feces or indirectly through contact with virus-contaminated fomites (eg, environment, personnel, equipment). Viral replication occurs initially in the lymphoid tissue of the oropharynx, with systemic illness resulting for subsequent hematogenous dissemination. CPV preferentially infects and destroys rapidly dividing cells of the small-intestinal crypt epithelium, lymphopoietic tissue, and bone marrow. Destruction of the intestinal crypt epithelium results in epithelial necrosis, villous atrophy, impaired absorptive capacity, and disrupted gut barrier function, with the potential for bacterial translocation and bacteremia.

Lymphopenia and neutropenia develop secondary to destruction of hematopoietic progenitor cells in the bone marrow and lymphopoietic tissues (eg, thymus, lymph nodes, etc) and are further exacerbated

by an increased systemic demand for leukocytes. Infection in utero or in pups <8 wk old or born to unvaccinated dams without naturally occurring antibodies can result in myocardial infection, necrosis, and myocarditis. Myocarditis, presenting as acute cardiopulmonary failure or delayed, progressive cardiac failure, can be seen with or without signs of enteritis. However, CPV-2 myocarditis is infrequent, because most bitches have CPV antibodies from immunization or natural exposure.

Clinical Findings: Clinical signs of parvoviral enteritis generally develop within 5–7 days of infection but can range from 2–14 days. Initial clinical signs may be nonspecific (eg, lethargy, anorexia, fever) with progression to vomiting and hemorrhagic small-bowel diarrhea within 24–48 hr. Physical examination findings can include depression, fever, dehydration, and intestinal loops that are dilated and fluid filled. Abdominal pain warrants further investigation to exclude the potential complication of intussusception. Severely affected animals may present collapsed with prolonged capillary refill time, poor pulse quality, tachycardia, and hypothermia—signs potentially consistent with septic shock. Although CPV-associated leukoencephalomalacia has been reported, CNS signs are more commonly attributable to hypoglycemia, sepsis, or acid-base and electrolyte abnormalities. Inapparent or subclinical infection is common.

Lesions: Gross necropsy lesions can include a thickened and discolored intestinal wall; watery, mucoid, or hemorrhagic intestinal contents; edema and congestion of abdominal and thoracic lymph nodes; thymic atrophy; and, in the case of CPV myocarditis, pale streaks in the myocardium. Histologically, intestinal lesions are characterized by multifocal necrosis of the crypt epithelium, loss of crypt architecture, and villous blunting and sloughing. Depletion of lymphoid tissue and cortical lymphocytes (Peyer's patches, peripheral lymph nodes, mesenteric lymph nodes, thymus, spleen) and bone marrow hypoplasia are also seen. Pulmonary edema, alveolitis, and bacterial colonization of the lungs and liver may be seen in dogs that died of complicating acute respiratory distress syndrome, systemic inflammatory response syndrome, endotoxemia, or septicemia.

Diagnosis: CPV enteritis should be suspected in any young, unvaccinated, or

incompletely vaccinated dog with relevant clinical signs, especially those living in or newly acquired from a shelter or breeding kennel. During the course of the illness, most dogs develop a moderate to severe leukopenia characterized by lymphopenia and neutropenia. Leukopenia, lymphopenia, and the absence of a band neutrophil response within 24 hr of starting treatment has been associated with a poor prognosis. Prerenal azotemia, hypoalbuminemia (GI protein loss), hyponatremia, hypokalemia, hypochloremia, and hypoglycemia (due to inadequate glycogen stores in young puppies and/or sepsis, potentially a poor prognostic indicator), and increased liver enzyme activities may be noted on the serum biochemical profile. Commercial ELISAs for detection of antigen in feces are widely available and have good to excellent sensitivity and specificity, even for the more recently evolved CPV-2c strain. All animals with relevant clinical signs should be immediately tested, so appropriate isolation procedures can be initiated. Most clinically ill dogs shed large quantities of virus in the feces. However, false-negative results can be seen early in the course of the disease (before peak viral shedding), because of the dilutional effect of large volume diarrhea, or after the rapid decline in viral shedding that tends to occur within 10–12 days of infection. False-positive results can be seen within 4–10 days of vaccination with modified-live CPV vaccine. Alternative ways to detect CPV antigen in feces include PCR testing, electron microscopy, and virus isolation. Serodiagnosis of CPV infection requires demonstration of a 4-fold increase in serum IgG titer throughout a 14-day period or detection of IgM antibodies in the absence of recent (within 4 wk) vaccination.

Treatment and Prognosis: The main goals of treatment for CPV enteritis include restoration of fluid, electrolyte, and metabolic abnormalities and prevention of secondary bacterial infection. In the absence of significant vomiting, oral electrolyte solutions can be offered. Administration SC of an isotonic balanced electrolyte solution may be sufficient to correct mild fluid deficits (<5%) but is insufficient for dogs with moderate to severe dehydration. Most dogs will benefit from IV fluid therapy with a balanced electrolyte solution. Correcting dehydration, replacing ongoing fluid losses, and providing maintenance fluid needs are

essential for effective treatment. Dogs must be monitored for development of hypokalemia and hypoglycemia. If electrolytes and serum blood glucose concentration cannot be routinely monitored, empirical supplementation of IV fluids with potassium (potassium chloride 20–40 mEq/L) and dextrose (2.5%–5%) is appropriate.

If GI protein loss is severe (albumin <20 g/L, total protein <40 g/L, evidence of peripheral edema, ascites, pleural effusion, etc), colloid therapy should be considered. Nonprotein colloids (eg, pentastarch, hetastarch) can be administered in boluses (5 mL/kg, maximum of 20 mL/kg) throughout at least 15 min. The remainder of the maximal dosage of 20 mL/kg can be administered as a constant-rate infusion throughout 24 hr, and the volume of crystalloids administered decreased by 40%–60%. Alternatively, transfusion of fresh frozen plasma may partially replace serum albumin while providing serum protease inhibitors to counter the systemic inflammatory response. There is no evidence to support the use of serum from dogs recovered from CPV-enteritis (convalescent or hyperimmune serum) as a means of passive immunization.

Antibiotics are indicated because of the risk of bacterial translocation across the disrupted intestinal epithelium and the likelihood of concurrent neutropenia. A β -lactam antibiotic (eg, ampicillin or cefazolin [22 mg/kg, IV, tid]) will provide appropriate gram-positive and anaerobic coverage. For severe clinical signs and/or marked neutropenia, additional gram-negative coverage (eg, enrofloxacin [5 mg/kg/day, IM or IV] or gentamicin [6 mg/kg/day, IV]) is indicated. Aminoglycoside antibiotics must not be administered until dehydration has been corrected and fluid therapy established. Enrofloxacin has been associated with articular cartilage damage in rapidly growing dogs 2–8 mo old and should be discontinued if joint pain or swelling develops. Second- or third-generation cephalosporins (eg, cefoxitin, ceftazidime, cefovecin, others) can also be considered for their relatively wide spectrum of activity against gram-positive and gram-negative bacteria.

Antiemetic therapy is indicated if vomiting is protracted, perpetuates dehydration and electrolyte abnormalities, or limits oral administration of medications and nutritional support. α -Adrenergic antagonists (eg, prochlorperazine, 0.1–0.5 mg/kg, SC, tid) can worsen hypotension in hypovolemic animals, whereas prokinetic agents (eg, metoclopra-

mide, 0.3 mg/kg, PO or SC, tid, or 1–2 mg/kg/day as a constant-rate infusion) may increase the risk of intussusception; use of either agent should be restricted to dogs that are rehydrated and being appropriately monitored. In dogs with CPV enteritis, maropitant (1 mg/kg/day, IV) and ondansetron (0.5 mg/kg, IV, tid) appear to be equally effective at controlling vomiting, although maropitant may be associated with an improved ability to maintain body weight during illness. Vomiting may persist despite antiemetic administration. Antidiarrheals are not recommended, because retention of intestinal contents within a compromised gut increases the risk of bacterial translocation and systemic complications. A successful protocol for outpatient treatment of dogs with parvoviral enteritis, consisting of maropitant (1 mg/kg/day, SC), cefovecin (8 mg/kg, SC, every 14 days), and SC crystalloid fluids (tid), has been described.

Previous anecdotal recommendations for nutritional management of CPV enteritis included withholding food and water until cessation of vomiting. However, evidence suggests early enteral nutrition is associated with earlier clinical improvement, weight gain, and improved gut barrier function. For anorectic dogs, placement of a nasoesophageal or nasogastric tube for continual feeding of a prepared liquid diet (eg, Clinicare®, or dilute, blended canned diet) should be instituted within 12 hr of hospital admission. Once vomiting has subsided for 12–24 hr, gradual reintroduction of water and a bland, low-fat, easily digestible commercial or homemade (eg, boiled chicken or low-fat cottage cheese and rice) diet is recommended. Partial or total parenteral nutrition is reserved for dogs with anorexia >3 days that cannot tolerate enteral feeding.

Oseltamivir is an antiviral agent, usually used to treat influenza virus infections in people. In a single published study of naturally occurring CPV enteritis in dogs, treatment with oseltamivir (2 mg/kg, PO, bid for 5 days) did not decrease duration of hospitalization, clinical disease severity, or mortality. However, treated dogs did not experience weight loss or a decrease in WBC count, as were observed in untreated control dogs. The potential for induction of drug resistance to human or avian influenza viruses has led some to question the appropriateness of oseltamivir administration to animals. Other adjunctive treatments such as recombinant human granulocyte colony-stimulating factor, recombinant bactericidal/permeability-increasing

protein, and feline interferon- ω have not been shown to be beneficial.

Intussusception, bacterial colonization of IV catheters, thrombosis, urinary tract infection, septicemia, endotoxemia, acute respiratory distress syndrome, and sudden death are potential complications of CPV enteritis. Most puppies that survive the first 3–4 days of illness make a full recovery, usually within 1 wk. With appropriate supportive care, 68%–92% of dogs with CPV enteritis will survive. Dogs that recover develop longterm, possibly lifelong immunity.

Prevention and Control: To limit environmental contamination and spread to other susceptible animals, dogs with confirmed or suspected CPV enteritis must be handled with strict isolation procedures (eg, isolation housing, gowning and gloving of personnel, frequent and thorough cleaning, footbaths, etc). All surfaces should be cleaned of gross organic matter and then disinfected with a solution of dilute bleach (1:30) or a peroxygen, potassium peroxymonosulfate, or accelerated hydrogen peroxide disinfectant. The same solutions may be used as footbaths to disinfect footwear.

To prevent and control CPV, vaccination with a modified-live vaccine is recommended at 6–8, 10–12, and 14–16 wk of age, followed by a booster administered 1 yr later and then every 3 yr. Because of potential damage by CPV to myocardial or cerebellar cells, inactivated rather than modified-live vaccines are indicated in pregnant dogs or colostrum-deprived puppies vaccinated before 6–8 wk of age. It has been suggested that the presence of maternally acquired CPV antibodies may interfere with the effectiveness of vaccination in puppies <8–10 wk old. However, current modified-live CPV vaccines are sufficiently immunogenic to protect puppies from infection in the presence of low levels of interfering maternal antibody, and vaccination of 4-wk-old puppies with a high antigen titer vaccine results in seroconversion and may decrease the window of susceptibility to infection. Current vaccine products protect similarly well against CPV-2 as against other strains of the virus.

As described above, CPV can remain viable in the environment for an extended period. In a kennel, shelter, or hospital situation, cages and equipment should be cleaned, disinfected, and dried twice before reuse. The same concepts can be applied to a home situation. Removal of contaminated

organic material is important in outdoor situations where complete disinfection is not practical. Disinfectants can be applied outdoors with spray hoses, but disinfection will be less effective than when applied to clean, indoor surfaces. In a home situation, only fully vaccinated puppies (at 6, 8, and 12 wk) or fully vaccinated adult dogs should be introduced into the home of a dog recently diagnosed with CPV enteritis. Booster vaccination of in-contact healthy dogs that are up-to-date on parvovirus vaccination is reasonable but potentially unnecessary given the extended duration of immunity to CPV.

COLITIS

The colon helps maintain fluid and electrolyte balance and absorb nutrients; it is also the major site of fecal storage until expulsion and provides an environment for microorganisms. Disruptions to normal colonic function lead to changes in both absorption and motility; clinically, this often manifests as large-bowel diarrhea. Approximately one-third of dogs with a history of chronic diarrhea have colitis. Chronic colitis is defined as inflammation of the colon that is present for ≥ 2 wk. Inflammation of the colon reduces the amount of water and electrolytes absorbed and changes colonic motility by suppressing the normal colonic contractions that mix and knead and by stimulating giant migrating contractions (ie, more powerful contractions that rapidly propel intestinal contents). Colitis has been classified into four forms: lymphocytic-plasmacytic, eosinophilic, neutrophilic, and granulomatous. Lymphocytic-plasmacytic is the most common form in both dogs and cats. Most dogs are middle-aged, and there is no sex predilection. There may be an association between colitis and perianal fistula, especially in German Shepherds. Cats with chronic colitis tend to be middle-aged and more commonly purebred. Typically, there is an increased number of lymphocytes and plasmacytes in the lamina propria (less frequently in the submucosa and muscularis).

Eosinophilic colitis is characterized by an increased number of eosinophils in the lamina propria. It is less common than lymphocytic-plasmacytic colitis, the animals tend to be younger, and it is more difficult to treat. Infectious agents, parasites, and food allergies may be inciting factors, but none has been proved. The CBC may reveal eosinophilia. Hypereosinophilic syndrome in cats is a variant of eosinophilic enteritis with eosinophilic involvement not

only of the bowel but also of the liver, spleen, mesenteric lymph nodes, kidney, adrenal glands, and heart.

Granulomatous colitis (GC) is a rare, breed-specific inflammatory bowel disease of young Boxer dogs. It is seen as a segmental, thickened, partially obstructed segment of bowel (ileum and colon most commonly), characterized by the presence of macrophages and other inflammatory cells within the lamina propria. These macrophages are not periodic acid-schiff positive. Because of the histologic characteristics, it is important to exclude inflammation secondary to fungal disease, intestinal parasites, feline infectious peritonitis, and foreign material. Treatment remains controversial. Although surgery was previously recommended because GC was refractory to medical treatment and associated with high mortality rates, recent research using culture-independent molecular analysis has shown a correlation between GC and *Escherichia coli* invasion within colonic mucosal macrophages. Current treatment recommendations for GC require antimicrobials effective against *E. coli* and that penetrate intracellularly, such as enrofloxacin.

Etiology and Pathophysiology:

Inflammation of the colon may be acute or chronic. In most cases, the inciting factors are unknown. Bacterial, parasitic, fungal, traumatic, uremic, and allergic causes have been postulated. Inflammation may be the result of a defect in mucosal immunoregulation. After initial mucosal injury, submucosal lymphocytes and macrophages become exposed to luminal antigens and subsequently trigger inflammation. An exaggerated reaction to dietary or bacterial factors within the lumen of the bowel, genetic predisposition, psychologic pathology affecting the neurologic or vascular supply to the colon, or sequelae of previous infectious or parasitic disease have also been implicated.

In acute colitis, there is mucosal infiltration with neutrophils and epithelial disruption and ulceration. Chronic colitis is most often characterized by mucosal infiltration of plasma cells and lymphocytes, fibrosis, and sometimes ulceration. Goblet cells are stimulated to secrete excessive quantities of mucus. Absorption of water and electrolytes is impaired, and motility is reduced. Inflammation disrupts intracellular tight junctions and reduces the transmucosal electrical potential difference, interrupting the ability of the colon to absorb sodium. Normal segmentation is

inhibited; giant migrating muscular contractions proceed down the length of the colon and rapidly expel luminal contents. The inflamed bowel is more sensitive to stretch, and contents entering the colon stimulate strong migrating muscular contractions, an urge to defecate, and abdominal discomfort.

Fructooligosaccharides (FOSs) enhance colonic microflora and assist in the prevention and treatment of colonic disease. These complex carbohydrates are not digested in the small intestine. They are fermented by specific colonic bacteria that use them as an energy source. FOSs promote the growth of beneficial bacteria and inhibit growth of potentially harmful bacteria. They are responsible for the production of short-chain fatty acids (SCFAs).

SCFAs (acetate, propionate, butyrate) are an important energy source essential for maintenance of normal mucosal health. They help maintain intestinal motility and ameliorate intestinal inflammation. Alteration of fatty acids leads to mucosal atrophy and injury.

Clinical Findings: The most common clinical sign of chronic colitis is large-bowel diarrhea, characterized by mucus, hematochezia, tenesmus, and occasionally pain when defecating. There is often an increased urgency and frequency of defecation, with decreased fecal volume per bowel movement. Weight loss and vomiting can occur but are uncommon; they are seen more often when small intestine is involved. Clinical signs may wax and wane. Initially, the clinical signs may be sporadic, but progression usually occurs. Physical examination is unremarkable in most cases. A thorough rectal examination may reveal rectal polyps or malignant neoplasms that can mimic signs of chronic colitis.

Diagnosis: The initial approach should include a complete history and physical examination, including rectal palpation and evaluation of feces. Fecal smears for *Giardia* and fungal elements (*Histoplasma capsulatum*, *Pythium insidiosum*), fecal flotation for parasite identification (*Trichuris vulpis* in dogs, *Tritrichomonas foetus* in cats), and culture for bacteria (*Campylobacter*, *Salmonella*, *Clostridium*) are suggested in cases of chronic colitis. Rectal cytology is an important tool to exclude other causes of large-bowel diarrhea. It can reveal inflammatory cells, neoplastic cells, and certain infectious

agents (eg, *H. capsulatum*). Cases of suspected clostridial colitis (>5 endospores per field) should be confirmed by identifying *Clostridium perfringens* enterotoxin A and B in feces using a commercially available ELISA after a fecal bacterial culture is performed.

A dietary trial is recommended before pursuing more advanced diagnostics. If clinical signs persist, a CBC, biochemical profile, and urinalysis should be performed to exclude other diseases; however, in most cases of chronic colitis, the results are normal. For cats, feline leukemia virus/feline immunodeficiency virus testing is also recommended as well as a thyroid level if age appropriate. Routine abdominal radiographs are also usually normal. Contrast radiographs may occasionally demonstrate intraluminal narrowing, which could indicate an infiltrative disease process. Ultrasonography allows the visualization of colonic mucosa, localized lesions, and the size and echogenicity of lymph nodes.

Colonoscopy is indicated to visually inspect the mucosal surface of the colon and to obtain biopsy specimens. Preparation of the colon is essential to avoid missing small or subtle lesions because of residual fecal material on the mucosal surface. Food should be withheld for 24–48 hr before the procedure, followed by a combination of enemas and an oral colonic lavage solution. Several agents can be used to clean the bowel, such as sodium picosulfate and bisacodyl. Multiple samples from the cecum and ascending, transverse, and descending colon should be obtained, regardless of gross morphologic appearance. Because of poor correlation between gross appearance and histopathologic results, results should be interpreted in light of the physical examination and history. A normal mucosal biopsy or one with evidence of a hyperplastic mucosa, in conjunction with clinical signs supportive of large-intestinal diarrhea, is compatible with irritable bowel syndrome. Peripheral eosinophilia is invariably present in cats with hypereosinophilic syndrome.

Treatment and Control: If possible, the inciting cause should be identified and eliminated. Food should be withheld for an initial 24–48 hr in animals with acute colitis in an effort to “rest” the bowel.

Because shedding of ova by whipworms is intermittent, therapeutic deworming (eg, fenbendazole 50 mg/kg/day, for 3 days, repeated in 3 wk and again in 3 mo if there is a positive response) should be done even if results of fecal examinations are negative.

Supplementing the diet with fiber (1–6 tsp of psyllium hydrophilic mucilloid or 1–4 tbsp of coarse wheat bran/feeding) improves diarrhea in many animals. Dietary fiber reduces free fecal water, prolongs luminal transit time (increasing the opportunity to absorb water), absorbs toxins, increases fecal bulk and stretches the colonic smooth muscle, and improves contractility. However, the addition of fiber alone rarely results in complete resolution of clinical signs of large-intestinal diarrhea in dogs, and beneficial effects may take as long as 6 wk to become evident. Over time, the fiber dose can be reduced or eliminated in some dogs and a standard dog food substituted without causing a return of the diarrhea.

Novel protein diets have effectively controlled clinical signs of colitis in both dogs and cats. The protein source used should be one to which the animal has not previously been exposed. In one study, clinical signs associated with lymphocytic-plasmacytic colitis resolved in all dogs within ~2 wk after feeding a low-residue, digestible, hypoallergenic diet (1 part low-fat cottage cheese and 2 parts boiled white rice). Thereafter, most dogs were maintained without recurrence of clinical signs on commercially available prescription diets they had not been previously fed. Currently, a number of commercially available diets contain rice with mutton or lamb, venison, or rabbit.

Hydrolyzed diets have also been effective in treatment of colitis. These specialized diets disrupt the protein structure sufficiently to remove any allergens and allergenic epitopes and, therefore, prevent immune recognition.

If feeding a high-fiber or novel protein diet is not beneficial, a commercial, low-residue diet may be tried, especially one that contains FOSs.

Cats with lymphocytic-plasmacytic colitis may respond to dietary management alone (eg, lamb and rice, horsemeat, or a commercially available diet). In one study, cats were initially treated with dietary fiber or with dietary fiber and pharmacologic intervention (prednisone, tylosin, or sulfasalazine). Most cats were eventually maintained on high-fiber diets or a highly digestible diet.

Metronidazole is considered one of the primary pharmacologic agents in chronic colitis in cats. Its therapeutic effects include antiprotozoal and antimicrobial activity and inhibition of some aspects of cell-mediated immunity. It is not usually used as a sole agent but rather in combination with either

dietary management or another drug. Although metronidazole is well tolerated in both dogs and cats, adverse effects can occur (mostly neurologic, eg, nystagmus, ataxia, vestibular signs, seizures), either with chronic therapy or at high dosages. However, neurotoxicoses should be reversible within 5–7 days after treatment is discontinued.

Tylosin, a macrolide antibiotic used primarily in food animals, is useful in chronic enteropathies, because it interferes with bacterial adhesion to the mucosa and has some antibacterial and immunomodulating effects. It targets mainly facultative and obligate anaerobic gram-positive bacteria and some gram-negative bacteria. However, *E. coli* and *Salmonella* are resistant to tylosin. Tylosin is well tolerated in both dogs and cats with minimal effects.

Clinical signs resolve more rapidly when anti-inflammatory medication is given, along with the change in diet. Sulfasalazine, prednisone or prednisolone, and azathioprine are used most commonly. Sulfasalazine is often used to treat lymphocytic-plasmacytic colitis in dogs (12.5 mg/kg, qid for 14 days, then 12.5 mg/kg, bid for 28 days). Longterm use is discouraged, because it predisposes to keratoconjunctivitis sicca. Sulfasalazine is a prostaglandin synthetase inhibitor and has antileukotriene activity. It consists of mesalamine linked to sulfapyridine in an azochemical bond; this linkage prevents absorption in the upper GI tract and allows most of the drugs to be transported to the large intestine. Once it has reached the large intestine, it is metabolized by cecal and colonic bacteria, releasing both components. Mesalamine acts locally to reduce colonic mucosal inflammation. Sulfapyridine is believed to be systemically absorbed and therefore does not have any local therapeutic effect in colitis but is blamed for the adverse effects of sulfasalazine. Salicylates are metabolized in the liver by hepatic enzymatic processes involving glucuronyl transferase. Because cats are deficient in this enzymatic pathway, salicylates have prolonged half-lives in this species. Therefore, sulfasalazine is not used as the drug of choice in colitis in cats because of the risk of salicylate toxicity.

Glucocorticoids, in combination with dietary management and metronidazole, are the treatment of choice for chronic colitis in cats. They may be introduced into the therapeutic plan for dogs when the previously discussed therapies are not successful or if the 5-aminosalicylates result in adverse effects. If used in combination with sulfasalazine or metronidazole,

prednisone may be given at a reduced dosage. Prednisone should be started at 2 mg/kg/day, PO; for 2 wk after clinical signs resolve, the dosage should be reduced by 25% every 2–4 wk, which can usually maintain remission.

Cats usually tolerate glucocorticoids very well; adverse effects are common in dogs and include polyuria, polydipsia, polyphagia, GI bleeding, increased susceptibility to infection, iatrogenic hyperadrenocorticism, and pituitary-adrenocortical suppression.

Budesonide is a nonhalogenated glucocorticoid used in treatment of Crohn's disease in people. Budesonide undergoes significant first-pass metabolism in the liver; theoretically, this should reduce the adverse effects often seen with traditional glucocorticoids, because little of the active drug is systemically available. In one study of 10 healthy dogs, the pituitary-adrenocortical axis was suppressed, but no other adverse effects were seen.

Immunosuppressive drugs are mostly used in combination with glucocorticoids when the response is not satisfactory with the latter alone. The most commonly used are azathioprine and chlorambucil in dogs and cats. Azathioprine (2 mg/kg/day, and then tapered), alone or in combination with prednisone, has been used to control clinical signs associated with lymphocytic-plasmacytic colitis. Azathioprine may be considered in cases that are poorly responsive to prednisone or to prednisone with sulfasalazine. The serious adverse effects of azathioprine in cats (myelosuppression and hepatotoxicity) limit its use in feline colitis. Instead, chlorambucil (0.1–0.2 mg/kg or 1 mg/cat, daily initially until clinical signs are markedly improved, which may require 4–8 wk) is used in cats in combination with prednisone if needed.

Cyclosporine has been effective in steroid-refractory cases of colitis, but it has not been evaluated in cats. Adverse effects include GI disturbances, gingival disease, and alopecia.

Some animals also require short-term use of motility modifiers until inflammation is controlled. Loperamide (0.1–0.2 mg/kg, bid-qid) stimulates segmental activity and slows passage of fecal contents. It also decreases colonic secretion, enhances salt and water absorption, and increases anal sphincter tone. It is contraindicated in cases of infectious colitis (eg, caused by *Salmonella*, *Campylobacter*, or *Clostridium*).

Prognosis: The short-term prognosis for chronic colitis is good for both dogs and cats. However, long-term prognosis for

complete resolution without relapses appears poor. Most cases of inflammatory bowel disease are not curable, and some form of treatment will likely be necessary longterm. For some animals, especially cats, longterm management of chronic colitis may be possible with diet alone.

Most cases of idiopathic lymphocytic-plasmacytic colitis respond to appropriate dietary and medical changes. Stricture formation and extensive fibrosis warrant a more guarded prognosis. Eosinophilic colitis in dogs responds favorably to controlled diets and glucocorticoid therapy. In cats, the prognosis is more guarded, and more aggressive treatment with immunosuppressive agents is required. Hypereosinophilic syndrome is a progressive, fatal disease that has no effective treatment in animals.

Histiocytic colitis of Boxers carries a grave prognosis unless treatment is started early in the course of the disease. The immunoproliferative enteropathy of Basenjis also carries a poor prognosis; most dogs die within 2 yr of diagnosis, although some have been reported to live as long as 5 yr. Similarly, the prognosis for the diarrheal syndrome reported in Lundehunds is also poor.

CONSTIPATION AND OBSTIPATION

Constipation is the infrequent or difficult evacuation of feces, which are typically dry and hard. Constipation is a common clinical problem in small animals. In most instances, the problem is easily rectified; however, in more debilitated animals, accompanying clinical signs can be severe. As feces remain in the colon longer, they become drier, harder, and more difficult to pass. Obstipation is intractable constipation characterized by an inability to evacuate the mass of dry, hard feces; impaction extending from the rectum to the ileocolic valve can result. Megacolon is a pathologic condition of hypomotility and dilation of the large intestine that results in constipation and obstipation.

Etiology and Pathophysiology: Peristaltic waves are responsible for the aboral movement of fecal material in the colon. Giant migrating waves that occur intermittently throughout the day move this matter farther and more rapidly. These waves constitute the “gastrocolic reflex” and are common after ingestion of a meal. A reduction or loss of these waves may contribute to constipation. Similarly, an

increase in segmentation wave activity may predispose to constipation. However, diet is the most important local factor affecting colonic function.

Chronic constipation may be due to intraluminal, extraluminal, or intrinsic (ie, neuromuscular) factors. Intraluminal obstruction is most common and is due to the inability to pass poorly digested, often firm matter (eg, hair, bones, litter) mixed with fecal material. The lack of water intake or the reluctance to defecate on a regular basis because of environmental (eg, stress) or behavioral (eg, dirty litter box) factors or painful anorectal disease predisposes to formation of hard, dry feces. Intraluminal tumors may also impede the passage of feces. Extraluminal obstruction may be caused by compression of the colon or rectum from a narrowed pelvic inlet after suboptimal healing of pelvic fractures or from enlarged sublumbar lymph nodes or prostate gland. Colonic stricture due to trauma or neoplasia should also be considered. Finally, some animals (usually cats) with chronic constipation or obstipation may have megacolon, likely caused by a lesion of the neuromuscular bed of the colon. The etiology of megacolon often remains undiagnosed. Other diseases that affect neuromuscular control of the colon and rectum include hypothyroidism, dysautonomia, and lesions of the spinal cord (eg, Manx sacral spinal cord deformity) or pelvic nerves. Hypokalemia and hypercalcemia also adversely affect muscular control. Some drugs (eg, opioids, diuretics, antihistamines, anticholinergic agents, sucralfate, aluminum hydroxide, potassium bromide, and calcium channel-blocking agents) promote constipation via differing mechanisms.

Clinical Findings: The classic clinical signs of constipation are tenesmus and the passage of firm, dry feces. If the passage of feces is hindered by an enlarged prostate or sublumbar lymph nodes, the feces may appear thin or "ribbon-like" in appearance. Abdominal palpation and rectal examination can confirm the presence of large volumes of retained fecal matter. Passed feces are often putrid. Some animals are quite ill and also have lethargy, depression, anorexia, vomiting (especially cats), and abdominal discomfort.

Diagnosis: A history of dietary indiscretion and physical evidence of retained feces confirms the diagnosis. Detailed information regarding the duration of constipation and influencing factors may help determine

the cause, as will a history of ingestion of indigestible material that may increase fecal bulk or cause pain that can terminate the defecation reflex. Other historical factors that may be relevant include recent surgery, previous pelvic trauma, and possibly radiation therapy. A complete neurologic examination with special emphasis on caudal spinal cord function should be performed to identify neurologic causes of constipation, eg, spinal cord injury, pelvic nerve trauma, and Manx sacral spinal cord deformity.

Abdominal palpation and rectal examination, including evaluation of the prostate and sublumbar lymph nodes, should be performed to determine the presence of perineal hernia, foreign material, pain, or masses. Plain abdominal radiographs may help establish the inciting factor(s) of fecal retention and give some indication of what the feces contain (eg, bones). A barium enema, ultrasonography, or colonoscopy may facilitate demonstration of obstructive lesions or predisposing causes of chronic constipation.

A CBC, biochemical profile including a serum T_4 level, urinalysis, and detailed neurologic examination should be completed in cases of chronic or recurring constipation.

Treatment and Control: Affected animals should be adequately hydrated. Mild constipation can often be treated by dietary adjustment consisting of avoidance of dietary indiscretion, ready access to water and high-fiber diets, and use of suppository laxatives. Continued or longterm use of laxatives should be discouraged unless absolutely necessary to avoid constipation.

A number of pediatric rectal suppositories are available for management of mild constipation. They include dioctyl sodium sulfosuccinate (DSS; emollient laxative), glycerin (lubricant laxative), and bisacodyl (stimulant laxative). The use of suppositories requires a compliant pet and a willing owner. Suppositories can be used alone or in conjunction with oral laxative therapy.

Mild to moderate or recurrent episodes of constipation may require administration of enemas or manual extraction of impacted feces, or both. Types of enemas include warm tap water (5–10 mL/kg), warm isotonic saline (5–10 mL/kg) with or without a mild soap to act as an irritant, DSS (5–10 mL/cat), mineral oil (5–10 mL/cat), or lactulose (5–10 mL/cat). Enema solutions should be administered slowly with a 10–12 French rubber catheter or feeding tube.

Phosphate-containing enemas must be avoided in cats.

If enemas are unsuccessful, manual extraction of impacted feces may be needed. After adequate rehydration, the animal should be anesthetized with an endotracheal tube in place to prevent aspiration in case the colonic manipulation induces vomiting. Complete removal of all feces may require 2–3 attempts over as many days. Concurrent fluid and electrolyte abnormalities should also be corrected.

Laxatives are classified as bulk-forming, lubricant, emollient, osmotic, or stimulant types. Most act on fluid transport mechanisms and colonic motor stimulation. They should be avoided in the presence of dehydration. Bulk-forming laxatives are added to the diet. These products are dietary fiber supplements of poorly digestible polysaccharides and celluloses derived principally from cereal grains, wheat bran, and psyllium. They absorb water, soften feces, add bulk, stretch the colonic smooth muscle, and improve contractility. Many constipated cats respond to dietary supplementation with one of these products. Dietary fiber is preferable because it is well tolerated, more effective, and more physiologic than other laxatives. Commercial fiber-supplemented diets are available, or the pet owner may add psyllium (1–4 tsp/meal), wheat bran (1–2 tbsp/meal), or pumpkin (1–4 tbsp/meal) to canned food. Animals should be well hydrated before starting fiber supplementation to minimize the potential for impaction of fiber in the constipated colon.

Emollient laxatives are anionic detergents that increase the miscibility of water and lipids in digesta, thereby enhancing lipid absorption and impairing water absorption. DSS and disocetyl calcium sulfosuccinate are emollient laxatives available in oral and enema form. Docusate sodium (cats: 50-mg capsule/day; dogs: 50-mg capsule, 1–4/day) and docusate calcium (cats: 50-mg capsule, 1–2/day; dogs: 50-mg capsule, 2–3/day) are other examples of emollient laxatives.

Mineral oil and white petroleum are lubricant laxatives that impede colonic water absorption and permit greater ease of fecal passage. These effects are moderate, and lubricant laxatives are beneficial only in mild cases of constipation. Mineral oil use should be limited to rectal administration because of the risk of aspiration pneumonia with oral administration.

Hyperosmotic laxatives consist of poorly absorbed polysaccharides (eg, lactulose,

0.5 mL/kg, PO, bid-tid), magnesium salts (eg, magnesium citrate, magnesium hydroxide, magnesium sulfate), and the polyethylene glycols. Lactulose is the most effective agent of this group. The organic acids produced from lactulose fermentation stimulate colonic fluid secretion and propulsive motility. Lactulose osmotically retains water in the bowel to soften fecal material. It is also useful in management of hepatic encephalopathy because it decreases luminal pH, reduces bacterial production of ammonia, and favors formation of ammonium ions that are poorly absorbed. Stimulant laxative products (eg, bisacodyl [cats and small dogs: 5 mg; medium-sized dogs: 10 mg; large dogs: 15–20 mg]) increase the propulsive activity of the bowel. They are contraindicated in the presence of bowel obstruction.

Colonic prokinetic agents (eg, cisapride) enhance colonic propulsive motility by activating colonic smooth muscle 5-hydroxytryptamine-2A receptors in a number of species. Anecdotal experience suggest that cisapride (0.1–0.5 mg/kg, PO, bid-tid) effectively stimulates colonic propulsive motility in cats with mild to moderate idiopathic constipation. Higher dosages (up to 1 mg/kg) may be necessary in cats with moderate to severe constipation. No significant adverse effects have been reported in cats treated with cisapride at dosages of 0.1–1 mg/kg, PO, bid-tid. Cats with longstanding obstipation and megacolon are not likely to improve with cisapride therapy.

Ranitidine and nizatidine, H_2 -receptor antagonists, are reported to stimulate colonic motility by inhibiting acetylcholinesterase. They stimulate motility by increasing the amount of acetylcholine available to bind smooth muscle muscarinic cholinergic receptors.

To prevent recurrence, high-fiber diets are recommended, ready access to water should be maintained, and frequent opportunities to defecate allowed.

Cases of simple intraluminal obstruction due to dietary indiscretion respond well to bowel evacuation and prevention of this habit in the future. Chronic constipation unresponsive to medical management (eg, some cats with megacolon) may respond to subtotal or total colectomy. Colectomy with colocolonic, ileocolonic, or jejunocolonic anastomosis may be performed depending on the extent of the disease. Mild to moderate diarrhea may occasionally persist for weeks to months after surgery, and some cats may have recurrent constipation. Pelvic osteotomy without colectomy has

been recommended for cats with pelvic fracture malunion and hypertrophic megacolon of <6 mo duration. In such cases, pathologic hypertrophy may be reversible with early pelvic osteotomy. Subtotal colectomy is recommended in cats with pelvic fractures if hypertrophy and clinical signs have persisted for >6 mo. In these cases, hypertrophy is followed by muscular degeneration and pathologic dilatation, and pelvic osteotomy alone will not provide relief from obstruction.

FELINE ENTERIC CORONAVIRUS

Feline enteric coronavirus (FECV) is an enveloped, single-stranded RNA virus that is highly prevalent in domestic cat populations worldwide. Infection is often subclinical or characterized by transient, mild GI illness in kittens. Mutation of FECV to a biotype capable of infection and replication within macrophages is responsible for development of feline infectious peritonitis (FIP), a highly fatal, multisystemic disease (*see* p 780).

Etiology and Pathophysiology: Fecal shedding of FECV begins within 1 wk of initial infection and persists at high levels for 2–10 mo, followed by an extended period (up to 24 mo) of lower level, potentially intermittent, viral shedding. At least 13% of infected cats shed the virus indefinitely.

Cats become infected through ingestion or inhalation of virus-containing feces or through contact with contaminated fomites (eg, litter boxes, mutual grooming, housing, personnel). FECV is relatively fragile but can survive in dry environments for up to 7 wk. Close contact between cats (eg, catteries and multicat households) facilitates transmission. Vertical transmission from infected queens to kittens does occur. Kittens generally do not begin to shed virus before 9–10 wk of age, although viral shedding as early as 4 wk of age has been reported. Soon after infection, virus may replicate in oropharyngeal tissue, resulting in transient (hours to days) salivary shedding. FECV infects and replicates in mature apical epithelial cells of the intestinal villi, causing brush border shortening and destruction.

Clinical Findings: Most FECV infections are clinically inapparent or characterized by mild, self-limiting gastroenteritis. Occasionally, vomiting and diarrhea can be acute and severe or chronic and unresponsive to treatment. Although diarrhea is the most

common clinical sign of infection in kittens, upper respiratory tract signs have also been reported.

Diagnosis: The viral DNA can be detected in feces by reverse transcriptase PCR (RT-PCR). Because chronic carriers of FECV tend to be asymptomatic, FECV can be assumed to be the cause of the diarrhea only after other causes (eg, infectious, dietary, inflammatory bowel disease, neoplasia, etc) have been excluded. The clinical utility of serologic evaluation for antibodies to FECV is questionable. Positive coronavirus antibody titers are detected in up to 40% of pet cats and in up to 90% of cats in catteries or multicat households. Positive FECV antibody titers are indicative only of exposure to the virus and are not suggestive of the etiology of the current disease, do not correlate with the risk of developing FIP, and are not diagnostic for FIP. Histologic lesions suggestive of FECV enteritis include intestinal villous fusion, atrophy, or sloughing. Because these lesions are nonspecific, definitive diagnosis requires immunohistochemical or immunofluorescent detection of viral antigen in intestinal epithelial cells.

Treatment, Control, and Prevention:

The mild, transient clinical signs are unlikely to require therapy. Treatment, if required, is symptomatic and supportive (ie, fluid therapy, oral electrolyte solutions, antiemetics). There is no specific antiviral therapy. Death due to the FECV-associated gastroenteritis is uncommon.

Control and prevention of FECV are usually a concern only in breeding catteries and rescue shelters. Ingestion of virus-contaminated fecal particles should be prevented as much as possible. Fecal contamination of the environment can be minimized with sufficient litter box numbers, daily litter box cleaning, weekly litter box disinfection, and clipping/cleaning fur from the hind end of long-haired cats. FECV can survive indoors for up to 7 wk under dry conditions but is readily inactivated by most commercial disinfectants.

Ideally, cats should be housed in small (three or four cats), closed groups. The room, cages, bedding, and litter boxes should be disinfected between groups. Although impractical in a shelter situation, cats should be housed in groups according to their antibody (immunofluorescent antibody test seropositive or seronegative) and virus shedding (based on fecal PCR) status. Seropositive cats can be retested every 3–6 mo and moved into seronegative

groups as their antibody titer decreases. In a rescue or shelter situation, cats should be housed singly. Identification of FECV carrier cats requires nine monthly, consecutive positive fecal RT-PCR tests, whereas identification of a cat that has eliminated FECV infection requires five consecutive negative fecal RT-PCR tests.

Seropositive cats should be mated only to other seropositive cats, and seronegative cats to other seronegative cats. Kittens born of seropositive matings or to a seropositive queen are protected from infection by maternally derived immunity until ~6 wk of age. Kittens weaned from seropositive queens by 6 wk of age are unlikely to acquire infection from the queen. Serologic testing of kittens should be delayed until 10–11 wk of age, by which time seroconversion is likely.

New cats should be serologically tested before introduction into a cattery or breeding program. Only seronegative and virus-free (fecal PCR) cats should be introduced into an FECV free cattery or a cattery attempting to eliminate the virus. Seropositive cats are less likely to develop FIP than seronegative cats when introduced to an FECV endemic environment. Vaccination with an intranasal, temperature-sensitive FECV mutant is not generally recommended but can be considered in seronegative cats >16 wk old introduced into an FECV-endemic environment. Vaccination will lead to seroconversion and does not completely protect cats previously exposed to FECV from developing FIP.

GASTRIC DILATION AND VOLVULUS

(Bloat)

Gastric dilation and volvulus (GDV) is an acute, life-threatening condition that primarily affects large- and giant breed dogs. Immediate medical and surgical intervention is required to optimize chance of survival.

Etiology and Pathophysiology: The etiology of GDV is unknown, but several phenotypic and environmental risk factors have been identified for developing GDV. Breeds at risk of GDV include the Great Dane, German Shepherd, Irish Setter, Gordon Setter, Weimaraner, Saint Bernard, Standard Poodle, and Bassett Hound. No sex predisposition exists, and dogs appear to be at increased risk with advancing age. Other reported predisposing factors include lean body condition, deep/narrow thoracic

conformation, a first-degree relative with a history of GDV, stress, aggressive or fearful behavior, once daily feeding, dry food, rapid consumption of food, previous splenic disease, and increased gastric ligament laxity.

It is unclear whether dilation or volvulus occurs first during the development of GDV, although it is postulated that volvulus occurs first. Dilation of the stomach results from accumulation of gas and/or fluid, and volvulus prevents the normal release of these contents. During volvulus, the pylorus and duodenum first migrate ventrally and cranially. Viewed from a caudal to cranial direction, the stomach may rotate from 90° to 360° in a clockwise fashion about the distal esophagus. This rotation displaces the pylorus to the left of midline, entrapping the duodenum between the distal esophagus and the stomach. Depending on the degree of volvulus, the spleen may vary in position from the left caudodorsal to the right craniodorsal abdomen. A volvulus of >180° causes occlusion of the distal esophagus.

After volvulus of the stomach, gas is trapped within this compartment and intragastric pressure rises. Gastric outflow obstruction may be caused by compression of the duodenum by the distending stomach against the body wall, or it may be due to the presence of neoplasia, a gastric foreign body, or pyloric stenosis. Splenic entrapment often accompanies GDV. The progressively distending stomach compromises venous return by compression of the caudal vena cava. Sequestration of blood in the dilated splanchnic, renal, and posterior muscular capillary beds results in portal hypotension, GI tract ischemia, hypovolemia, and systemic hypotension. These factors combine with the loss of fluid in the obstructed stomach and a lack of water intake to produce signs of hypovolemic shock. Dogs are at risk of endotoxemia, hypoxemia, metabolic acidosis, and disseminated intravascular coagulation.

Clinical Findings: Dogs may present with a history of nonproductive retching, hypersalivation, and restlessness. Acute or progressive abdominal distention may be noted, or the affected dog may be found recumbent and depressed with an enlarged abdomen.

Physical examination findings include an enlarged or tympanic abdomen. Abdominal pain and/or splenomegaly may be appreciated on abdominal palpation. Progression from gastric dilation to volvulus predisposes to hypovolemic shock. Signs of shock are common and can include weak

peripheral pulses, tachycardia, prolonged capillary refill time, pale mucous membranes, and dyspnea. An irregular heart rate and pulse deficits indicate the presence of a cardiac arrhythmia. Additionally, the expanding stomach may compress the thoracic cavity and inhibit diaphragmatic movement, leading to respiratory distress.

Diagnosis: Suspicion of GDV is usually high after considering the history, signalment, and clinical signs. Radiographs help distinguish simple gastric dilation from GDV. The preferred radiographic views for identification of GDV are right lateral and dorsoventral recumbency. Ventrodorsal positioning must be avoided because of the potential for aspiration of gastric contents.

The right lateral radiograph usually reveals a large, distended, gas-filled gastric shadow with the pylorus located dorsal and slightly cranial to the fundus. The gastric shadow is frequently compartmentalized or divided by a soft-tissue "shelf" between the pylorus and fundus. This shelf, or reverse "C" sign, is created by the folding of the pyloric antral wall onto the fundic wall. Splenic enlargement or malposition may be noted on radiographs. Gas within the gastric wall is suggestive of tissue compromise, whereas free gas within the abdomen indicates gastric rupture.

PCV, total solids, electrolytes, blood glucose, and serum lactate levels should be evaluated, and blood drawn for a CBC, serum biochemical profile, and coagulation assays. Continuous ECG and blood pressure monitoring are recommended.

Prerenal azotemia is a common finding in animals with GDV and is secondary to systemic hypotension. Increased CK levels may be present due to striated muscle damage, and serum potassium levels may increase subsequent to cell membrane damage. Serum ALT and AST levels may increase secondary to hypoxic damage. Increased lactate is a common finding and is secondary to systemic hypotension and inflammation. Hyperlactatemia (>6 mmol/L) is associated with an increased likelihood of gastric necrosis and the need for partial gastric resection.

Treatment: Immediate goals in treatment of GDV include restoring circulating volume and gastric decompression. Rapid surgical correction of the volvulus follows initial patient stabilization. Because duration of clinical signs is one of the risk factors of GDV-associated death, it is imperative to recognize and correct this condition immediately.

Correction of hypovolemia is the first treatment priority and is achieved by rapid fluid replacement with one or more large bore (16- to 18-gauge) IV catheters placed in cranial (jugular, cephalic) veins. Shock rate (90 mL/kg/hr) fluid therapy with crystalloids should begin immediately. Fluid therapy with combinations of crystalloids, colloids (eg, hetastarch at a rate of 10–20 mL/kg, IV), or hypertonic saline (eg, 7% hypertonic saline solution with dextran 70 at a rate of 5 mL/kg over 15 min) can be considered for animals in severe shock, and the rate of crystalloid fluid infusion reduced by as much as 40% if these products are used. These fluid rates are guidelines only, and fluid resuscitation choices must be tailored to the individual patient's needs. Flow-by oxygen should be provided during stabilization. Electrolyte and acid-base disturbances are usually corrected by adequate fluid therapy and gastric decompression. Because of the potential risk of endotoxemia and GI translocation of bacteria, antibiotics (eg, ampicillin 22 mg/kg, tid-qid, and continued for 2–3 days after surgery) are often given.

Gastric decompression occurs concurrently with fluid resuscitation. Initial decompression attempts should be made with an orogastric tube, which can be performed after sedation with fentanyl (2–5 mcg/kg, IV) or hydromorphone (0.05–0.1 mg/kg, IV), with or without diazepam (0.25–0.5 mg/kg, IV). Agents that cause vasodilation (eg, phenothiazines) should be avoided. A stomach tube is measured from the incisors to the last rib and marked. The tube must not be placed beyond this marking. The lubricated tube is introduced into the mouth (often held open with a roll of tape or bandage material) while the dog is in a sitting position. Some resistance is typically encountered at the esophageal-gastric sphincter. Gentle manipulation and counterclockwise movement of the tube may be necessary to allow passage of the tube into the stomach, but caution must be exercised because it is possible to perforate the esophagus with the tube. Once the tube enters the stomach, gastric gas rapidly escapes. Successful passage of a stomach tube does not exclude the presence of volvulus. After gas and stomach contents are released from the stomach via the tube, the stomach should be lavaged with warm water to decrease the rate of redilation with gas.

If an orogastric tube cannot be readily passed, percutaneous gastrocentesis may be performed to release excess gastric gas.

An area (10 cm × 10 cm) over the right abdominal wall caudal to the last rib and ventral to the transverse vertebral process is clipped and aseptically prepared. Percussion of the area should reveal tympany; this helps avoid accidental puncture of an overlying spleen. If a tympanic structure is not appreciated, the left paracostal region should be assessed. A large-bore needle or over-the-needle catheter is introduced through the skin and body wall into the stomach at the site of greatest tympany. Decompression usually allows for subsequent passage of an orogastric tube and lavage of the stomach.

Surgical correction of GDV rapidly follows the initial stabilization. Aseptic preparation of the abdomen is performed before surgery, and a cranioventral midline approach is performed. Before correcting the gastric torsion, the stomach should be decompressed with the help of an assistant placing an orogastric tube or via gastrocenesis intraoperatively. The stomach is then returned to its normal position, and the stomach and spleen are evaluated for ischemia. Any areas of ischemic gastric wall are removed, and a splenectomy is performed if necessary. Extensive gastric necrosis and necrosis of the gastric cardia are considered poor prognostic indicators. The stomach is emptied of contents, and a gastropexy is performed to decrease risk of recurrence. Several gastropexy techniques have been described and include a simple incisional pexy, a circumcostal (belt-loop) pexy, and a tube gastrotomy and pexy.

Pre-, intra-, and postoperative monitoring should include continuous ECG, intermittent blood pressure measurement, and frequent assessment of vital parameters, PCV, total solids, electrolytes, blood glucose, and serum lactate.

Postoperative medical management includes IV fluid therapy and analgesia. Food should be withheld for 48 hr after surgery. Antiemetic agents (metoclopramide at 0.2–0.5 mg/kg, SC, or 1–2 mg/kg/day, constant-rate IV infusion; maropitant at 1 mg/kg/day, SC) may be administered in cases of continued vomiting. Postoperative cardiac arrhythmias are common, but treatment is often not indicated. Criteria to initiate antiarrhythmic therapy include signs of persistent tachycardia (>140 bpm), hypotension (systolic blood pressure <90 mmHg), hypoperfusion (prolonged capillary refill time, weak pulses), “R on T wave” pattern (a phenomenon that predisposes to ventricular fibrillation), or multifocal ventricular premature contractions. A bolus of 2% lidocaine (2–4 mg/kg, slowly IV) can

be administered and repeated twice in a 30-min period if necessary; a continuous IV infusion (30–80 mcg/kg/min) may be indicated to control arrhythmias. Cardiac arrhythmias associated with GDV are often difficult to control. If the arrhythmia is poorly responsive to this therapy, procainamide (6–10 mg/kg, IV over 15 min) should be given. Life-threatening arrhythmias may respond to 20% magnesium sulfate (0.15–0.3 mEq/kg, or 12.5–35 mg/kg, IV over 15–60 min).

Less common postoperative complications can include life-threatening conditions such as sepsis, peritonitis, and disseminated intravascular coagulation.

Overall mortality rate associated with GDV is ~25%–30%. Risk factors associated with short-term death from GDV include duration of clinical signs >6 hr before examination, performing splenectomy and a partial gastrectomy, hypotension at any time during hospitalization, peritonitis, sepsis, and disseminated intravascular coagulation. Preoperative plasma lactate concentration has been shown to be a good predictor of gastric necrosis and a negative prognostic indicator for outcome for dogs with GDV.

Prophylactic gastropexy is currently being recommended by many veterinary surgeons for breeds at risk or for dogs with relatives that have been affected by GDV. Prophylactic gastropexy can be performed at the time of sterilization surgeries (spay/neuter). Minimally invasive techniques such as laparoscopic-assisted gastropexy are gaining favor. Prophylactic gastropexy has not been shown to prevent development of GDV if performed at the time of neuter but has been shown to help prevent recurrence if performed at the time of the first GDV correction. However, in one study of five large dog breeds predisposed to GDV, mortality was reduced (versus no gastropexy) ranging from 2.2-fold (Rottweiler) to 29.6-fold (Great Dane). A prospective study reported a median survival time of 547 days in dogs that underwent gastropexy versus 188 days for dogs that did not. Owners of breeds at high risk of GDV should be educated about the risk factors for and signs of GDV, and advised to seek immediate veterinary care if clinical signs are apparent. Additional precautions include avoiding stress, feeding multiple rather than single daily meals, avoiding exercise immediately after feeding, and not using elevated food dishes.

GASTRITIS

Gastritis is a general term used to describe a syndrome of acute or chronic vomiting

secondary to inflammation of the gastric mucosa. Irritation, infection, antigenic stimulation, or injury (eg, chemical, erosion, ulceration) of the gastric mucosa stimulates the release of inflammatory and vasoactive mediators with subsequent disruption of gastric epithelial cells, increased gastric acid secretion, and impaired gastric barrier function. Visceral receptors sensitive to gastric distention, gastric inflammation, and tonicity of gastric contents send impulses via vagal and sympathetic nerves to the vomiting center of the medulla oblongata, thereby stimulating the vomiting reflex.

Acute Gastritis: In acute gastritis, vomiting of sudden onset is presumed or confirmed to be secondary to inflammation of the gastric mucosa. Causes include dietary indiscretion or intolerance (eg, ingestion of novel, spoiled, or contaminated foods, or of foreign material), drug or toxin ingestion (eg, antibiotics, NSAIDs, corticosteroids, plants, chemicals), systemic illness (eg, pancreatitis, uremic gastropathy, hypoadrenocorticism), endoparasitism (eg, *Physaloptera* sp [dog], *Ollulanus* sp [cat]), or bacterial (eg, *Helicobacter*-associated disease) or viral (eg, canine parvovirus gastroenteritis, feline panleukopenia) infection. Vomiting of sudden onset is characteristic. The vomitus may contain bile, food, froth, blood (frank or digested), or evidence of an ingested substance (eg, grass, bones, foreign material, etc). Additional clinical signs depend on the severity and frequency of vomiting as well as on the underlying cause.

Diagnosis is usually based on a thorough history, clinical findings, and response to symptomatic treatment. A specific diagnosis should be sought if the animal has had access to foreign objects or toxins, if clinical signs do not resolve within 2 days of symptomatic therapy, if hematemesis or melena are present, if the animal is systemically unwell, or if abnormalities are noted on abdominal palpation. Dogs may signal the presence of cranial abdominal discomfort by adopting a "praying" posture (hindquarters raised and chest and forelegs held close to floor), which seems to provide some sense of relief. A CBC, serum biochemical profile, and urinalysis may be followed by more specific clinicopathologic testing (eg, basal serum cortisol concentration, adrenocorticotropic hormone [ACTH] stimulation test, evaluation of vomitus for specific toxins). Diagnostic imaging, including plain and/or barium contrast abdominal radiographs and abdominal ultrasound, may be indicated.

Treatment of acute gastritis is generally symptomatic and supportive. Small amounts of oral fluids can be given frequently, with the volume increasing as vomiting subsides. Ice (crushed or cubes) can be provided as the only source of water initially. Subcutaneous administration of an isotonic balanced electrolyte solution may be sufficient to correct mild fluid deficits (<5%). If dehydration is moderate to severe or the clinical condition of the animal warrants IV fluid therapy, a more extensive diagnostic evaluation is indicated. If vomiting is acute, oral intake should be discontinued for ≥24 hr. Small amounts of a bland, low-fat, easily digestible diet (eg, boiled lean beef, chicken, or cottage cheese and rice, or a commercially available prescription diet) fed frequently can be introduced, with gradual transition to the usual diet over 3–5 days.

Antiemetic drugs should be used to control vomiting only after an etiologic diagnosis has been made or if vomiting is protracted or severe enough to cause dehydration or electrolyte imbalances. Metoclopramide (0.3 mg/kg, PO or SC, tid, or 1–2 mg/kg/day as a constant-rate infusion) increases gastric contractions; relaxes the pyloric sphincter; and increases gastric, duodenal, and proximal jejunal peristalsis. It is contraindicated in confirmed or suspected GI obstructions. Alternative antiemetics include maropitant (1 mg/kg/day, SC, or 2 mg/kg/day, PO, for 5 days) and ondansetron (0.1–1 mg/kg, PO, once to twice daily). Gastroprotectants such as H_2 -receptor antagonists (eg, famotidine 0.5–1 mg/kg, PO, SC, or IV, bid) or proton pump inhibitors (eg, omeprazole 0.7–2 mg/kg/day, PO, or pantoprazole 1 mg/kg/day, IV) may also be indicated. In dogs, omeprazole may provide better gastric acid suppression and better prevention of exercise-induced gastritis than famotidine.

Chronic Gastritis: Chronic gastritis should be considered in animals with intermittent or persistent vomiting that lasts >7 days and that cannot be attributed to dietary indiscretion or intolerance; drug, toxin, or foreign body ingestion; systemic illness; endoparasitism; infection (bacterial or viral); or neoplasia. The most common clinical sign is intermittent vomiting of food or bile. Systemic illness, weight loss, and GI ulceration are infrequent and should raise suspicion of a more serious condition or diffuse GI inflammation (eg, inflammatory bowel disease, pythiosis, etc).

Histologic evaluation of endoscopic or surgical gastric biopsies is required for

definitive diagnosis and classification of chronic gastritis. A CBC, serum biochemical profile, urinalysis, total thyroid hormone concentration (cats), basal serum cortisol concentration possibly with an ACTH-stimulation test (to exclude canine hypoadrenocorticism), and fecal evaluation for endoparasitism are indicated but are frequently unremarkable in animals with chronic gastritis. Diagnostic imaging (plain and/or barium contrast abdominal radiographs, abdominal ultrasound) can identify foreign objects, neoplasia, pyloric stenosis, gastric antral mucosal hypertrophy, discrete or multifocal mucosal or mural abnormalities, intra-abdominal lymphadenomegaly, or other intra-abdominal pathology, and is indicated before gastric biopsy.

Lymphocytic-plasmacytic gastritis and **eosinophilic gastritis** are characterized by diffuse infiltration of the gastric mucosa and lamina propria with lymphocytes and plasma cells, or eosinophils, respectively. Similar cellular infiltrates may be seen in the small intestine. Concomitant lymphoid hyperplasia, mucosal atrophy, or mucosal fibrosis is infrequently seen. Dietary allergy or intolerance, occult parasitism, or hyperimmune response to normal antigens have been proposed as possible causes. Eosinophilic gastritis with eosinophilia and/or skin lesions should raise suspicion for dietary sensitivity or hypereosinophilic syndrome (cats).

Animals with mild clinical signs and mild histologic lesions may respond to symptomatic care (see p 387), empirical deworming, and exclusive feeding of a hypoallergenic or novel protein diet (eg, balanced homemade diet or many commercially available options). In addition to symptomatic care, empirical deworming, and dietary modification, animals with moderate to severe, histologically confirmed disease generally require immunosuppressive therapy. Prednisone (or prednisolone in cats) is started at 2 mg/kg/day, PO (dogs), or 2–4 mg/kg/day, PO (cats), and tapered to the lowest dosage that controls clinical signs. Assuming continued clinical remission, prednisone therapy is ultimately discontinued and strict adherence to dietary therapy maintained. If clinical signs persist despite gastroprotectant therapy, dietary modification, and prednisone therapy, treatment with an additional immunosuppressive agent (dogs: azathioprine 2 mg/kg, PO, every 24–48 hr; cats >4 kg: chlorambucil 2 mg [total dose], PO, every 48 hr for 2–4 wk then tapered to 2 mg every 72–96 hr; cats <4 kg: chlorambu-

cil 2 mg [total dose] every 72 hr; dogs and cats: cyclosporine 3–5 mg/kg/day, PO) can be considered.

Chronic atrophic gastritis is often characterized by marked mononuclear cell infiltration, thinning of the gastric mucosa, and atrophy of the gastric glands. A unique, breed-associated form of atrophic gastritis in Norwegian Lundehunds has not been associated with *Helicobacter* spp infection but has been associated with gastric adenocarcinoma. The role, if any, of *Helicobacter* spp infection in the development of atrophic gastritis is unknown. However, if *Helicobacter* spp organisms are identified in gastric biopsy specimens, treatment is indicated (see p 394). Additional treatment options include dietary management and immunosuppression as for lymphocytic-plasmacytic and eosinophilic gastritis (see above); however, data with respect to treatment efficacy and prognosis are lacking.

Chronic hypertrophic gastropathy is characterized by diffuse or focal hypertrophy of the gastric mucosa, muscularis, or both, with variable inflammatory infiltrates. The lesion is often most pronounced in the pyloric region, with resultant gastric outflow obstruction. Projectile vomiting of food within hours of eating may be described. Older, male, small-breed dogs are overrepresented (eg, Lhasa Apso, Shih Tzu, Maltese, Miniature Poodle). Hypergastrinemia due to exaggerated secretion (eg, gastrin-secreting neoplasia, Basenji gastroenteropathy) or inadequate clearance (eg, hepatic or renal disease, achlorhydria) may initiate mucosal hypertrophy. Surgical correction via pyloroplasty and/or removal of hypertrophied tissue may be required to alleviate clinical signs.

GASTROINTESTINAL NEOPLASIA

GI neoplasia is uncommon in dogs and cats, with gastric tumors representing <1% and intestinal tumors <10% of overall neoplasia in these species. GI neoplasms tend to be malignant. The average age of dogs with GI neoplasia is 6–9 yr and of cats 10–12 yr.

Etiology and Pathophysiology: Specific etiologic agents for GI neoplasia have not been identified. The increased risk of Belgian Shepherds for gastric carcinoma, and of Siamese cats for intestinal adenocarcinoma and lymphoma may reflect genetic predispositions. Feline leukemia has been suggested to be an underlying factor in development of feline GI lymphoma, even in cats with a negative retroviral status.

Helicobacter infections are associated with gastric neoplasia in people, but similar direct links have not been established in dogs or cats.

Adenocarcinomas are the most common GI neoplasia in dogs and are typically found in the duodenum, colon, and rectum. Gastric adenocarcinomas are common in dogs and frequently affect the lower 1/3 of the stomach (eg, lesser curvature and pyloric region). Adenocarcinoma is commonly identified in the feline intestinal tract, especially in the jejunum and ileum. Adenocarcinomas are very aggressive and frequently metastasize to regional lymph nodes, liver, and lung. At the time of diagnosis in dogs, as many as 44% of intestinal and as many as 95% of gastric adenocarcinomas have metastasized. Adenomas and carcinomas *in situ* are uncommonly found in the GI tract of dogs or cats. These polyp-like masses are usually solitary and located in the colon or rectum in dogs.

Lymphoma is the most common feline GI neoplasia, and it is also common in dogs. GI lymphoma most commonly affects the small intestine as well as extra-gastrointestinal organs such as the liver. Two subtypes of feline GI lymphoma have been reported: a low-grade, small-cell lymphocytic lymphoma and a more aggressive, poorly differentiated, large-cell, lymphoblastic lymphoma. Canine GI lymphoma is usually poorly differentiated and aggressive, similar to lymphoblastic lymphoma in cats.

GI stromal tumors (GISTs) are mesenchymal in origin in dogs; they are rarely seen in cats. One of the major diagnostic criteria for GISTs include positive c-kit (CD117) reaction on immunohistochemistry. Before the recognition of GISTs, many of these tumors were likely classified as leiomyosarcomas. GISTs typically are found in the cecum and large intestine. In contrast, leiomyosarcomas are most common in the stomach and small intestine. The metastatic rate is as high as 30% with leiomyosarcomas and likely lower with GISTs. Uncommon GI tumors of dogs and cats include mast cell tumors, leiomyomas and leiomyosarcomas, fibrosarcomas, and plasmacytomas.

Clinical Findings: Clinical signs of GI neoplasia depend on the location and extent of the tumor and its possible metastases or paraneoplastic syndromes (eg, hypercalcemia, hypoglycemia). The most common clinical signs associated with GI neoplasia include vomiting (with or without blood), anorexia, weight loss, diarrhea, and lethargy. Signs of constipation or tenesmus

may accompany colonic and rectal tumors. An abdominal mass or organomegaly may be palpable on physical examination. Abdominal pain and ascites may reflect peritonitis secondary to a ruptured portion of neoplastic bowel.

Diagnosis: Routine laboratory studies and plain radiographs do not show specific changes associated with GI neoplasia. Hypoglycemia is often associated with leiomyomas/leiomyosarcomas. Hypercholesterolemia and increased alkaline phosphatase activity has been seen in some nonlymphomatous neoplasia. Microcytic anemia with or without hypoproteinemia is a common finding with ulcerated masses and chronic blood loss. Electrolyte and acid-base disturbances may reflect ongoing vomiting and can include hyponatremia, hypokalemia, and metabolic alkalosis or acidosis. Paraneoplastic hypercalcemia has been associated with lymphoma and intestinal adenocarcinoma.

Contrast abdominal radiographs may reveal mass lesions in the GI tract or areas of ulceration. Abdominal ultrasonography may reveal focal or diffuse thickening of the GI tract and loss of normal layering. Regional lymph nodes may be enlarged, and splenomegaly and/or hepatomegaly may accompany some cases of GI lymphoma. Ultrasound can facilitate fine-needle aspirates or needle biopsy sample collection for cytologic or histologic analysis.

Endoscopy of the upper and lower GI tract can facilitate identification and partial-thickness biopsy of GI neoplasia. However, endoscopic biopsy collection is limited by the small size and superficial nature of the biopsy, because some GI tumors are submucosal and this technique may only collect superficial mucosa. A false diagnosis of gastritis or enteritis may reflect inflammation of the mucosa overlying a neoplastic process. In one study, endoscopic biopsies were adequate to detect feline gastric lymphoma but not adequate to differentiate inflammatory bowel disease from lymphoma in the GI tract. Recent studies suggest that endoscopic ileal biopsies aid in the diagnosis of lymphoma and other GI diseases, compared with endoscopic duodenal biopsies. Full-thickness surgical biopsies collected via laparoscopy or laparotomy may more suitably establish a diagnosis and will allow for biopsy of regional lymph nodes and liver to evaluate for metastasis. Immunohistochemistry may be required to differentiate between types of neoplasia for GI biopsies.

PCR for antigen receptor rearrangement detects clonality of a population of lymphocytes and can aid in the diagnosis of GI lymphoma when performed on inconclusive biopsy sections, especially in cats.

Treatment and Prognosis: Surgical excision of the tumor is recommended for nonmetastatic, nonlymphomatous neoplasia. Curative resection, with margins of ≥ 4 cm, should be attempted.

The median survival time for GI adenocarcinoma in dogs is 10–15 mo if the tumor was focal and completely resected but only 3 mo if metastasis is present at diagnosis. Adjuvant chemotherapy (eg, carboplatin) may be prescribed; optimized chemotherapy protocols for treatment of GI adenocarcinoma have not been reported. GI lymphoma is typically treated with chemotherapy. Phenotypic variations of feline GI lymphoma warrant different treatment strategies.

Small-cell (well-differentiated, low-grade) lymphoma is treated with prednisone (2 mg/kg/day, PO) and chlorambucil (either 2 mg PO every other day or 15 mg/m² daily for 4 days, every 3 wk). The prognosis associated with small-cell GI lymphoma is good, with a median survival time of 765 days. Poorly differentiated GI lymphoma in dogs and cats is poorly responsive to chemotherapy. If treatment is attempted, a multidrug chemotherapy protocol (eg, Wisconsin-Madison) is recommended, but complete remission rates are low, and median survival times are usually <3 mo. Focal lymphoma may be surgically excised, and follow-up chemotherapy may be recommended. GISTs and leiomyosarcomas are slow-growing and slow to metastasize. In a study of dogs with a diagnosis of either leiomyosarcoma or GIST, median survival time was 37 mo after complete resection, although another report suggests that GISTs are associated with a better survival rate than leiomyosarcomas. Malignant GI neoplasia usually has a poor prognosis (survival <6 mo), even with surgical and medical therapy. Benign lesions, such as leiomyomas and colorectal adenomas, have a good prognosis with surgical excision.

GASTROINTESTINAL OBSTRUCTION

GI obstruction often leads to intractable vomiting, the consequences of which can be life-threatening and include possible aspiration, electrolyte and acid-base disturbances, and dehydration. Depending on the underlying cause of the obstruction, the site can undergo tissue damage resulting

in perforation, endotoxemia, and hypovolemic shock. Therefore, GI obstruction should be treated as an emergency.

Etiology and Pathophysiology: GI obstruction can be secondary to extraluminal, intramural, or intraluminal causes. The most common extraluminal cause of GI obstruction is intussusception, in which an invaginated segment of the GI tract becomes enveloped by an antegrade or retrograde segment. Intussusception can be secondary to endoparasitic infection, parvoviral infection, foreign body ingestion, or neoplasia, but is often idiopathic. Intestinal intussusception occurs most commonly at the ileoceocolic junction. Gastroesophageal and pylorogastric intussusceptions are uncommon, acute, severe forms of intussusception associated with a high mortality rate. German Shepherds may be predisposed to gastroesophageal intussusception. Intestinal entrapment in hernias or mesenteric rents can result in strangulation of bowel and rapid development of hypovolemic shock.

Intramural obstruction can be caused by infiltrative disease such as neoplasia, fungal infection (eg, pythiosis), and granulomas (eg, secondary to feline infectious peritonitis). Pyloric stenosis can cause gastric outflow obstruction and has been reported as a congenital condition in brachycephalic breeds. Intraluminal obstruction commonly occurs in dogs and cats secondary to ingestion of a foreign body.

Most cases of acute vomiting are not a result of GI obstruction and are self-limiting. Vomiting may be a result of dietary indiscretion, parasitic infection, bacterial or viral gastroenteritis, anxiety, or motion sickness. In these cases, treatment usually involves withholding food for a short period, feeding an easily digested diet, and offering small amounts of water frequently. Careful monitoring for persistent vomiting, depression, abdominal discomfort, and/or fever is critical. If vomiting persists, reevaluation is warranted. Abdominal palpation should be performed, looking for signs of a foreign body or abdominal discomfort. Careful examination of the oral cavity in cats, looking for evidence of yarn, thread, or needles, is important. Abdominal radiographs should be performed, looking for radiopaque foreign objects or signs of intestinal distention, indicating possible obstruction.

Obstruction secondary to foreign body ingestion can be partial or complete if the

foreign body is unable to pass through the GI tract. Linear or small foreign bodies are more likely to cause partial obstruction, whereas large, round objects often result in complete obstruction. Foreign bodies are usually objects that cannot be digested (eg, plastic, rocks), are slowly digested (eg, bones), or are too large to pass through the GI tract. Some dogs are indiscriminate eaters and will consume such objects, whereas cats more typically ingest linear foreign bodies (eg, string, yarn, dental floss) while playing with them.

GI obstruction may be due to one or more foreign bodies. The decision to treat medically or proceed with surgery can be a challenge. Some small objects identified radiographically will pass through the GI tract. Passage of these objects can be monitored with serial radiographs if the animal is clinically stable. Failure of these objects to pass within 48 hr, serial radiographic evidence that the objects are not moving, or a deterioration of clinical signs necessitate surgical removal. Presence of uncooked bone matter in the stomach should be monitored but is usually resolved by normal digestive processes in the stomach.

Regardless of underlying etiology, unresolved GI obstruction leads to distention of the more proximal GI tract with fluid and gas. If entrapment of GI loops results secondary to hernias or mesenteric rents, strangulation and bowel incarceration occurs. Venous return is impaired but arterial flow maintained, leading to congestion, anoxia, and necrosis. Obstruction or strangulation of bowel can result in devitalization of the GI tissue and translocation of bacteria such as *Escherichia coli* and *Clostridium* spp from the GI lumen to the tissue. If not corrected, edema, hemorrhage, mucosal sloughing, and eventually bowel necrosis occur.

Clinical Findings: Intussusception occurs most commonly in young dogs. Intestinal intussusception typically causes signs of abdominal pain, vomiting, and diarrhea with or without blood. More proximal intussusceptions (ie, gastroesophageal, pylorogastric) result in vomiting and regurgitation.

Young cats and young, large-breed dogs are more likely to present with signs of foreign body obstruction than older animals. Clinical signs are variable, depending on duration, degree, and location of the foreign body but often include vomiting and anorexia. Vomiting is less common with distal, small-intestinal

obstruction. Diarrhea, weight loss, lethargy, and signs of septic shock are less common. Physical examination may be unremarkable or may reveal signs of abdominal pain or a palpable intestinal mass. Physical examination must be thorough and include inspection of the oral cavity, because linear foreign bodies in cats may be anchored to the base of the tongue. If a linear foreign body is present in the oral cavity, it must be cut immediately and never pulled in hopes of retrieving the foreign body.

Signs of hypovolemic shock and abdominal pain usually accompany cases of intestinal incarceration.

Diagnosis: Laboratory findings associated with GI foreign bodies include leukocytosis with a mild left shift. Marked leukocytosis or leukopenia with a degenerative left shift can be present in cases of GI perforation and secondary bacterial peritonitis or sepsis. A wide variety of electrolyte and acid-base changes have been described. Proximal GI obstruction has typically been associated with hypochloremia, hypokalemia, and metabolic alkalosis, whereas more distal GI obstruction is associated with metabolic acidosis. In a study in dogs, hypochloremia and metabolic alkalosis were the two most common changes regardless of the site of GI obstruction. Hyperlactatemia and hemoconcentration (increased PCV and total solids) are also frequently identified.

Plain radiographs may assist in diagnosis of GI obstruction in cases of radiopaque foreign bodies. Complete obstruction may result in radiographic findings such as ileus and intestinal loop dilation with fluid and/or gas, whereas linear foreign bodies can create intestinal plication. These findings are not specific for GI foreign bodies, however, and can be seen with other causes of GI obstruction, including intestinal stricture, adhesions, intussusception, and neoplasia. Contrast abdominal radiographs may be useful in detection of radiolucent foreign bodies that create filling defects and in cases of intussusception. Barium is commonly used for contrast radiographs, but if GI perforation is suspected, aqueous iodine or iohexol should be used instead.

Abdominal ultrasonography can help identify the presence of GI foreign bodies and dilation of intestinal loops with fluid. Transverse sonographic views of intestinal intussusceptions often show a "target-like" lesion with concentric hyperechoic and hypoechoic rings. Large amounts of intestinal gas may obscure the ultrasound view. Signs of peritonitis and GI perforation

detectable with radiographs or ultrasound include abdominal effusion or free gas. Abdominal effusion, if present, should be cytologically examined to evaluate for septic peritonitis. Endoscopic examination may help identify foreign bodies and mass lesions.

Treatment: Small, smooth foreign bodies may pass uneventfully through the GI tract. If this approach is taken, monitoring with abdominal radiographs to track the movement of the foreign body is recommended. If the foreign body is not moving, and if obstruction or worsening of clinical signs is apparent, intervention is required.

In most cases, removal of detected foreign bodies via endoscopic or surgical retrieval is recommended because of the potential for obstruction or perforation. Detection of colonic foreign bodies is often incidental, and these usually do not require removal. If a colonic foreign body is causing clinical signs, endoscopic removal is preferred over surgically opening the colon. Fluid, electrolyte, and acid-base disturbances should be corrected before anesthesia if possible.

Endoscopic or surgical retrieval of foreign bodies causing GI obstruction is associated with a high survival rate. The utility of endoscopy is typically limited to the retrieval of gastric foreign bodies. Endoscopy cannot assess the GI tract distal to the pyloric or proximal duodenal region. If endoscopy is used to retrieve a proximal GI foreign body, the scope should be passed into the small intestine as distally as possible for evaluation, with radiographs taken before recovery from anesthesia to exclude the presence of multiple foreign bodies.

An exploratory laparotomy is indicated if a foreign body distal to the pyloric region is present, if there are foreign bodies at multiple locations, if there are signs of septic peritonitis, or if endoscopy is not available. Exploratory laparotomy is also indicated over endoscopy in cases of suspected intussusception and obstruction secondary to a mass lesion. The entire GI tract must be inspected for objects that could cause obstruction. Vitality of the GI tract must also be assessed, and areas of perforation or ischemia resected. If a linear foreign body is present in the stomach and extends into the small intestine, gentle manipulation may easily free the foreign body from its distal attachments, allowing removal through the gastrotomy incision. Otherwise, multiple enterotomies may be indicated. The minimal number of enterotomies possible to remove

the foreign body or bodies is recommended to help decrease the risk of postoperative dehiscence. Linear foreign bodies in cats can be particularly challenging, because the foreign material may be a single piece of thread, yarn, or dental floss that is not palpable, which makes assessment of its length difficult. Multiple solid, smooth intestinal foreign bodies can often be "milked" through the intestine and removed through one incision. Linear foreign bodies are more likely to cause GI mucosal damage and devitalization and can affect a large section of the GI tract. Devitalized or perforated areas of the GI tract must be resected, and the remaining GI tract anastomosed. Intussusceptions are manually reduced or resected, and the remaining bowel anastomosed if reduction is not possible or the bowel loop appears compromised. Laparoscopic-assisted exploration and foreign body retrieval is gaining popularity among veterinary surgeons with suitable expertise and equipment.

After foreign body retrieval, correction of fluid, electrolyte, and acid-base disturbances should continue. Peritonitis is treated with antibiotics and closed suction drains. If the animal is not vomiting, water may be offered 12 hr after anesthetic recovery. Food may be introduced 12–24 hr after recovery if there is no vomiting.

Prognosis and Prevention: Outcome for animals with GI foreign body obstruction is good if the condition is recognized and treated quickly. Animals with severe clinical signs resulting from systemic factors such as concurrent infection or debilitation, hypovolemia, and shock are at higher risk of delayed healing and incisional breakdown. Marked preoperative hypoalbuminemia (<2 – 2.5 g/dL) is associated with a higher rate of postoperative dehiscence. Animals presenting with signs of peritonitis or sepsis have more postoperative complications and are at higher risk of enterotomy dehiscence. Animals with signs of peritonitis, or those requiring resection of a large amount of intestine leading to short-bowel syndrome, have a guarded prognosis. Dehiscence of the intestinal surgical site most commonly occurs 3–5 days after surgery at the end of the lag phase of healing. Until this point, most tensile strength has been provided by formation of a fibrin seal that is degraded by macrophages 3–5 days after surgery. Postoperative dehiscence usually requires a second surgery and is associated with a high mortality rate.

Gastroesophageal and pylorogastric intussusceptions are associated with a high mortality rate, and rapid diagnosis and surgical intervention are essential to maximize chance of survival in these cases. GI obstruction secondary to neoplasia is uncommon, and prognosis depends on the type of neoplasia.

GASTROINTESTINAL ULCERS

Ulceration and disruption of the GI mucosal barrier can be a consequence of several drugs and diseases in small animals. As a result, gastroprotectant therapies are widely used in veterinary patients.

Etiology and Pathophysiology:

The gastric mucosal barrier is a complex defense mechanism that protects the normal mucosa from the harsh chemical environment of the gastric luminal contents. The acids, pepsin, and proteolytic enzymes normally present in the gastric lumen have a pH of 2. The mucous layer provides a weak buffer, maintaining a pH of 4–6 and neutralizing the acidic luminal contents. The GI barrier is maintained by a protective layer that includes mucosal cells, tight junctions, and a thick layer of mucus. High blood flow to this area supports cellular metabolism and rapid renewal of injured cells. Prostaglandins (mainly E and I) help maintain the GI mucosal blood flow and integrity, increase secretion of mucus and bicarbonate, decrease acid secretion, and stimulate epithelial cell turnover. Tight junctions seal the cellular layers of the gastric mucosa, ensuring that the luminal contents do not leak into or around these cells. The small amount of gastric acid that diffuses into the epithelial cells is quickly cleared by the high blood flow to this area.

A defect in the GI mucosal barrier leads to a self-perpetuating cycle of mucosal damage. Injury to this barrier allows hydrochloric acid, bile acids, and proteolytic enzymes to degrade the epithelial cells, disrupt lipid membranes, and induce inflammation and apoptosis. Back diffusion of luminal contents through the tight junctions leads to inflammation and hemorrhage of the GI cells, with further acid secretion mediated by inflammatory cells and their products. Mast cell degranulation occurs, causing histamine release that perpetuates further gastric acid secretion. The inflammatory environment also causes decreases in blood flow (resulting in ischemia), ability for cellular repair, and secretion of mucus and cytoprotective prostaglandins. Mucosal

ulceration can result, exposing the submucosa or deeper layers of the GI tissue to the luminal contents.

In the normal GI tract, the potential disruptive properties of the luminal contents are balanced by the defense mechanisms of the GI mucosal barrier. However, many drugs and disease have the potential to upset the balance between the harsh luminal contents and the GI protective barrier.

The incidence of GI ulceration in dogs and cats is unknown. NSAID administration, neoplasia, and hepatic disease are the most common causes in dogs. NSAIDs can cause direct topical damage to the GI mucosa, and inhibition of cyclooxygenase (COX)-1 decreases production of protective prostaglandins. The use of COX-2-specific NSAIDs is thought to decrease GI ulceration, but ulceration and perforation still occur with use of these medications. Corticosteroids potentiate the effects of mucosal damage by decreasing cell turnover and mucus production and by stimulating gastrin (and acid) production.

Hepatic disease is associated with increased gastric acid secretion and alterations in mucosal blood flow, potentially leading to ulcer formation. Primary GI neoplasia such as lymphoma, adenocarcinoma, leiomyoma, and leiomyosarcoma can result in ulceration. Additionally, paraneoplastic syndromes secondary to mast cell tumors and gastrinomas (Zollinger-Ellison syndrome) have been associated with increased gastric hydrochloric acid production and ulceration in dogs.

Other drugs and diseases associated with GI ulceration in dogs include corticosteroid use in dogs with spinal disease, renal disease, hypoadrenocorticism, stress, primary GI disease (eg, inflammatory bowel disease), extreme exercise (eg, sled dog racing), shock, and sepsis. The role of *Helicobacter* infection in GI ulceration is unknown, because *Helicobacter* organisms have been found in healthy dogs and cats.

GI ulceration is uncommonly reported in cats. Neoplasia (eg, lymphoma, adenocarcinoma) has been associated with GI ulceration in cats, but the cause is often unknown.

Clinical Findings: Specific clinical signs of GI ulceration include melena, hematemesis, and hematochezia. Abdominal pain, anorexia, and signs of underlying disease may be present. Cats with GI ulceration rarely show specific signs such as melena or hematemesis but frequently show signs of

life-threatening hemorrhage. Animals with severe ulceration and/or GI perforation may present with signs of pain, weakness, pallor, and shock. Clinical signs of a causative factor may be seen. Some dogs and cats with GI ulceration do not show any clinical signs.

Diagnosis: A CBC, serum biochemistry profile, and urinalysis can help differentiate primary GI disease from non-GI disease and can identify metabolic derangements resulting from GI disease. Additional testing, such as liver function tests or an adrenocorticotrophic hormone stimulation test, may be warranted depending on the clinical findings and initial test results.

Abdominal radiographs generally do not help diagnose GI ulceration, but they can help exclude GI obstruction, intussusceptions, and peritonitis. Abdominal ultrasonography may show abnormalities in GI wall thickness or presence of a mass, but its primary utility is the identification of non-GI lesions. Endoscopy allows visualization of the esophagus, stomach, duodenum, and colon and identification of mucosal lesions and ulcers. Endoscopy also allows for fine-needle aspirates of lesions or collection of biopsy samples, although full-thickness surgical biopsies may be required to identify infiltrative disease and tumors. Ulcerated areas should be biopsied only on the periphery to avoid perforation. Gastric fluid can be tested for pH to help diagnose hypersecretory states.

Treatment and Control: Primary treatment of GI ulceration is directed at the underlying cause. Supportive care may be required to correct metabolic derangements and can include fluid therapy. Medication directed at the ulcer itself reduces gastric acidity, prevents further destruction of GI mucosa, and promotes ulcer healing. In general, antiulcerative therapy should be continued for 6–8 wk.

Gastric acid production is stimulated by histamine (most potent), gastrin, and acetylcholine. Drugs that decrease acid secretion help protect damaged GI mucosa. H_2 -receptor blockers (eg, cimetidine, famotidine) help promote mucosal healing, and some agents also act as prokinetics (eg, ranitidine). Famotidine (0.5–1 mg/kg, bid, PO, SC, or IV) has been shown to be more potent in reducing gastric pH than other H_2 -blockers such as cimetidine or ranitidine. Proton pump inhibitors (eg, omeprazole 0.5–1 mg/kg/day, PO, or pantoprazole 0.5–1 mg/kg/day, IV) offer more complete inhibition of gastric acid secretion and are therefore useful for more severe ulcers.

Prophylactic use of H_2 -blockers and proton pump inhibitors to prevent GI ulceration is controversial but may be considered in animals receiving NSAIDs or that have other risk factors.

Cytoprotective agents include antacids and sucralfate. Antacids are weak bases that help neutralize gastric acid within the stomach lumen. These drugs may also promote gastric prostaglandin production. Aluminum or magnesium-containing antacids are considered the most effective agents with the fewest adverse effects, although these drugs can lead to constipation. Because of their short half-life (2–3 hr), animals may experience a rebound gastric acidity between doses, and the drugs must be given frequently. Sucralfate (dogs: 0.5–1 g, PO, bid-td; cats: 0.25 g, PO, bid-td) is a polyaluminum sucrose sulfate that binds to areas of eroded or ulcerated GI mucosa. Because this drug inhibits absorption, it should not be given within 1–2 hr of food or other drugs.

The prostaglandin E_2 analogue misoprostol is used to help prevent NSAID-associated ulcer formation but does not assist in mucosal healing or decrease acid secretion.

Prophylactic use of antibiotics can be considered in cases of major GI mucosal barrier disruption or shock, or in other cases when clinicopathologic signs (eg, fever, hematochezia, leukopenia, neutrophilia) suggest that bacterial translocation is of concern. First-line antibiotic therapy includes the β -lactams, with additional gram-negative coverage if necessary.

Prognosis: The prognosis for GI ulceration in dogs is favorable when the underlying cause can be treated or removed, ulceration is mild, or the condition is rapidly diagnosed and treated. Ulceration associated with severe or end-stage conditions (eg, hepatic insufficiency) is difficult to control. Mortality rates associated with GI perforation range as high as 70%.

GI ulceration in cats is often related to neoplasia. Intensive care frequently is needed because of the high prevalence of marked hemorrhage. In one report, median survival of cats with gastric ulceration treated with surgery and palliative care ranged from 12–15 mo. Cats with GI ulceration secondary to a non-neoplastic disease have less severe clinical disease and a good prognosis.

HELICOBACTER INFECTION

Helicobacter spp are commonly found in the stomachs of both healthy and vomiting

dogs and cats, but their significance is not well defined. Although *H pylori* infections in people have been linked to gastritis, peptic ulcers, and a higher rate of gastric neoplasia, similar direct casual relationships between *Helicobacter* infections and GI disease have not been established in dogs and cats.

Etiology and Pathophysiology:

Helicobacter organisms are spiral or curved, gram-negative, motile, flagellated organisms. *H pylori* is the most commonly reported species in human GI infections, but non-*H pylori* organisms (such as *H felis*, *H heilmannii*, and *H bizzozeronii*) are more common in dogs and cats. At least 38 different *Helicobacter* species have been identified in animals, and infected animals can harbor multiple species.

Helicobacter organisms have been identified most commonly in the gastric tissue of dogs and cats, especially in the fundus and cardia of the stomach, but they are also found in the intestinal tract. Colonization of gastric mucosa appears to be most prevalent in the surface mucus layer, as well as within the gastric glands and parietal cells. There have been sporadic reports of *Helicobacter* organisms identified in the hepatic tissue of a dog with multifocal necrotizing hepatitis, as well as in healthy cats and in cats with cholangiohepatitis.

Transmission of *Helicobacter* infections between groups of dogs or cats is unclear, and reservoir hosts have not been defined. Because of the increased rate of morbidity and mortality associated with *Helicobacter* infections in people, concern of zoonotic transmission has been raised (see below).

Clinical Findings and Diagnosis:

Studies report as many as 100% of healthy dogs and cats are positive for *Helicobacter* infections; similar infection rates are reported in vomiting dogs and cats. In people, *H pylori* infection is associated with gastritis, peptic ulcers, and an increased risk of gastric neoplasia. Gastritis, vomiting, and diarrhea have been associated with *Helicobacter* infection, although a direct causal relationship has not been identified. Peptic ulceration is rarely associated with *Helicobacter* infections in dogs and cats.

Diagnosis involves upper GI endoscopy or exploratory laparotomy. Surface mucus from a large area of the stomach can be obtained by taking brush samples via endoscopy. If organisms are present, they are readily identified under 100 $\times$ oil-immersion magnification. Because brush cytology

samples a large area of the stomach, the sensitivity of this test is high.

Gastric biopsies should be obtained from multiple areas in the stomach, because organism distribution can be patchy. Routine H&E staining is usually sufficient to identify organisms, although special silver stains may be required if the organisms have a glandular location. Mucosal inflammation, glandular degeneration, and lymphoid follicle hyperplasia accompany some infections. Cytology and histopathology is not sufficient to identify specific species. A commercially available rapid urease test to detect production of bacterial urease in gastric biopsies can identify the presence of *Helicobacter* organisms. However, because cytology and histopathology are highly sensitive and specific for detection of *Helicobacter* infections, urease testing may not add further diagnostic information in some cases.

Noninvasive tests for *Helicobacter* infection available in the research setting include urea breath testing, fecal antigen detection, and serology.

Treatment: The lack of knowledge regarding the pathogenicity of *Helicobacter* infections in dogs and cats makes treatment decisions difficult. *H pylori* infections in people are treated with double or triple antimicrobial agent therapy plus an acid secretory inhibitor (eg, clarithromycin, amoxicillin, bismuth, and ranitidine) for 2 wk, and similar therapeutic approaches have been used in veterinary medicine.

Currently, the role of *Helicobacter* as a causative agent of gastritis in dogs and cats is unclear. Treatment decisions for dogs and cats should be based on presence of *Helicobacter*, in combination with appropriate clinical signs and/or gastric lesions. In many veterinary studies, *Helicobacter* infections have been difficult to eradicate. Recommended treatment regimens include amoxicillin or tetracycline, metronidazole, bismuth subsalicylate, and a proton pump inhibitor (eg, omeprazole) or H_2 -receptor blocker (eg, famotidine) for 2–3 wk. Other treatment combinations of omeprazole and azithromycin or clarithromycin have been described. Although many dogs and cats treated with the above combinations did not experience longterm eradication of *Helicobacter* infection, when retested, the frequency of vomiting and gastric lesions did improve with therapy for many patients.

Zoonotic Risk: Zoonotic transmission of *Helicobacter* infections from dogs and cats

to people is possible. *H. canis*, *H. felis*, *H. heilmannii*, and other species naturally colonize the stomachs of dogs and cats, and these strains of *Helicobacter* have been linked to gastritis, ulcers, and lymphoma in people. Whereas many strains of *Helicobacter* in dogs and cats are genetically distinct from those implicated in human infections, at least one case report documents a genetically identical strain of *H. heilmannii* infecting pet dogs and a child in the same house. Although some studies have suggested a higher risk of *Helicobacter* infection in people in contact with dogs and cats, other research refutes this. Given the unknown risk of transmission, proper hygiene practices are encouraged, and identification of infections in dogs and cats with chronic gastritis and vomiting is likely prudent.

HEMORRHAGIC GASTROENTERITIS

Hemorrhagic gastroenteritis (HGE) is a syndrome of dogs characterized by acute vomiting and hemorrhagic diarrhea, often accompanied by hemoconcentration. Young (median age 5 yr), small and toy breed dogs (Yorkshire Terrier, Miniature Pinscher, Miniature Schnauzer, Miniature Poodle, Maltese) are overrepresented. No sex predisposition has been identified.

Etiology and Pathophysiology:

The precise etiology and pathogenesis are unclear, but suspicion that HGE is the result of infection with or hypersensitivity to *Clostridium perfringens* seems reasonable. *Clostridium* spp has been identified by bacterial culture or immunohistopathology in small-intestinal biopsies from dogs with HGE, suggesting an association with clostridial overgrowth. Acute intestinal mucosal hemorrhagic necrosis and neutrophilic inflammation are the predominant histologic lesions, with the most severe lesions occurring in the large intestine. Histologic mucosal lesions are not generally identified in the stomach, leading some to suggest "acute hemorrhagic diarrhea syndrome" may be a more appropriate descriptor. Leakage of fluid, plasma proteins, and RBCs into the intestinal lumen occur secondary to increased intestinal permeability.

Clinical Findings: An acute onset of profuse hemorrhagic diarrhea (often said to resemble raspberry jam) in a small or toy breed dog is characteristic of HGE. Vomiting, anorexia, lethargy, and abdominal

pain are common. Vomiting may precede the onset of bloody diarrhea. Marked, peracute fluid loss can result in hypovolemic shock before clinically recognizable dehydration. Other historical findings (eg, dietary indiscretion, vaccination status, etc) are unremarkable. HGE is not considered contagious.

Diagnosis: The diagnosis is typically based on signalment and acute onset of clinical signs with hemoconcentration (PCV 55%) and normal to slightly decreased total plasma protein concentration. Selective culture for fecal pathogens (eg, *Clostridium* spp, *Salmonella* spp, *Yersinia* spp, *Clostridium* spp, *Campylobacter* spp, enterotoxigenic *Escherichia coli*, etc) and evaluation for *Clostridium* spp enterotoxin by fecal ELISA can be considered. Abnormalities on CBC are usually limited to hemoconcentration and neutrophilic leukocytosis. If neutropenia is present, sepsis and/or parvovirus enteritis may be a concern. Serum biochemical profile may be unremarkable or show mild panhypoproteinemia, hypoglycemia (sepsis, decreased intake with limited hepatic glycogen stores), and electrolyte abnormalities consistent with GI loss and decreased intake (ie, hypokalemia, hyponatremia, hypochloremia). There have been anecdotal reports of mildly prolonged (<10%) coagulation times (activated clotting time, prothrombin time, partial thromboplastin time), potentially attributable to inflammation or interference due to hemoconcentration. If coagulation times are moderately or markedly prolonged, coagulopathy or disseminated intravascular coagulation (DIC) should be investigated. Basal serum cortisol concentration should be normal to increased and is an appropriate screening test for hypoadrenocorticism. Radiographic and ultrasound abnormalities should be limited to diffuse ileus and fluid-filled loops of bowel. Differential diagnoses include bacterial, viral (eg, parvovirus, coronavirus), and parasitic (eg, *Trichuris vulpis*, *Ancylostoma* spp, *Uncinaria* spp) gastroenteritis; systemic disturbances with secondary GI involvement (eg, hypoadrenocorticism, pancreatitis, renal failure, hepatic disease, etc); coagulopathy (eg, rodenticide toxicosis, thrombocytopenia, thrombocytopathia, etc); severe GI ulceration; neoplasia; and GI perforation of any etiology.

Treatment and Prognosis: Aggressive IV fluid therapy is the mainstay of treatment. The rate of isotonic fluid administration is

based on patient perfusion, degree of dehydration, and ongoing losses. Dogs markedly hypoproteinemic or in shock may benefit from synthetic or natural colloid (stored or fresh frozen plasma) therapy. Parenteral antibiotics effective against *Clostridium* spp (eg, ampicillin 22 mg/kg, IV, tid-qid, or metronidazole 7.5 mg/kg, IV, bid) and to decrease the potential for sepsis secondary to intestinal bacterial translocation are indicated. Additional antibiotic coverage for gram-negative bacteria (eg, enrofloxacin 5–10 mg/kg/day, IV) is indicated in animals with sepsis or neutropenia. In a prospective study of dogs with HGE and no clinical indices of sepsis, treatment with amoxicillin-clavulanic acid did not affect mortality rate, duration of hospitalization, or severity of clinical signs. This might suggest not all cases of HGE are due to primary bacterial infection or that the bacteria involved may not be susceptible to amoxicillin-clavulanic acid. Depending on serum potassium concentration, maintenance fluids should be supplemented with potassium chloride at 20–40 mEq/L to prevent development of hypokalemia. Hypoglycemic dogs require dextrose supplementation (2.5%–5%) of maintenance IV fluids. Additional supportive care, including antiemetic therapy and dietary management, are as described above (see CANINE PARVOVIRUS, p 373, and ACUTE GASTRITIS, p 387). Rehydration with a balanced oral electrolyte solution (an initial volume of 7% dehydration [to be replaced over 12 hr] should be offered every 4 hr, along with volumes to account for maintenance fluid requirements and ongoing losses) may be appropriate for dogs with mild dehydration and mild clinical signs.

Prognosis is good with appropriate treatment. However, serious complications, including marked hypoproteinemia, DIC, sepsis, hypovolemic shock, and death, can occur.

INFLAMMATORY BOWEL DISEASE

Idiopathic inflammatory bowel disease (IBD) constitutes a group of GI diseases characterized by persistent clinical signs and histologic evidence of inflammatory cell infiltrate of unknown etiology. The various forms of IBD are classified by anatomic location and the predominant cell type involved. Lymphocytic-plasmacytic enteritis is the most common form in dogs and cats, followed by eosinophilic inflammation. There are occasional reports of inflammation with a granulomatous

pattern (regional enteritis). A neutrophilic predominance in the inflammatory infiltrate is rare. A mixed pattern of cellular infiltrate is described on many occasions. Certain unique IBD syndromes occur more often in some breeds, such as the protein-losing enteropathy/nephropathy complex in Soft-coated Wheaten Terriers, immunoproliferative enteropathy of Basenjis, IBD in Norwegian Lundehunds, and histiocytic ulcerative colitis in Boxers.

Etiology and Pathophysiology: The etiology of IBD is unknown. Several factors may be involved, such as GI lymphoid tissue (GALT); permeability defects; genetic, ischemic, biochemical, and psychosomatic disorders; infectious and parasitic agents; dietary allergens; and adverse drug reactions. IBD may also be immune mediated. The intestinal mucosa has a barrier function and controls exposure of antigens to GALT. The latter can stimulate protective immune responses against pathogens, while remaining tolerant of harmless environmental antigens (eg, commensal bacteria, food). Defective immunoregulation of GALT results in exposure and adverse reaction to antigens that normally would not evoke such a response. Although dietary allergy is an unlikely cause of IBD (except in eosinophilic gastroenteritis), it may contribute to increased mucosal permeability and food sensitivity.

Current evidence supports the likely involvement of hypersensitivity reactions to antigens (eg, food, bacteria, mucus, epithelial cells) in the intestinal lumen or mucosa. More than one type of hypersensitivity reaction is involved in IBD. For example, type I hypersensitivity is involved in eosinophilic gastroenteritis, whereas type IV hypersensitivity is likely involved in granulomatous enteritis. The hypersensitivity reaction incites the involvement of inflammatory cells, resulting in mucosal inflammation that impairs the mucosal barrier, in turn facilitating increased intestinal permeability to additional antigens. Persistent inflammation may result in fibrosis.

Clinical Findings: There is no apparent age, sex, or breed predisposition associated with IBD; however, it may be more common in German Shepherds, Yorkshire Terriers, Cocker Spaniels, and purebred cats. The mean age reported for development of clinical disease is 6.3 yr in dogs and 6.9 yr in cats, but IBD has been documented in dogs <2 yr old. Clinical signs are often chronic and sometimes cyclic or intermittent.

tent. Vomiting, diarrhea, changes in appetite, and weight loss may be seen. In a retrospective study of cats with lymphocytic-plasmacytic enterocolitis, weight loss, intermittent vomiting progressing to more frequent vomiting on a daily basis, diarrhea, and anorexia were seen most often. Vomiting, melena, and cranial abdominal pain are often seen with gastroduodenal ulceration and erosion. Weight loss, vomiting, diarrhea, ascites, and peripheral edema can be seen in the cases of protein-losing enteropathy. Pulmonary thromboembolism is a rare complication; however, it can occur if there is severe intestinal protein loss (loss of antithrombin III). Clinical signs of large-intestinal diarrhea, including anorexia and watery diarrhea, are not uncommon.

An association between gastric dilation and volvulus (see p 384) and IBD in dogs has also been postulated. In this case, inflammation of the bowel may cause alterations in gastric motility and emptying and in GI transit time, thus predisposing to dilation and volvulus.

An association between inflammatory hepatic disease, pancreatitis, and IBD has been reported in cats, although an etiology for this triad of diseases has not been established. However, cats with cholangiohepatitis should also be evaluated for IBD and pancreatitis. Although unproved, it has been suggested that severe IBD in cats may progress to lymphosarcoma.

Diagnosis: There are no specific abnormalities on CBC, biochemical evaluations, or radiographs.

Hypoproteinemia due to reduced dietary intake and malabsorption or increased loss via the GI tract may be seen. Hypocalcemia and hypocholesterolemia may be attributed to malabsorption. Increases in serum amylase as a consequence of bowel inflammation have been reported. Hypokalemia secondary to anorexia, potassium loss from vomiting and diarrhea, and mild increases in serum levels of liver enzymes can be expected. Low serum levels of folate and cobalamin because of malabsorption are also documented.

Eosinophilia may be associated with eosinophilic enteritis; however, this is not a sensitive parameter. Microcytic anemia may be present with loss of iron, associated with chronic loss of blood. Nonresponsive anemia, if present, likely reflects anemia of chronic or inflammatory disease.

Erythrocytosis, associated with fluid loss from vomiting and diarrhea, and a stress leukogram may be seen. Radiographic

changes may include gas or fluid distention of the stomach and increased total diameter of small-intestinal loops. Contrast films may show diffuse or focal mucosal irregularities suggestive of infiltrative disease. Loss of contrast can be related to ascites.

Fecal examination is important to exclude other causes of mucosal inflammation, such as nematodes, *Giardia* infection, and bacterial infection. *Giardia* may be difficult to detect because of intermittent shedding, and empirical treatment with fenbendazole is recommended in all cases.

Abdominal ultrasonography can be used to assess all abdominal organs, examine the entire intestinal tract, and measure wall thickness (although the latter measurement is of no significant value in IBD diagnosis). Small-intestinal hyperechoic mucosal striations are frequently associated with mucosal inflammation and protein-losing enteropathy. Ultrasonography also helps eliminate the possibility of disease in other organs, localize the disease, and determine whether endoscopy would allow biopsy of the site.

Endoscopy allows examination of the esophagus, stomach, duodenum, and sometimes the jejunum, depending on the size of the animal. Colonoscopy allows exploration of the colon. In some cases, gross mucosal lesions may be seen endoscopically, including erythema, friability, enhanced granularity, erosion, and ulceration. In many cases, the endoscopic appearance is normal. However, biopsy samples should always be taken, because the macroscopic and microscopic appearance of the intestinal mucosa are poorly correlated. At least six biopsies of each segment of the GI tract are recommended. Endoscopy is the easiest way to collect biopsy samples, but such samples are superficial and usually can be collected only from the proximal small intestine. One study suggested that ileal biopsies can reveal lesions not apparent in the duodenum and, therefore, should be performed routinely. More specifically, feline lymphoma was much more likely to be found in the ileum than the duodenum. In some cases, exploratory celiotomy and full-thickness biopsy are necessary to reveal histopathologic changes at the level of the mucosa (eg, dilation of the lacteals in lymphangiectasia). However, wound healing can be compromised if there is severe hypoproteinemia or if urgent steroid treatment is needed. For this reason, most clinicians choose to perform endoscopic biopsies unless biopsies of other abdominal organs are required.

Small populations of lymphocytes, plasma cells, macrophages, eosinophils, and neutrophils are normal components of intestinal mucosal tissue. Increased numbers of plasma cells, lymphocytes, eosinophils, and neutrophils in the lamina propria are seen in IBD. However, these morphologic features may also be seen with other causes of GI disease (eg, *Giardia*, *Campylobacter*, *Salmonella*, lymphangiectasia, lymphosarcoma). Although histopathologic assessment of intestinal biopsy material remains the gold standard for diagnosis of many IBDs, it has marked limitations. Specimen quality can vary, pathologic diagnoses are inconsistent, and differentiation between normal specimens and those showing IBD and even lymphoma can be difficult. Biopsy must always be considered in relation to clinical signs, and the animal treated accordingly.

Treatment and Control: The goals of therapy are to reduce diarrhea and vomiting, promote appetite and weight gain, and decrease intestinal inflammation. If a cause can be identified (eg, dietary, parasitic, bacterial overgrowth, drug reaction, etc), it should be eliminated.

Dietary manipulation by itself may be effective in some cases (eg, in chronic colitis); in other cases, it can enhance the efficacy of concurrent medical therapy, allowing for the drug dosage to be reduced or for drug therapy to be discontinued once clinical signs are in remission. Corticosteroids, azathioprine, sulfasalazine, tylosin, and metronidazole are among the drugs most often used in management of IBD.

Unless the animal is debilitated, it is better to institute therapeutic modalities sequentially. The frequency and nature of clinical signs should be monitored, and therapy adjusted as needed. Treatment should begin with anthelmintic/antiparasitic medication (eg, fenbendazole at 50 mg/kg/day, PO, for 3–5 days). This is followed by dietary modification (preferably with an antigen-limited or hydrolyzed protein diet) for 3–4 wk, then a 3- to 4-wk antibacterial trial (usually tylosin 10 mg/kg, PO, tid, or metronidazole 10 mg/kg, PO, bid), and finally trial immunosuppressive therapy (initially prednisolone, 1 mg/kg, PO, bid).

Dietary modification generally involves feeding a hypoallergenic or elimination diet with a source of protein to which the animal has not been previously exposed (eg, home-made diets of lamb and rice or venison and rice, commercial diets). This diet should be the sole source of food for a minimum of 4–6 wk; no treats of any kind should be fed.

Dogs with large-intestinal diarrhea may benefit from diets high in insoluble fiber content (see p 379). Supplementation of dietary fiber alone is rarely effective in animals with severe inflammatory cell infiltrate.

Sulfasalazine (and related drugs) are often used in dogs when IBD is limited to the large intestine. In the colon, this drug is split to release 5-aminosalicylic acid, which exerts its anti-inflammatory activity in the mucosa. The principal adverse effects in dogs are keratoconjunctivitis sicca and vasculitis. Because of the risk of salicylate toxicity in cats (see p 379), sulfasalazine is not routinely used in feline colitis. Newer aminosalicylic drugs without some of sulfasalazine's adverse effects are available, eg, olsalazine (dogs: 10–20 mg/kg, PO, tid) and mesalamine (dogs: 10 mg/kg, PO, tid).

The use of antibiotics can be justified in part by the potential to treat any undiagnosed enteropathogens. Metronidazole (10–20 mg/kg, PO, bid) is the preferred antibacterial for most forms of IBD in small animals. It may have immunomodulatory effects. Tylosin (10 mg/kg, PO, tid) may also have immunomodulatory effects and may have some efficacy in canine IBD. Histiocytic ulcerative colitis of Boxers is responsive to enrofloxacin, which supports the hypothesis that this particular form of IBD is the consequence of an infection with a specific organism.

Corticosteroids may be useful for both small- and large-intestinal disease. Initial dosages are 2 mg/kg/day for prednisone or prednisolone and 0.25 mg/kg/day for dexamethasone. Adverse effects include polyuria, polydipsia, polyphagia, and GI disturbances (eg, vomiting, melena, diarrhea). Dosages should be tapered every 7–10 days to the lowest possible dose required to control clinical signs and, if possible, discontinued altogether. An enteric-coated formulation of the glucocorticoid budesonide has successfully maintained remission in human IBD. A preliminary study has shown apparent efficacy in dogs and cats, but information on use of this drug is limited. It undergoes substantial first-pass elimination via rapid inactivation in the liver; the result is lower systemic bioavailability and reduced effects on the hypothalamic-pituitary-adrenal axis, making iatrogenic hyperadrenocorticism less common than with other glucocorticoids. The optimal dosage in dogs is unknown. Anecdotally, a dosage of 1 mg/m²/day, PO, in dogs, and 1 mg/cat/day, PO, in cats, has been recommended.

In refractory cases, adding an immunosuppressive drug to corticosteroid therapy may be beneficial. Azathioprine (for dogs) and chlorambucil (for cats) can be used. The dosage of azathioprine is 2.2 mg/kg/day, PO. Adverse effects include myelosuppression, pancreatitis, and hepatotoxicity. The dosage of azathioprine can be tapered after several weeks. Typically, the prednisone is tapered first (by 25% every 2–3 wk). After prednisone has been tapered to 0.5 mg/kg every other day without a relapse, then azathioprine is given every other day. If response to steroids is poor, even if combined with azathioprine, cyclosporine can be added at 5–10 mg/kg/day, PO, for at least 8–10 wk. No study has been done to compare cyclosporine and azathioprine. However, one recent study suggested that the combination of chlorambucil-prednisolone was more efficient to treat chronic enteropathy with concurrent protein-losing enteropathy in dogs than the azathioprine-prednisolone protocol.

Azathioprine is not recommended in cats because of sensitivity to adverse effects. Instead, cats are treated with a combination of prednisone and chlorambucil (0.1–0.2 mg/kg or 1 mg/cat). Clinical signs typically improve in 3–5 wk, although 4–8 wk of treatment may be needed. A CBC should be done every 2 wk to monitor for evidence of myelosuppression.

Adjunctive treatment may include ursodeoxycholic acid in cats (10–15 mg/kg/day, PO), cobalamin supplementation (20 mg/kg, SC, every 7 days for 4 wk and then every 28 days for a further 3 mo) in dogs and cats, and other supportive therapy as needed.

The response rate to treatment of IBD is variable. Quality of life tends to be poor, and prognosis is guarded. Hypoalbuminemia is a negative prognostic sign. Prognosis is worse in cases with severe histologic lesions, mucosal fibrosis, eosinophilic enteritis, protein-losing enteropathy, or hypereosinophilic syndrome. Relapses occur and are most often precipitated by dietary indiscretion.

MALABSORPTION SYNDROMES

Malabsorption is the defective uptake of a dietary constituent resulting from interference with its digestion or absorption, due to either exocrine pancreatic insufficiency (EPI) or small-intestinal disease. Malabsorption typically results in diarrhea, altered appetite, and weight loss, but a number of animals (especially cats) will not have overt diarrhea because of the ability of the colon to conserve water.

The primary function of the small intestine is digestion and absorption of

nutrients, and it occurs in sequential phases: intraluminal digestion, mucosal digestion and absorption, and delivery of nutrients to the body. Many chronic, small-intestinal diseases cause malabsorption by interfering with one or several of these processes. Malabsorptive syndromes have been studied in most detail in dogs, but basic diagnostic and therapeutic principles are relevant to other species.

Physiology: The normal digestive processes convert polymeric dietary nutrients into forms (mainly monomers) that can cross the luminal surface (brush border) of intestinal absorptive epithelial cells (ie, enterocytes). Most digestive enzymes are secreted by the pancreas; EPI is thus a major cause of malabsorption. Terminal digestion before absorption is performed by brush border enzymes, either at the brush border surface of the enterocyte in association with transport proteins for the specific products, or when released into the intestinal lumen through cleavage by pancreatic peptidases or through loss of senescent enterocytes.

The main dietary carbohydrates are starch, glycogen, sucrose, and lactose. Starch and glycogen are first hydrolyzed by pancreatic amylase to the oligosaccharides maltose, maltotriose, and α -limit dextrins. These oligosaccharides and ingested disaccharides (sucrose, lactose) are further hydrolyzed to monosaccharides by enzymes located on the brush border of the enterocytes. Brush border lactase activity declines after weaning, especially in cats, and animals may become lactose intolerant, especially if the brush border has been damaged by another disease. The final products of mucosal hydrolysis (glucose, galactose, and fructose) are actively transported into the enterocyte by sodium-linked carrier-mediated processes, driven by a sodium-potassium ATPase. Once in the cell, glucose is not used by the glycolytic pathway but is passed by facilitated diffusion via a transport protein on the basolateral enterocyte membrane down a concentration gradient into the extracellular space, and then by diffusion into the portal venous circulation.

Protein digestion and absorption follow a similar pattern. Proteolytic enzymes from the stomach and pancreas degrade protein into a mixture of short-chain oligopeptides, dipeptides, and amino acids. Oligopeptides are further hydrolyzed by brush-border peptidases to dipeptides and amino acids that cross the brush-border membrane on specific carrier proteins.

Fat-soluble molecules do not need specific carriers to cross the phospholipid barrier of the brush border. However, intraluminal degradation of large lipids is essential. Fat in the duodenum stimulates release of cholecystokinin, which, in turn, stimulates secretion of pancreatic lipase. After solubilization by bile salt micelles, triglycerides are digested by pancreatic lipase to monoglycerides and free fatty acids. At the enterocyte membrane, the monoglycerides and free fatty acids disaggregate from the micelle and are passively absorbed into the cell. Released bile acids remain within the lumen and are ultimately reabsorbed by the ileum and undergo enterohepatic recycling. Once inside the cell, the monoglycerides and free fatty acids are reesterified to triglycerides and incorporated into chylomicrons, which subsequently enter the central lacteal of the villus, being delivered to the venous circulation via the thoracic duct. Medium-chain triglycerides (C_8 – C_{10}) may be absorbed directly into the portal blood, providing an alternative route for fat uptake in case of lymphatic obstruction, but some do normally enter the circulation via the thoracic duct. Consequently, they are no longer recommended in management of lymphangiectasia.

Etiology and Pathophysiology:

Malabsorption is a consequence of interference with mechanisms responsible for either the degradation or absorption of dietary constituents (see TABLE 7).

Diseases that disrupt the synthesis or secretion of digestive pancreatic enzymes cause maldigestion with subsequent malabsorption, so that the end result is the same. An important syndrome is EPI (see p 409), which occurs if there is a loss of ~85%–90% of exocrine pancreatic mass. EPI is characterized by severe maldigestion–malabsorption of starch, protein, and most notably, fat. In dogs, EPI is most commonly due to acinar atrophy; chronic pancreatitis is less common and is seen in older animals, and pancreatic hypoplasia is a rare congenital cause. EPI in dogs is often complicated by secondary antibiotic-responsive diarrhea, which further disrupts nutrient digestion and absorption. EPI is relatively uncommon in cats and is most frequently due to chronic pancreatitis.

Intraluminal effects of bacteria can also have important consequences. Bacterial deconjugation of bile salts interferes with micelle formation, which results in malabsorption of lipid. Deconjugated bile salts and hydroxy fatty acids exacerbate diarrhea by stimulating colonic secretion.

TABLE 7 MECHANISMS OF MALABSORPTION

Location	Disease	Mechanism
Luminal	Exocrine pancreatic insufficiency	Lack of pancreatic enzymes (maldigestion)
	Antibiotic-responsive diarrhea, secondary small-intestinal bacterial overgrowth	Bacterial activity: bile salt deconjugation, fatty acid hydroxylation, competition for cobalamin and nutrients
Mucosal	Inflammatory bowel disease, infectious enteropathies, dietary sensitivities, neoplastic infiltration	Mucosal damage: inflammation, brush border defects, disturbed enterocyte function, reduction of surface area
	Villous atrophy	Reduction in surface area, immature enterocytes due to increased cell turnover
	Brush border enzyme deficiencies	Lactase deficiency, diffuse small-intestinal disease
Postmucosal	Lymphangiectasia	Lymphatic obstruction impairs delivery of chylomicrons
	Vasculitis, portal hypertension	Impaired delivery

True small-intestinal bacterial overgrowth (SIBO) can be secondary to defective gastric acid secretion, interference with normal motility or mechanical obstruction of the intestine, interference with the function of the ileocecal valve, and local immunodeficiency. In other cases, there is no evidence of overgrowth and no defined cause but a lack of overt mucosal damage. However, a positive response to antibiotic therapy indicates that the malabsorption is related to bacteria, perhaps in how the innate immune system (toll-like receptors) respond to bacterial components. Originally called idiopathic SIBO, this syndrome is better termed antibiotic-responsive diarrhea (ARD).

Fat malabsorption may also be seen with a deficiency of intraluminal bile salts due to cholestatic liver disease, biliary obstruction, or ileal disease resulting in defective absorption of conjugated bile salts.

Small-intestinal disease can cause malabsorption by reduction of the number or function of individual enterocytes. Diffuse diseases of the mucosa can result in reduced activities of brush border enzymes, decreased carrier-protein function, decreased mucosal absorptive surface area, and interference with final transport of nutrients into the circulation. Weight loss may be compounded by reduced nutrient intake due to inappetence. In addition, malabsorbed nutrients exert strong intraluminal osmotic effects that diminish intestinal and colonic absorption of water and electrolytes, resulting in diarrhea. This may be exacerbated if mucosal damage is accompanied by intestinal inflammation, which can cause secretory and permeability diarrhea.

Potential causes of mucosal damage include idiopathic inflammatory bowel disease (IBD), enteric pathogens (eg, enteric viruses, pathogenic bacteria, *Giardia*, *Histoplasma*, *Pythium*), dietary sensitivity, ARD, and intestinal neoplasia (eg, lymphosarcoma). Histologic changes such as villous atrophy and infiltration with inflammatory cells indicate intestinal disease but do not identify the underlying cause. For example, lymphocytic-plasmacytic enteritis may be a common response pattern of the intestinal mucosa to more than one provocative agent, particularly microbial and dietary antigens. Definite associations with parasites, pathogenic bacteria, and dietary sensitivity have been demonstrated in dogs, but often the underlying cause cannot be identified.

Mucosal damage may also occur without obvious changes under light microscopy.

This is typified by infection with enteropathogenic *Escherichia coli* (which specifically cause ultrastructural damage to microvilli in an attaching-effacing lesion) and by ARD in dogs, which can cause biochemical damage to the intestinal brush border, interfering with enterocyte function.

The main brush border enzyme deficiency reported is a relative lactase deficiency, leading to milk intolerance in adult dogs and cats. Acquired brush border defects also may be seen in the course of generalized small-intestinal disease.

Postmucosal obstruction may be seen with lymphatic obstruction (especially lymphangiectasia) and vascular compromise (portal hypertension, vasculitis). Intestinal lymphangiectasia causes intestinal protein loss as well as severe fat malabsorption.

Usually, in malabsorption a number of nutrients are affected and consequently diarrhea occurs; malabsorption of a single ingredient without any GI signs is rare (eg, selective cobalamin malabsorption in Giant Schnauzers, Australian Shepherds, and Border Collies). Again, it should be noted that the large absorptive capacity of the colon may prevent overt diarrhea in some animals (especially cats) despite significant malabsorption and weight loss.

Clinical Findings: Clinical signs of malabsorption are mainly the result of lack of nutrient uptake and losses in the feces. The duration, severity, and primary cause determine the severity of signs, which typically include chronic diarrhea, weight loss, and altered appetite (anorexia or polyphagia). The absence of diarrhea does not exclude the possibility of severe GI disease. Weight loss may be substantial despite a ravenous appetite, sometimes characterized by coprophagia and pica. Typically, animals with malabsorption are systemically well unless there is severe inflammation or neoplasia. Nonspecific signs may include dehydration, anemia, and ascites or edema in cases of hypoproteinemia. Thickened bowel loops or enlarged mesenteric lymph nodes may be palpable, especially in cats.

Diagnosis: Chronic diarrhea and weight loss are nonspecific signs common to a variety of systemic and metabolic diseases, as well as malabsorption, although, typically, systemic diseases cause anorexia. A thorough diagnostic approach in dogs and cats with signs suggestive of malabsorption

is therefore needed to help exclude association with possible underlying systemic or metabolic disease. A precise diagnosis is also important to determine treatment and prognosis.

The history is particularly important, because it may suggest specific dietary intolerance, indiscretion, or sensitivity. Weight loss may indicate malabsorption or protein-losing enteropathy (PLE) but may also be due to anorexia, vomiting, or extraintestinal disease. Small- and large-intestinal diarrhea may be distinguished by a number of features (see TABLE 1, p 157). This distinction is more helpful in dogs than in cats, which rarely have exclusively large-intestinal disease. Suspected large-intestinal disease in dogs may be further evaluated by colonoscopic biopsy of the large intestine. However, if signs of large-intestinal disease are accompanied by weight loss or large volumes of feces, then there is probably also concurrent small-intestinal disease.

A thorough physical examination should be performed. Abdominal palpation is essential to identify abnormalities, and rectal examination is required even when no large-intestinal disease is suspected, both to provide a fecal sample and possibly to identify previously unreported melena. In older cats, the thyroid should be palpated carefully and serum T_4 assayed, because signs of hyperthyroidism can closely mimic those of malabsorption.

Initial evaluation should include a CBC, biochemical profile, urinalysis, fecal examination, abdominal ultrasonography and, when indicated by clinical signs or abnormal abdominal palpation, plain radiography. Hematologic correlates in small-intestinal diseases sometimes include anemia of chronic blood loss (microcytic, hypochromic) or chronic inflammation (normocytic, normochromic); neutrophilia and/or monocytosis associated with intestinal inflammation, infectious enteropathies, or neoplasia; eosinophilia associated with parasitism and eosinophilic enteritis; and lymphopenia that may be associated with intestinal lymphangiectasia in dogs. Lymphocytosis in a dog with diarrhea raises the suspicion of hypoadrenocorticism.

Biochemical tests and urinalysis help to exclude systemic diseases that cause chronic diarrhea, most notably hypoadrenocorticism, protein-losing nephropathies, renal failure, and liver disease. Hypoproteinemia frequently is secondary to PLE and

is seen more commonly in dogs than cats. In most cases of PLE, serum albumin and globulin are both low, but a low albumin alone does not exclude it; inflammatory bowel disease (IBD) and neoplasia are rarely associated with hyperglobulinemia as well as hypoalbuminemia. Liver enzymes (ALT, AST) may be increased as a consequence of increased intestinal permeability, allowing more antigens to reach the liver; in such cases, a bile acid stimulation test as well as ultrasonography should be performed to exclude primary liver disease. However, in cats there may be concurrent IBD and cholangitis. Hypocholesterolemia may develop with fat malabsorption and is most notable in lymphangiectasia. Urinalysis is important to exclude renal causes of hypoalbuminemia and/or renal disease. However, sometimes both may be seen together (eg, the familial PLE and nephropathy of Soft-coated Wheaten Terriers). Hyperthyroidism in cats should be excluded by measuring serum T_4 concentrations. Serologic tests for feline leukemia and feline immunodeficiency viruses should also be performed, not only because both may be associated with secondary, chronic diarrhea but also because they are important prognostic factors. Feline infectious peritonitis and toxoplasmosis have also been described as occasional causes of chronic diarrhea in cats.

The presence of fat, undigested muscle fibers, or starch in feces may provide indirect evidence for malabsorption, but these are unreliable. Feces should be examined for parasites (especially hookworms and *Giardia* in dogs and *Trichostrongylus axei* and *Giardia* in cats) and potentially pathogenic bacteria (including *Salmonella* and *Campylobacter*). Speciation of *Campylobacter* isolates by PCR allows distinction of the pathogenic *C. jejuni* from the more common and probable commensal *C. upsaliensis*. Pathogenic *Escherichia coli* are emerging as a potentially important problem in dogs, but molecular techniques to identify genes encoding pathogenicity determinants are required for diagnosis. *Giardia* can be detected using serial zinc sulfate fecal flotations or a commercially available ELISA; the latter is easier to perform, and its sensitivity is better than fecal flotation performed by inexperienced personnel. *Trichostrongylus* typically causes colitis in cats rather than malabsorption and is best diagnosed by pouch culture or PCR. Detection of excessive leukocytes on fecal cytology may indicate chronic intestinal

inflammation or the presence of enteric pathogens. Cytology of rectal scrapings may reveal *Histoplasma* organisms.

Abdominal radiography is more useful when vomiting is present or palpable abnormalities are detected, but ultrasonography is an important part of the investigation of most small-intestinal diseases. It can be used to measure intestinal wall thickness, layering, and luminal diameter and to detect other intestinal lesions (eg, masses, intussusception), mesenteric lymphadenopathy (in neoplasia and inflammatory bowel disease), and abnormalities in other organs. Mucosal striations have been associated with lymphatic dilatation.

Once obvious dietary, systemic, parasitic, and infectious causes of chronic small-intestinal diarrhea have been eliminated, the next step is differentiation of EPI from intestinal malabsorption; the diagnosis of EPI is relatively straightforward, whereas that of small-intestinal disease is more complex. Numerous tests have been used for dogs and cats with suspected EPI, but they are too inaccurate or impractical to be recommended. Assay of serum trypsin-like immunoreactivity (TLI) is a highly sensitive and specific test and should be used for diagnosis of EPI. This assay measures trypsinogen, some of which normally leaks from the pancreas into the blood, thereby providing an indirect assessment of functional pancreatic tissue. In EPI, functional exocrine tissue is severely depleted and serum TLI concentrations are extremely low, clearly distinguishing EPI from other causes of malabsorption. This test requires a fasted serum sample. Species-specific canine and feline TLI tests are available.

The diagnosis of small-intestinal disease is difficult because of limitations of routine screening procedures, the need for biopsy, and frequently the absence of diagnostic histologic changes. Bacteriologic culture of duodenal fluid obtained endoscopically or at laparotomy has been used to confirm a diagnosis of ARD. However, the exact cut-off point at which small-intestinal bacterial numbers are considered excessive is a matter of debate, because numbers $>10^5$ total or $>10^4$ obligate anaerobic colony-forming units (CFU)/mL may be found in apparently clinically healthy dogs, depending on circumstances, including environment, diet, scavenging, and coprophagia.

The assay of serum folate and cobalamin (vitamin B₁₂) concentrations can be a helpful initial test in assessment of

small-intestinal disease. Folate is absorbed primarily by the proximal small intestine (jejunum), whereas cobalamin is absorbed by the distal small intestine (ileum). As a result, serum folate concentrations can be decreased in proximal small-intestinal diseases, serum cobalamin concentrations can be decreased in distal diseases, and both can be decreased in diffuse enteropathies. Other factors such as the severity, extent, and duration of a mucosal abnormality; dietary intake; and vitamin supplementation also influence these concentrations. In addition, EPI can affect serum folate and cobalamin concentrations, and changes in serum folate and cobalamin concentrations are unreliable for the diagnosis of ARD and secondary antibiotic-responsive diarrhea. The validity of serum folate and cobalamin concentrations as markers of small-intestinal disease in cats is less clear, but low serum cobalamin concentrations may be found with both small-intestinal disease and EPI. Hypocobalaminemia is particularly associated with IBD and alimentary lymphoma and results in metabolic changes, including methylmalonic acidemia, that can lead to anorexia; low cobalamin concentrations are an indication for parenteral supplementation.

A further indirect approach to detect small-intestinal disease is assessment of intestinal function and permeability by oral administration of test substances that are subsequently measured in blood or urine samples. Historically, the xylose absorption test was used to assess intestinal function, but it was insensitive, especially in cats, and is no longer used. Measurements of the differential absorption of D-xylose/3-O-methyl-D-glucose and of intestinal permeability have not been shown to be clinically useful. Hydrogen breath testing after oral administration of individual sugars was considered a simple test to detect malabsorption and to assess transit time, but it has also fallen out of favor. Attempts to diagnose ARD by breath hydrogen or measurement of serum unconjugated bile acids were unreliable, because bacterial numbers may not actually be increased in ARD.

IV administration of ⁵¹Cr-labeled albumin (or ⁵¹CrCl₃ to label endogenous albumin) has been used historically to document PLE in dogs. Measurement of 3-day fecal excretion of this radioactive marker provides an estimation of labeled albumin and hence protein loss into the intestinal lumen. However, its use is very limited because of the use of radioactive markers. An alternative approach is the measurement

of α -1 protease inhibitor in the feces. This plasma protein is lost into the intestinal lumen together with albumin, but unlike albumin it is an antiprotease and is excreted in the feces essentially intact. Species-specific assays have been developed. Three fresh fecal samples passed by spontaneous evacuation are required; any GI bleeding invalidates the result.

Definitive diagnosis of chronic small-intestinal disease typically includes histologic examination of intestinal biopsies taken by endoscopy or at laparotomy. Endoscopy is minimally invasive and allows visualization of the mucosa and targeted biopsy sampling. However, endoscopic mucosal biopsies may not always give an adequate representation of deeper disease and are limited to the parts of the small intestine (duodenum and sometimes proximal jejunum and ileum) that can be visualized via colonoscopy. Endoscopic biopsy is preferred initially because the risk of intestinal surgical wound dehiscence can exceed 10% in debilitated, malnourished, or hypoproteinemic animals. However, surgery is the preferred option when there is a concern about deeper or extraintestinal disease or a focal lesion. If a laparotomy is performed, multiple elliptical, longitudinal biopsy samples should be collected from the duodenum, jejunum, and ileum; mesenteric lymph nodes should be biopsied and other organs examined.

Histologic examination of intestinal biopsy specimens can identify morphologic changes in intestinal inflammation (including lymphocytic-plasmacytic enteritis and eosinophilic enteritis), intestinal lymphangiectasia, villous atrophy, and intestinal neoplasia. The description of morphologic abnormalities can provide a baseline to evaluate response to treatment if sequential small-intestinal biopsies are possible. Morphologic abnormalities may also provide prognostic information, because more severe enteropathies tend to be more difficult to manage. However, there may be minimal or no obvious abnormalities in certain disorders (eg, ARD) despite considerable interference with intestinal function. Histologic descriptions alone provide little information on possible etiology or underlying mechanisms of damage, which would clearly assist effective management. Furthermore, inconsistencies in histologic descriptions between pathologists is a recognized problem. However, the World Small Animal Veterinary Association GI Standardization Group has published a

descriptive template as a basis for concordance.

Treatment: Treatment of malabsorption involves treatment of the primary cause (if identified), dietary therapy, and management of complications. Management of EPI in dogs is relatively straightforward (*see* p 409) and includes feeding a low-fiber diet that contains moderate levels of fat or highly digestible fat, very digestible carbohydrate, and high-quality protein. Specific treatment involves lifelong supplementation of each meal with pancreatic extract. Powdered extracts (1 tsp/10 kg body wt) are preferable to tablets, capsules, and most enteric-coated preparations. Fresh or frozen pancreas can be used as an alternative (100 g/meal for an adult German Shepherd). If the response to pancreatic replacement therapy is poor, secondary antibiotic-responsive diarrhea may be suspected, and the animal should be treated concurrently with oral antibiotics for ≥ 1 mo (*see* below). Acid suppressants (eg, H_2 -receptor blockers, such as cimetidine or ranitidine; proton pump inhibitors, such as omeprazole) may be given 20 min before a meal to inhibit acid secretion and to minimize acid degradation of enzymes in the pancreatic extract, but they are expensive and their value is questionable. Oral multivitamin supplementation should be considered as supportive therapy, but cobalamin (500–1,000 mcg/wk until normalized) should be given parenterally. Dietary requirements of cats with EPI can generally be met by conventional commercial diets, but pancreatic replacement therapy is still needed, as well as parenteral cobalamin supplementation in cats with low serum cobalamin concentrations.

Effective treatment of **small-intestinal disease** depends on the nature of the disorder, but therapy may be empirical when a specific diagnosis cannot be made. In dogs with ARD, a low-fat diet may help by minimizing secretory diarrhea due to bacterial metabolism of fatty acids and bile salts. Oral broad-spectrum antibiotic therapy with oxytetracycline (10–20 mg/kg, tid for 28 days) has been successful. Metronidazole (10–20 mg/kg, bid) and tylosin (20 mg/kg, tid) are effective alternatives; there is rarely a need to use other antibiotics, and the nontargeted use of fluoroquinolones should be avoided. Repeated or longterm treatment may be necessary in dogs with **idiopathic ARD**. Vitamin supplementation may be helpful, particularly for animals with cobalamin

deficiency. Secondary antibiotic-responsive diarrhea usually resolves with appropriate management of the underlying disease, but idiopathic ARD can be difficult to control, especially in young German Shepherds, which are predisposed to developing the condition.

Dietary modification is an important aspect of the management of small-intestinal disease in both dogs and cats. Diets generally contain moderate levels of limited protein sources and highly digestible carbohydrates (to reduce protein antigenicity, reduce osmolar effects, and improve nutrient availability) and low to moderate levels of fat. In addition, they are lactose and gluten free; may be fiber-restricted; and may contain increased levels of antioxidants, prebiotics (eg, fructo-oligosaccharides), or omega-3 fatty acids. These additives are thought to modulate the inflammatory response and increase the health of the bacterial gut flora and enterocytes. Treatment with an exclusion diet consisting of a single novel protein source or a hydrolyzed protein should be used as trial therapy when dietary sensitivity is suspected. Intestinal inflammation is sometimes a manifestation of dietary sensitivity, and an initial exclusion food trial is indicated in mild cases of IBD before other treatments. Boiled white rice and potato are suitable carbohydrate sources, while fish, lamb, or chicken are often used as a protein source, depending on the dietary history. Cottage cheese, horsemeat, rabbit, or venison may be acceptable alternatives. Commercial exclusion diets are not necessary to diagnose food hypersensitivity; however, they are preferred for maintenance to reduce potential dietary imbalances. Protein hydrolysates may be the most effective diets to detect dietary sensitivity. The response to an exclusion diet is often rapid, but the diet must be fed for at least 3 and, in a few cases, up to 10 wk before being considered a failure. Oral prednisolone (1 mg/kg, bid for 2–4 wk, followed by a reducing dose) in combination with an exclusion diet may be useful in animals in which idiopathic IBD is suspected but dietary sensitivity has not yet been excluded.

Treatment of idiopathic inflammatory bowel disease should initially attempt to eliminate or control an underlying antigenic stimulus that may be playing a primary or secondary role in the damage. Treatment should first involve the use of a protein hydrolysate diet. The diet should comprise digestible carbohydrate (preferably rice, which is most digestible) and high-quality protein. Restriction of fat content may also

be valuable and can minimize the secretory diarrhea that is a consequence of bacterial metabolism of fatty acids and bile salts. Oral prednisolone (1 mg/kg, bid for 1 mo, followed by a reducing dose) is indicated in cases of intestinal disease with an obvious inflammatory component, such as lymphocytic-plasmacytic enteritis and eosinophilic enteritis. In more severe cases, it may be necessary to add chlorambucil (2–6 mg/m²/day, PO, until remission, followed by drug tapering) in cats or azathioprine (2–2.5 mg/kg/day) in dogs.

Cats are often given adjunctive metronidazole (10 mg/kg, bid), the beneficial effect of metronidazole may be a result of an inhibition of cell-mediated immune responses as well as anaerobic antibacterial activity. However, the value of metronidazole in combination with prednisolone in the treatment of IBD in dogs has been questioned.

In **lymphangiectasia**, a severely fat-restricted, calorie-dense, highly digestible diet reduces diarrhea but tends to exacerbate weight loss. Supplementation with fat-soluble vitamins is advised, and additional medium-chain triglycerides have been recommended as an easily absorbable fat source that bypasses the lymphatics, although this mechanism is now doubted. Prednisone/prednisolone therapy may be beneficial for its anti-inflammatory and immunosuppressive effects, especially if there is associated lipogranulomatous lymphangitis. The response to treatment is variable; clinical signs may sometimes abate for months or even years, but the longterm prognosis is grave.

Giardiasis can be treated with metronidazole or fenbendazole, and **histoplasmosis** with itraconazole (cats) or ketoconazole (dogs), with or without amphotericin B. In cases of **lymphosarcoma**, treatment involves an appropriate chemotherapy regimen, but response is poor in dogs and in cats with lymphoblastic forms. In cats, treatment of **small-cell villous lymphoma** with oral prednisone and chlorambucil is associated with prolonged remission.

Prognosis: The prognosis in cases of malabsorption is good if there is a simple solution, eg, 85% of cases of EPI respond well to enzyme replacement therapy. The prognosis is worse the more severe the small-intestinal pathology. A poorer prognosis has been associated with severe intestinal inflammation, neoplastic disease, severe weight loss, hypoalbuminemia and ascites (PLE), anorexia, and hypocalcemia.

THE EXOCRINE PANCREAS

The pancreas has both endocrine and exocrine functions. The exocrine pancreas is made up of pancreatic acinar cells and a duct system that opens into the proximal duodenum. Pancreatic acinar cells synthesize and secrete digestive enzymes (eg, amylase, lipase, and others) or inactive proenzymes, and zymogens (eg, trypsinogen, chymotrypsinogen, proelastase, phospholipase, and others) of digestive enzymes, which are essential for the digestion of dietary components such as proteins, triglycerides, and complex carbohydrates. The exocrine pancreas also secretes other essential substances, such as large amounts of bicarbonate, which buffers gastric acid, intrinsic factor, which is needed for cobalamin absorption, and colipase, which is an essential cofactor for pancreatic lipase.

PANCREATITIS

Pancreatitis is the most common exocrine pancreatic disease in both dogs and cats. It can be acute or chronic, depending on whether the disease has led to permanent changes of the pancreatic parenchyma, mainly atrophy and/or fibrosis. Both acute and chronic pancreatitis can be subclinical, mild and associated with vague clinical signs, or severe and associated with pancreatic necrosis and systemic complications. Thus a distinction between the two is clinically of little significance.

Etiology and Pathogenesis: Most cases of pancreatitis in dogs and cats are idiopathic. However, several risk factors have been described. Miniature Schnauzers have been identified to be dramatically overrepresented in some studies, and it has been speculated that they may have a genetic predisposition similar to that in families of human patients with hereditary pancreatitis. Other studies have reported an increased prevalence in Yorkshire Terriers, Cocker Spaniels, Dachshunds, Poodles, sled dogs, or other breeds. Dietary indiscretion is believed to be a common risk factor in dogs. Also, hypertriglyceridemia in dogs, if severe (ie, generally serum concentrations ≥ 500 mg/dL), is considered a risk factor for pancreatitis in dogs. Severe blunt

trauma, such as can be sustained during a traffic accident or in cats with high-rise syndrome, can also cause pancreatitis. Surgery has been considered another risk factor; however, most postsurgical cases of pancreatitis are now believed to be due to pancreatic hypoperfusion during anesthesia. Infectious diseases have been implicated, but the evidence for a cause and effect relationship is weak in most cases. In dogs, pancreatitis has been reported with *Babesia canis* or *Leishmania* infection. In cats, *Toxoplasma gondii*, *Amphimerus pseudofelineus*, and feline infectious peritonitis are considered most important.

Many drugs have been implicated in causing pancreatitis in people, but very few have been confirmed in dogs and cats. In general, most drugs should be viewed as potential causes of pancreatitis; cholinesterase inhibitors, calcium, potassium bromide, phenobarbital, L-asparaginase, estrogen, salicylates, azathioprine, thiazide diuretics, and vinca alkaloids are probably the most important.

Many different insults may ultimately lead to pancreatitis through a common pathway. Secretion of pancreatic juice decreases during the initial stages of pancreatitis. This is followed by co-localization of zymogen granules and lysosomes, leading to activation of trypsinogen to trypsin within the co-localized organelles. Trypsin, in turn, activates more trypsinogen and also other zymogens. Prematurely activated digestive enzymes lead to local damage of the exocrine pancreas with pancreatic edema, bleeding, inflammation, necrosis, and peripancreatic fat necrosis. The ensuing inflammatory process leads to recruitment of WBCs and cytokine production. The activated enzymes, and more importantly, the cytokines circulate in the bloodstream and lead to distant complications such as generalized inflammation, disseminated intravascular coagulation, disseminated lipodystrophy, pancreatic encephalopathy, hypotension, renal failure, pulmonary failure, myocarditis, or even multiorgan failure.

Clinical Findings: Anorexia (91%), vomiting (90%), weakness (79%), abdominal pain (58%), dehydration (46%), and diarrhea (33%) have been reported as the most common clinical signs in dogs with severe

pancreatitis. Clinical signs in cats with severe pancreatitis are even less specific, with anorexia (87%), lethargy (81%), dehydration (54%), weight loss (47%), hypothermia (46%), vomiting (46%), icterus (37%), fever (19%), and abdominal pain (19%) most commonly reported. Dogs and cats with milder forms of pancreatitis may be subclinical or may have only vague clinical signs, such as anorexia, lethargy, or diarrhea. The low rate of abdominal pain reported is remarkable given that >90% of human patients with pancreatitis report abdominal pain, so it is most likely due to lack of recognition in veterinary patients.

Diagnosis: A history of dietary indiscretion combined with vomiting and abdominal pain may suggest pancreatitis in dogs, but most cats present with nonspecific histories and clinical signs. Findings on CBCs and serum biochemistry profiles may suggest an inflammatory disease process but are nonspecific. In dogs, thrombocytopenia and neutrophilia with a left shift are common. Azotemia and increases in liver enzymes and bilirubin are common, nonspecific findings in both dogs and cats. Thus, while basic blood work is not useful for the diagnosis of pancreatitis, it is crucial to systematically evaluate the animal and diagnose systemic complications. Abdominal radiographs may show decreased detail in the proximal abdominal cavity and displacement of abdominal organs, but these findings are also nonspecific and a diagnosis based on radiographic findings alone is not reliable. However, abdominal radiographs are valuable in animals suspected of having pancreatitis to exclude other differential diagnoses. Abdominal ultrasonography, if stringent criteria are applied, is highly specific for pancreatitis, but pancreatic enlargement and fluid accumulation around the pancreas alone are not sufficient for diagnosis. A combination of pancreatic enlargement, fluid accumulation around the pancreas, changes in echogenicity (ie, decreased echogenicity suggesting pancreatic necrosis, increased echogenicity around the pancreas suggesting peripancreatic fat necrosis, increased echogenicity suggesting pancreatic fibrosis), and/or a pancreatic mass effect are suggestive of pancreatitis. Care should be taken not to overinterpret findings, because modern ultrasonographic equipment has a very high resolution, and pancreatic nodular hyperplasia may lead to changes in echogenicity, falsely suggesting the presence of pancreatitis. Also, the sensitivity of abdomi-

nal ultrasonography is highly operator-dependent, with sensitivities as high as 35% in cats and 68% in dogs in the most experienced hands.

Several diagnostic markers for pancreatitis have been evaluated in dogs and cats. In general, the clinical usefulness of serum lipase and amylase activity is limited in dogs and even more so in cats. In-clinic tests for the semiquantitative evaluation of serum pancreatic lipase immunoreactivity are available. A negative semiquantitative test suggests that pancreatitis is very unlikely, whereas a positive test suggests pancreatitis. In the latter case, pancreatic lipase immunoreactivity (PLI) concentration should be measured in a serum sample and evaluated to confirm the diagnosis and to determine a baseline concentration. This allows use of serum PLI concentration as a monitoring tool for the disease. In both dogs and cats, serum PLI concentration is highly specific for exocrine pancreatic function and is also the most sensitive diagnostic test for pancreatitis currently available (sensitivity >80%). However, as for any disease, no test should be used in isolation for diagnosis, and all clinical findings should be used in conjunction to arrive at the most appropriate diagnosis.

Pancreatic cytology or histopathology can also be used to definitively diagnose pancreatitis. Fine-needle aspiration of the pancreas is safe and can show acinar cells and inflammatory cells, allowing a definitive diagnosis of pancreatitis. However, lack of inflammatory cells does not exclude pancreatitis, because the inflammatory infiltrate can be highly localized. Pancreatic biopsy for histopathologic evaluation may be associated with a higher risk of pancreatitis than fine-needle aspiration (due to more aggressive pancreatic handling and longer anesthesia). Also, even if the presence of pancreatitis seems obvious on macroscopic examination of the pancreas, a biopsy specimen should be collected because the definitive diagnosis of pancreatitis requires the identification of an inflammatory infiltrate during histopathology. Finally, animals with severe pancreatitis are often poor anesthetic risks, and exploratory laparotomy or even fine-needle aspiration may not be justified.

Treatment: The mainstay of therapy of severe pancreatitis is supportive care with fluid therapy, vigorous monitoring, and early intervention to prevent systemic complications. Fluid therapy should be based on calculation of degree of dehydration (to be replaced over 4–8 hr if there is no

contraindication), maintenance, and ongoing losses (eg, due to vomiting or diarrhea). In those few cases in which the cause is known, specific therapy against the inciting cause may be initiated. Antibiotics are of questionable value and should not be used routinely. Resting the pancreas is suggested only if the animal vomits uncontrollably (ie, the animal vomits frequently and violently despite appropriate antiemetic therapy). In fact, early nutritional support is considered a key component of successful treatment of human patients with severe pancreatitis. Also, enteral nutritional support is considered superior to parenteral nutrition. Animals that vomit should be treated with an antiemetic, such as maropitant (NK1 antagonist), ondansetron or dolasetron (5HT₃ antagonists), or in most animals a combination of both. Even animals that do not actively vomit may benefit from such antiemetic support, because they may be nauseated, leading to hyporexia or even anorexia. Metoclopramide is not considered effective as an antiemetic agent and should not be used in these animals. Abdominal pain should be assumed to be present and treated until contrary evidence is available. Intermittent meperidine, butorphanol, or buprenorphine may be used in animals with mild or moderate abdominal pain. Animals with severe pain are often treated with a constant-rate infusion of an opioid, such as morphine, fentanyl, or methadone, or with a combination therapy of fentanyl, ketamine, and lidocaine. Plasma appears to be helpful in severe cases of canine pancreatitis. It should be given daily until improvement is significant or adverse effects are identified. Many other treatments have been investigated in dogs, cats, and people, but unfortunately none has been shown to be useful.

Animals with mild forms of pancreatitis should be carefully assessed for the presence of risk factors (eg, hypertriglyceridemia, hypercalcemia, history of medications that can cause pancreatitis) and concurrent diseases (eg, cholangitis, hepatitis, inflammatory bowel disease, diabetes mellitus). In dogs, feeding an ultra-low-fat diet is crucial for treatment success. In cats, a moderately fat-restricted diet is recommended. Antiemetic drugs are helpful for animals that may not eat due to nausea.

If animals do not respond to therapy, a trial with prednisone (dogs), prednisolone (dogs and cats), or cyclosporine (dogs or cats) may be attempted. Cyclosporine is advantageous in animals with concurrent diabetes mellitus, because it has a smaller

impact on insulin resistance than glucocorticoids. However, data are limited to date, and indiscriminate use of glucocorticoids or cyclosporine in dogs and cats with chronic pancreatitis should be discouraged.

The prognosis in mild cases is good, but prognosis in severe cases of pancreatitis is guarded in both dogs and cats. Systemic complications such as hypothermia, acidosis, hypocalcemia, and single- or multiple-organ failure are considered risk factors for a poor outcome. It can be challenging to identify severe cases early during the disease process and prevent complications in those animals.

EXOCRINE PANCREATIC INSUFFICIENCY

Exocrine pancreatic insufficiency (EPI) is a syndrome caused by insufficient synthesis and secretion of digestive enzymes by the exocrine portion of the pancreas. EPI is less common than pancreatitis in both dogs and cats, but it is the second most common exocrine pancreatic disorder in both species.

Etiology and Pathogenesis: Pancreatic acinar atrophy is the most common cause of EPI in German Shepherds, Rough Collies, and Eurasians, whereas chronic pancreatitis is the most common cause in dogs of other breeds and cats. Less common causes of EPI in dogs and cats are pancreatic or extrapancreatic masses that lead to obstruction of the pancreatic duct. The exocrine pancreas has a remarkable functional reserve, ~90% of which must be lost before clinical signs of EPI develop. Pancreatic acinar enzymes play an integral role in the assimilation of all major macronutrients, and a lack of pancreatic digestive enzymes leads primarily to maldigestion. However, animals with EPI also show evidence of malabsorption, the pathogenetic basis of which is less well understood (*see also* MALABSORPTION SYNDROMES, p 400). The nutrients remaining in the intestinal lumen lead to loose, voluminous feces and steatorrhea. The lack of nutrients also causes weight loss and may lead to vitamin deficiencies. In animals with EPI caused by chronic pancreatitis, destruction of pancreatic tissue may not be limited to the acinar cells, and concurrent diabetes mellitus may develop.

Clinical Findings: EPI due to pancreatic acinar atrophy is most frequent in young adult German Shepherds but has also been

described in Rough Collies and Eurasians. Dogs and cats with EPI due to other causes are usually middle-aged to older and can be of any breed. Clinical signs most commonly reported are polyphagia, weight loss, and diarrhea. Vomiting and anorexia are observed in some animals and may be a sign of concurrent conditions rather than EPI. The feces are most commonly pale, loose, and voluminous and may be malodorous. In rare cases, watery diarrhea may be seen. In a small portion of cats with EPI, the high fat content of the feces can lead to a greasy appearance of the hair coat, especially in the perianal and tail region.

Diagnosis: A serum trypsin-like immunoreactivity (TLI) concentration of ≤ 2.5 mcg/L in dogs or ≤ 8.0 mcg/L in cats is diagnostic for EPI. Because digestion of a macronutrient can often be accomplished by more than one enzyme, lack of exocrine pancreatic secretions does not necessarily lead to clinical signs. For example, several German Shepherds with subclinical EPI have been reported. These dogs had severely decreased serum TLI concentrations and a lack of exocrine pancreatic tissue, but no or only intermittent clinical signs of EPI.

An assay that measures fecal elastase in dogs has been validated. Unfortunately, some healthy dogs or dogs with chronic small-intestinal disease may have a severely decreased fecal elastase concentration, making this test much less reliable than serum TLI concentration.

Treatment: Most dogs and cats with EPI can be successfully treated by supplementation with pancreatic enzymes. Powder is more effective than tablets, capsules, and especially enteric-coated products. Initially, 1 teaspoon/10 kg should be given with each meal for dogs and 1 teaspoon/cat with each meal for cats. Once the clinical signs have completely resolved, the dose can be slowly decreased until the lowest effective dose has been reached. However, it should be noted that the lowest effective dose can vary between enzyme batches. Oral bleeding has been reported in 3 of 25 dogs with EPI treated with pancreatic enzyme supplements; the bleeding stopped in all three dogs after a dose reduction. Moistening the food and pancreatic powder mix may also decrease the frequency of this adverse effect.

Fresh pancreas may be a viable alternative to the use of powder; 1–3 oz (30–90 g) of raw chopped pancreas can replace

1 teaspoon of pancreatic extract. Raw pancreas can be kept frozen for several months without loss of enzymatic activity. Preincubation of the food with pancreatic enzymes or supplementation with bile salts is not necessary.

Even though pancreatic enzyme supplementation decreases the clinical signs in almost all animals, nutrient absorption, especially that of fats, is not normalized. Feeding low-fat diets to accommodate impaired fat digestion has been suggested, but this may further decrease fat assimilation and lead to deficiencies of fat-soluble vitamins and/or essential fatty acids. Some types of dietary fiber interfere with pancreatic enzyme activity, and a diet low in insoluble or nonfermentable fiber should be fed.

Enzyme supplementation alone may not lead to complete resolution of clinical signs; cobalamin deficiency should be considered as a possible cause. Cobalamin absorption depends on adequate synthesis and secretion of intrinsic factor. In both dogs and cats, the majority of intrinsic factor is synthesized and secreted by the exocrine pancreas, and >80% of dogs and almost all cats with EPI are cobalamin deficient. Also, cobalamin deficiency was the only independent risk factor for poor outcome in a study of dogs with EPI. Thus, serum cobalamin and folate concentrations should be routinely evaluated in small animals with suspected EPI. Dogs and cats with cobalamin deficiency, suggested by a severely decreased serum cobalamin concentration, should be parenterally supplemented with cobalamin. Other hypovitaminoses have also been reported in animals with EPI. For example, vitamin K deficiency leading to a coagulopathy has been reported in some cats with EPI.

Some animals may not respond to enzyme supplementation and cobalamin therapy and likely have concurrent small-intestinal disease. Animals with EPI commonly have concurrent small-intestinal dysbiosis and may need antibiotic therapy. Inflammatory bowel disease also occurs in some animals with EPI. In those that do not respond to therapy, a proton pump inhibitor can also be tried.

Prognosis: EPI results from an irreversible loss of pancreatic acinar tissue in most cases, and recovery is rare. However, with appropriate management and monitoring, these animals usually gain weight quickly, pass normal feces, and can live a normal life for a normal life span.

PANCREATIC NEOPLASMS

Neoplasias of the exocrine pancreas can be primary or secondary and can be classified as benign or malignant. Most exocrine pancreatic neoplasias in dogs and cats are secondary.

Pancreatic adenomas are benign tumors that are usually singular and can be differentiated from pancreatic nodular hyperplasia by the presence of a capsule. Pancreatic adenocarcinoma is the most common primary neoplastic condition of the exocrine pancreas in dogs and cats but is rare overall in both species.

Pathogenesis: Benign neoplasms of the exocrine pancreas can lead to transposition of organs of the cranial abdominal cavity. However, these changes are subclinical in most cases, and the diagnosis is often made as an incidental finding during necropsy. In rare cases, the neoplastic growth can obstruct the pancreatic duct and cause secondary atrophy of the remaining exocrine pancreas, leading to exocrine pancreatic insufficiency. Adenocarcinomas may lead to tumor necrosis if the tumor outgrows its blood supply. Tumor necrosis causes local inflammation, which can lead to clinical signs of pancreatitis. Malignant neoplasms may also spread to neighboring or distant organs.

Clinical Findings: The presentation of dogs and cats with exocrine pancreatic neoplasia is nonspecific, and many cases remain subclinical until late in the disease process. Some animals show clinical signs suggestive of pancreatitis. Obstructive jaundice may be seen if bile duct obstruction develops. Clinical signs related to metastatic lesions have also been reported in some cases of pancreatic adenocarcinoma and may present as lameness, bone pain, or dyspnea. Finally, paraneoplastic alopecia has been reported in cats with pancreatic adenocarcinoma.

Diagnosis: Several nonspecific findings, such as neutrophilia, anemia, hypokalemia, bilirubinemia, azotemia, hyperglycemia, and increased hepatic enzyme activities, have been reported in dogs and cats with pancreatic adenocarcinoma. However, results of routine blood tests may be unremarkable. Increased serum lipase and amylase activities and trypsin-like immunoreactivity and pancreatic lipase immunoreactivity concentrations have not been commonly reported in either dogs or

cats with pancreatic adenocarcinoma but may be seen in either species.

Radiographic findings are also nonspecific in most cases. Abnormal findings include decreased contrast in the cranial abdomen suggesting peritoneal effusion, transposition of the spleen caudally, and shadowing in the pyloric region. In some cases, abdominal radiographs suggest a cranial abdominal mass. Abdominal ultrasonography generally shows a soft-tissue mass near the pancreas, but in many cases, continuation of the mass with pancreatic tissue cannot be conclusively demonstrated. Also, neoplastic lesions of neighboring organs may be falsely presumed to be of pancreatic origin. Finally, animals with severe pancreatitis may show a mass effect in the area of the pancreas on abdominal ultrasonography that must not be confused with a pancreatic neoplasia.

If peritoneal effusion is present, a sample should be aspirated and evaluated cytologically. However, in most cases neoplastic cells do not readily exfoliate into the peritoneal effusion, and no neoplastic cells are identified on cytology. Fine-needle aspiration or transcutaneous biopsy under ultrasonographic guidance can be attempted when suspicious masses are identified. However, in many cases, the diagnosis is made at exploratory laparotomy or necropsy.

Treatment and Prognosis: Pancreatic adenomas are benign and theoretically do not require therapy unless they cause clinical signs due to the effects of an intra-abdominal space-occupying lesion. However, because the final diagnosis of pancreatic adenocarcinoma is often made at exploratory laparotomy, a partial pancreatectomy should be performed even in cases of suspected pancreatic adenoma. The prognosis in these cases is excellent. Animals with pancreatic adenocarcinomas often present at a late stage of the disease, and metastatic disease at the time of diagnosis is quite common in both dogs and cats. Common sites for metastasis are the liver, abdominal and thoracic lymph nodes, mesentery, intestines, and the lungs, but other metastatic sites have also been reported. In those few cases when gross metastatic lesions are not identified at the time of diagnosis, surgical resection of the tumor may be attempted, but clean surgical margins can almost never be achieved, and owners should be forewarned. Both chemotherapy and radiation therapy have shown little success in human or veterinary patients with pancreatic adenocarcinomas.

Thus, the prognosis for dogs and cats with pancreatic adenocarcinoma is grave.

PANCREATIC ABSCESES

By definition, a pancreatic abscess is a collection of pus, usually in proximity to the pancreas, containing little or no pancreatic necrosis. Pancreatic abscesses are considered a complication of pancreatitis, and thus their clinical presentation is similar to that of pancreatitis, although most cases are associated with mild chronic pancreatitis, and clinical signs may be more vague. A bacterial infection may or may not be present, but almost all cases reported in small animals have been sterile. Increased serum trypsin-like immunoreactivity and pancreatic lipase immunoreactivity concentrations have not been reported in dogs or cats with a pancreatic abscess, but anecdotal reports suggest that both serum parameters are increased in these animals. Surgical drainage and aggressive antimicrobial therapy are the treatments of choice in human patients with an infected pancreatic abscess. Dogs and cats may also respond favorably to surgical drainage. However, in one report, only slightly more than 50% of animals survived the immediate postsurgical period. Thus, given the mixed results and risks, difficulties, and expenses

associated with anesthesia, surgery, and postoperative care, surgery may not be warranted unless there is clear evidence of an enlarging mass and/or sepsis in a medically managed animal.

PANCREATIC PSEUDOCYST

A pancreatic pseudocyst is a collection of sterile pancreatic fluid enclosed by a wall of fibrous or granulation tissue; these structures are also considered a complication of pancreatitis. Several cases of pancreatic pseudocysts in dogs and cats have been described. Clinical signs are usually nonspecific and mimic those of pancreatitis. On abdominal ultrasonography, a cystic structure in close proximity to the pancreas can be identified. Aspiration of the pseudocyst is relatively safe and should be attempted for diagnostic and therapeutic purposes. Fluid from a pancreatic pseudocyst should have few cells and should not contain any evidence of inflammation. Pancreatic pseudocysts can be treated medically or surgically. Medical management involves ultrasonographic-guided percutaneous aspiration and close monitoring of the size of the pseudocyst. Surgery may be indicated in animals with persistent clinical signs or when the pseudocyst fails to regress over time.

GASTROINTESTINAL PARASITES OF SMALL ANIMALS

SPIROCERCA LUPI

(Esophageal worm)

Adult *Spirocerca lupi* are bright red worms, 40 mm (male) to 70 mm (female) long, generally located within nodules in the esophageal, gastric, or aortic walls. Infections are seen in southern areas of the USA as well as in many tropical and subtropical regions worldwide (eg, Greece, India, Israel, Japan, South Africa). Dogs are infected by eating an intermediate host (usually dung beetle) or a transport host (eg, chickens, reptiles, or rodents). The larvae migrate via the wall of the celiac artery to the thoracic aorta, where they usually remain for ~3 mo. Eggs are passed in feces ~5–6 mo after infection.

Clinical Findings: Most dogs with *S lupi* infection show no clinical signs, but when signs are present, they most commonly include weight loss, coughing, and dyspnea. When the esophageal lesion is very large (usually when it has become neoplastic), the dog has difficulty swallowing and may vomit repeatedly after trying to eat. Such dogs salivate profusely and eventually become emaciated. In addition, dogs may develop thickening of the long bones characteristic of hypertrophic osteopathy. These clinical signs are suggestive of spirocercosis with associated neoplasia in regions where the parasite is prevalent. Occasionally, a dog dies suddenly as the result of massive hemorrhage into the thorax after rupture of the aorta damaged by the developing worms.

Lesions: The characteristic lesions are aneurysm of the thoracic aorta, reactive granulomas of variable size around worms in the esophagus, and exostoses that bridge between ventral aspects of thoracic vertebrae. Esophageal sarcoma, often with metastases, is sometimes associated (apparently causally) with *S lupi* infection, particularly in hound breeds. Dogs with *Spirocerca*-related sarcoma often develop hypertrophic osteopathy (see p 1205).

Diagnosis: Diagnosis can be made by demonstrating the characteristic small ($11\text{--}15 \times 30\text{--}38 \mu\text{m}$), elongated eggs (by NaNO_3 [specific gravity 1.36] or sugar flotation) that contain larvae in the feces. However, eggs are sporadically voided in feces and can be difficult to find. Gastroscopy occasionally reveals a nodule or an adult worm. A presumptive diagnosis can be made by radiographic examination when it reveals dense masses in the esophagus; a positive-contrast barium study may help define the lesion. CT is an additional useful diagnostic tool, with a higher level of sensitivity than thoracic radiography for *S lupi*. However, while CT generally provides more information on the location and severity of the infection than radiographs, the specificity of the findings for *S lupi* is currently unclear.

Many infections are not diagnosed until necropsy. The granulomas vary greatly in size and location in the esophagus but usually are sufficiently characteristic to be diagnostic, even if the worms are no longer present. Worms and granulomas may be present in the lungs, trachea, mediastinum, stomach wall, or other abnormal locations. Healed aneurysms of the aorta persist for the life of the dog and are diagnostic of previous infection. When sarcomas are associated with the infection, the esophageal lesion usually is larger and often contains cartilage or bone; metastases frequently are present in the lungs, lymph nodes, heart, liver, or kidneys.

Treatment and Control: In endemic areas, dogs should be prevented from eating dung beetles, frogs, mice, lizards, etc., and not fed raw chicken scraps. In Europe, monthly treatment with topical moxidectin/imidacloprid is approved for use in dogs as a preventive for *S lupi* infection. Treatment of clinical cases is often not practical. However, efficacy has been demonstrated with doramectin (0.2 mg/kg, SC, three doses at 2-wk intervals; 0.4 mg/kg, SC, six doses at 2-wk intervals; 0.5 mg/kg, SC, two doses

2 wk apart; 0.5 mg/kg/day, PO, for 42 days; 0.8 mg/kg, SC, two doses 1 wk apart; additional treatments may be required), and with ivermectin (0.6 mg/kg, SC, two doses 2 wk apart) combined with prednisolone (0.5 mg/kg, PO, bid for 2 wk and then tapered), although none of these treatments is approved. The specific breed toxicity associated with ivermectin in Collies and other herding dog breeds also occurs with doramectin. Surgical removal usually is unsuccessful because of the large areas of the esophagus involved.

PHYSALOPTERA SPP

(Stomach worm)

Several species of these stomach nematodes of dogs and cats are seen throughout the world. They are usually firmly attached to the gastric mucosa. The males are ~30 mm long, and the females ~40 mm. The eggs are oval, $42\text{--}53 \times 29\text{--}35 \mu\text{m}$, thick-shelled, and larvated.

Encysted infective larvae of *Physaloptera* spp have been found in several species of insects, including beetles, cockroaches, and crickets. Mice and frogs may be paratenic hosts. After the dog or cat ingests the intermediate or paratenic host, development of larvae to adults is direct. Although infections are often subclinical, these parasites may cause gastritis that can result in vomiting, anorexia, and dark feces. Bleeding, ulcerated areas remain on the gastric mucosa when the parasites move to other locations; in heavy infections, anemia and weight loss may develop. Gastroscopy is the most efficient means of diagnosis, and immature worms are often found in the vomitus of puppies or kittens. The eggs are difficult to find in feces, because they do not readily float; eggs are best detected by fecal sedimentation. In cats, pyrantel pamoate (5 mg/kg, PO, two doses 2–3 wk apart; 20 mg/kg, PO, once) and ivermectin (0.2 mg/kg, SC or PO, two doses 2 wk apart) can be used for *Physaloptera* infections. In dogs, fenbendazole (50 mg/kg/day, PO, for 3 days), pyrantel pamoate (5 mg/kg, PO, two doses 2–3 wk apart; 15 mg/kg, PO, two doses 2–3 wk apart; 20 mg/kg, PO, once), and ivermectin (0.2 mg/kg, SC or PO, two doses 2 wk apart) can be used. None of these drug regimens is approved for treatment of *Physaloptera* in either dogs or cats.

OLLULANUS SP

Ollulanus tricuspis is a small worm, $\leq 1 \text{ mm}$ long, that infects several animal species,

typically cats and other felids, and occasionally induces a mild erosive or catarrhal gastritis. Vomiting minutes to a few hours after eating is a common sign. The female worms are viviparous, so massive infections can build up endogenously. Transmission is via vomitus. Diagnosis is by microscopic demonstration of larvae (~500 μm) or adult worms in vomitus or stomach contents. The use of a Baermann apparatus enables the separation of the worms from ingesta, after which they are easier to observe. Parasites are rarely seen in feces, because they are usually digested before being passed. Therapeutic efficacy in cats has been demonstrated with fenbendazole (20–50 mg/kg/day, PO, for 3 days) and levamisole (5 mg/kg, SC, once), although these are not approved treatments.

STRONGYLOIDES SP

Strongyloides stercoralis is a small, slender nematode that when fully mature is ~2 mm long, located at the base of the villi in the anterior half of the small intestine of dogs and cats. The worms are almost transparent and all but impossible to see grossly at necropsy. Usually, infections are associated with warm, wet, crowded, unsanitary housing. The species found most often in dogs is identical to that found in people.

The parasitic worms are all females. The eggs embryonate rapidly, and most larvae hatch before being passed in the feces. Under appropriate conditions of warmth and moisture, development in the environment is rapid; the third larval stage may be reached in little more than a day. Some of these larvae develop into infective filariform larvae; others develop into free-living worms that mate and produce progeny similar to that of the parasitic female. The filariform larvae penetrate the skin but also may infect a host via ingestion. Transmammary transmission is possible. Progeny may be shed in the feces 7–10 days after infection. Autoinfection caused by larvae that developed to the infective stage within the GI tract can result in infections in which dogs shed larvae for lengthy periods.

Clinical Findings: The presence of clinical signs indicates that a heavy infection has been building up for some weeks. A bloodstreaked, mucoid diarrhea, usually seen in young animals during hot humid weather, is characteristic. Emaciation is often prominent, and reduced growth rate may be one of the first signs. Appetite usually is good, and the dog is normally active in the earlier stages of the disease. In the absence

of concurrent secondary infections, there is little or no fever. Usually in advanced stages, there is shallow, rapid breathing and fever, and the prognosis is grave. Autoinfection may be induced by the use of corticosteroids or other factors that affect immunocompetence. There may be larvae in tissues, and these dogs are more likely to die. At necropsy, there can be evidence of verminous pneumonia with large areas of consolidation in the lungs as well as marked enteritis with hemorrhage, mucosal exfoliation, and much secretion of mucus.

Diagnosis: First-stage larvae (~380 μm long) are identified by direct microscopic evaluation of a small quantity of feces. Usually, the Baermann technique is used to separate larvae from fecal material. It is important to use fresh fecal material obtained from an infected dog so the larvae can be easily differentiated from hookworm larvae or free-living soil nematodes. Occasionally, eggs (50–60 $\times$ 30–35 μm) may be identified by flotation of fresh feces. Adult female worms can be identified by scraping the mucosa of the small intestine. They are only ~2 mm long, but the presence of eggs in the uterus easily differentiates them from larvae of other nematodes.

Treatment and Control: Poor sanitation and mixing of susceptible with infected dogs can lead to a rapid buildup of the infection in all dogs in a kennel or pen. Dogs with diarrhea should be promptly isolated from dogs that appear healthy. Direct sunlight, increased soil or surface temperatures, and desiccation are deleterious to all free larval stages. Thorough washing of wooden and impervious surfaces with steam or concentrated salt or lime solutions, followed by rinsing with hot water, effectively destroys the parasite. Because the disease in people can be serious, caution should be exercised when handling infected dogs. The disease in people (as in dogs) is much more likely to be severe if the person is immunosuppressed.

Infections in dogs can be treated with ivermectin (0.2 mg/kg, SC or PO, once, with a second dose 4 wk later; 0.8 mg/kg, PO, once), fenbendazole (50 mg/kg/day, PO, for 5 days, repeated 4 wk later), or thiabendazole (100–150 mg/kg/day, PO, for 3 days, repeated weekly until larvae are not detected in feces—toxicity may be seen with this regimen). In cats, fenbendazole (50 mg/kg/day, PO, for 3 days) can be used. These are not approved regimens in either cats or dogs. In all animals, feces should be

examined regularly for at least 6 mo after treatment to confirm efficacy.

ROUNDWORMS

The large roundworms (ascaridoid nematodes) of dogs and cats are common, especially in puppies and kittens. Of the three species *Toxocara canis*, *Toxascaris leonina*, and *Toxocara cati*, the most important is *T. canis*, not only because its larvae may migrate in people (as do larvae of *T. cati*), but also because infections are generally common and may impact puppy health. Also, fatal infections may occasionally be seen in young pups. *T. leonina* is seen in adolescent/adult dogs and cats. These species also infect wild carnivores, especially those in zoos or other captive settings.

In puppies, the usual mode of infection with *T. canis* is transplacental transfer. If pups <3 mo old ingest embryonated infective eggs, the hatched larvae penetrate the intestinal mucosa, reach the lungs via the liver and bloodstream, are coughed up, swallowed, and mature to egg-producing adults in the small intestine. However, when infective eggs of *T. canis* are swallowed by older dogs, the larvae hatch, penetrate the intestinal mucosa, and migrate to the liver, lungs, muscles, connective tissue, kidneys, and many other tissues, where development is arrested. In pregnant bitches, these dormant larvae mobilize and migrate into the developing fetus; they can be found in the intestine of puppies as early as 1 wk after birth. Some larvae migrate to the mammary gland, so pups may also be infected via the milk. During this perinatal period, the immunity of the bitch to ascarid infection is partially suppressed, and substantial numbers of eggs may be passed in the feces of the bitch. Development of

these patent infections appears to be associated with maturation of arrested larvae in the bitch, which migrate to the intestine via the lungs. Patency may also occur as a result of ingestion and maturation of larvae that are passed in the feces of puppies.

After ingestion of infective eggs, larvae of ascaridoid nematodes may migrate into the tissues of many animals and thus provide an alternative source of infection, particularly for cats and wild carnivores. Such migration also occurs if larvated eggs of *Toxocara* spp are swallowed by people. Most human infections are asymptomatic, but fever, persistent eosinophilia, and hepatomegaly (sometimes with pulmonary involvement) may occur, resulting in a condition known as **visceral larva migrans**. Rarely, a larva may settle in the retina and impair vision, resulting in a condition known as **ocular larva migrans**.

The life cycle of *T. cati* is similar to that of *T. canis*, except that no prenatal infection occurs. Furthermore, transmammary transmission appears to occur only when queens acquire infection during late gestation. Thus, overall, this route of infection appears to play a minor role in transmission. With *T. leonina*, migration is restricted to the intestinal wall so that neither prenatal nor transmammary transmission occurs.

Clinical Findings and Lesions: The first indication of infection in young animals is lack of growth and loss of condition. Infected animals have a dull coat and often are "potbellied." Worms may be vomited and are often voided in the feces. In the early stages, migrating larvae may cause an eosinophilic pneumonia, which can be associated with coughing. Diarrhea with mucus may be evident.

In puppies with severe infections, verminous pneumonia, ascites, fatty liver, and mucoid enteritis are common. Cortical kidney granulomas containing larvae may be seen.

Diagnosis: Infection in dogs and cats is diagnosed by detection of eggs in feces. Distinguishing the spherical, pitted-shelled eggs of *Toxocara* spp (*T. canis* 80–90 × 75 μm; *T. cati* 65 × 75 μm) from the oval, smooth-shelled eggs of *Toxascaris leonina* (75–85 × 60–75 μm) is important because of the public health significance of the former.

Treatment and Control: In dogs, compounds approved for treatment of

Toxocara canis ova (larger structures) and *Cystoisospora* oocysts (smaller structures).
Courtesy of Dr. Andrew Peregrine and Ontario Veterinary College.

roundworm infections include fenbendazole, milbemycin, moxidectin, piperazine, and pyrantel (see TABLE 8). In Europe, selamectin is approved to treat *T canis* infections with a single dose, whereas in Canada approved treatment requires two doses 1 mo apart. Preventive programs for heartworm infection using milbemycin, milbemycin/lufenuron, milbemycin/praziquantel, milbemycin/spinosad, moxidectin/imidacloprid, ivermectin/pyrantel, or ivermectin/pyrantel/praziquantel also control intestinal ascarid infections. In addition, selamectin is approved for this indication in some countries but not in the USA (see TABLE 8).

Drugs approved for treatment of ascarid infections in cats include emodepside, fenbendazole, milbemycin, moxidectin, piperazine, pyrantel, and selamectin (see TABLE 9). Heartworm-preventive programs that use milbemycin, milbemycin/praziquantel, moxidectin/imidacloprid, or selamectin also control ascarid infections in cats (see TABLE 9).

Environmentally resistant larvated eggs on the ground and somatic larvae in the bitch are the main reservoirs of infection. Perinatal transmission of infection can be greatly reduced by treating bitches with 1) daily doses of fenbendazole (25 mg/kg, PO) from day 40 of gestation to day 2 after whelping (approved in the UK), 2) ivermectin (0.3 mg/kg, SC) on days 0, 30, and 60 of gestation, and 10 days after whelping, 3) ivermectin (0.5 mg/kg) on days 38, 41, 44, and 47 of gestation, or 4) ivermectin (1 mg/kg) on days 20 and 42 of gestation; these uses of ivermectin are extra-label. Otherwise, to minimize egg output, pups should be treated as early as possible; ideally, treatment should be given 2 wk after birth and repeated at 2-wk intervals to 2 mo of age, and then monthly to 6 mo of age. Nursing bitches should be treated at the same times as puppies. In cats, perinatal transmission can be greatly reduced by treating queens with a single dose of emodepside/praziquantel spot-on in the last week of pregnancy. Kittens should be treated with an appropriate anthelmintic at 3, 5, 7, and 9 wk of age, and then monthly to 6 mo of age. Nursing queens should be treated at the same time as kittens. In other animals, the appropriate frequency of preventive treatment for roundworms should be based on a risk assessment of the animal's environment.

Because the eggs adhere to many surfaces and become mixed in soil and dust, strict hygiene should be observed by people,

particularly children, exposed to potentially contaminated animals or areas.

Baylisascaris in Dogs

The raccoon roundworm, *Baylisascaris procyonis*, is a common infection of raccoons in parts of North America and Europe. Adult parasites reside within the small intestine of raccoons and occasionally in the small intestine of dogs. It is thought that dogs become infected via ingestion of infective eggs or paratenic hosts (eg, rodents, rabbits, birds).

Ingestion of infective eggs results in visceral and neural larva migrans in many species, including people. As a result, the parasite is a significant zoonotic concern.

Clinical disease has not been reported in dogs with intestinal infections. However, signs are likely to be similar to those of *T canis* infections. In contrast, severe or fatal neural larva migrans has occasionally been reported in dogs.

Patent intestinal infections appear to occur uncommonly in dogs. However, it is likely that such infections are underdiagnosed; the eggs of *B procyonis* are similar in appearance to those of *T canis*, except they are slightly smaller (63–75 × 53–60 µm) and darker in color. Eggs of *B procyonis* may be found in dog feces as a result of ingestion of raccoon feces; shedding of such eggs should cease within 1–2 days.

Adult *B procyonis* and *T canis* passed in feces can be difficult to differentiate; female parasites should be dissected, and the eggs examined for identification.

Because of the zoonotic potential of *B procyonis* eggs, it is important that patent infections in dogs are diagnosed promptly and that appropriate treatment administered immediately. Ivermectin/pyrantel and milbemycin oxime/lufenuron at approved dosages have been shown to exhibit significant activity against intestinal infections in dogs with cure rates of 100% and 75%, respectively, after treatment with a single dose. However, these are not approved treatment protocols. Dogs should be confined and feces/parasites collected and disposed of for at least 3 days after treatment.

HOOKWORMS

Ancylostoma caninum is the principal cause of canine hookworm disease in most tropical and subtropical areas of the world. A *tubaeforme* of cats has a similar but more sparse distribution. A *braziliense* of dogs

and cats is sparsely distributed from Florida to North Carolina in the USA. It is also found throughout Central and South America and Africa. *A. ceylanicum* of dogs, cats, and people is widely distributed throughout Asia, the Middle East, and parts of South America. *Uncinaria stenocephala* is the principal canine hookworm in cooler regions; it appears to be the predominant canine hookworm in Canada and the northern fringe of the USA, where it is primarily a fox parasite. *U. stenocephala* also is seen in cats. *A. caninum* males are ~12 mm long, females, ~15 mm; the other species are somewhat smaller. The infective larvae of canine hookworms, particularly those of *A. braziliense*, may penetrate and wander under the skin of people and cause **cutaneous larva migrans**.

The elongate (>65 µm), thin-walled, hookworm eggs in the early cleavage stages (2–8 cells) are first passed in the feces 15–20 days after infection; they complete embryonation and hatch in 24–72 hr on warm, moist soil. Transmission may result from ingestion of infective larvae from the environment and additionally, in the case of *A. caninum*, via the colostrum or milk of infected bitches. Infections with *A. caninum*, *A. braziliense*, *A. tubaeforme*, or *A. ceylanicum* can also result from larval invasion through the skin, but this route is of little significance for *U. stenocephala*. Skin penetration in young pups is followed by migration of the larvae through the blood to the lungs, where they are coughed up and swallowed to mature in the small intestine. However, in animals >3 mo old, *A. caninum* larvae, after migration through the lungs, are arrested in the somatic tissues. These arrested larvae are activated during pregnancy, then accumulate in the mammary glands. Arrested development may also occur in the mucosa of the small

intestine; activation may occur after removal of adult worms from the intestine.

Clinical Findings: An acute normocytic, normochromic anemia followed by hypochromic, microcytic anemia in young puppies is the characteristic, and often fatal, clinical manifestation of *A. caninum* infection. Surviving puppies develop some immunity and show less severe clinical signs. Nevertheless, debilitated and malnourished animals may continue to be unthrifty and suffer from chronic anemia. Mature, well-nourished dogs may harbor a few worms without showing signs; they are of primary concern as the direct or indirect source of infection for pups. Diarrhea with dark, tarry feces accompanies severe infections. Anemia, anorexia, emaciation, and weakness develop in chronic disease.

Lesions: Anemia results directly from the bloodsucking and the bleeding ulcerations that result when *A. caninum* shift feeding sites. The amount of blood loss due to a single worm in 24 hr has been estimated to be up to 0.1 mL. There is no interference with erythropoiesis in uncomplicated hookworm disease. The liver and other organs may appear ischemic, and some fatty infiltration of the liver may occur. Hemorrhagic enteritis with a swollen intestinal mucosa that shows red, small ulcers and attached worms is usually seen in acute, fatal cases. *A. braziliense*, *A. tubaeforme*, *A. ceylanicum*, and *U. stenocephala* are not avid blood feeders, and anemia rarely develops. However, hypoproteinemia is characteristic, and serum seepage around the site of attachment in the intestine may reduce blood protein by >10%.

In dogs, dermatitis due to larval invasion of the skin may be seen with any of the hookworms but has been seen most frequently in the interdigital spaces with *U. stenocephala*; skin infections with *U. stenocephala* rarely mature. Pneumonia and lung consolidation may result from overwhelming infections in pups.

Diagnosis: The characteristic thin-shelled, oval eggs are easily seen on flotation of fresh feces from infected dogs and cats (*Ancylostoma* spp 52–79 × 28–58 µm; *Uncinaria* sp 71–92 × 35–58 µm). Acute anemia and death from infections acquired via milk may be seen in young pups before eggs are passed in their feces, ie, as early as 1–2 wk of age.

Treatment and Control: Bitches should be free of hookworms before breeding and

Hookworm eggs of *Ancylostoma* (smaller) and *Uncinaria* (larger) spp. Courtesy of Dr. Andrew Peregrine and Ontario Veterinary College.

TABLE 8

DRUGS FOR INTESTINAL HELMINTHS OF DOGS APPROVED IN THE USA AND UK

Drug or Drug Combination	Dosage (mg/kg)	Route of Administration	Helminths Active Against ^a
APPROVED ONLY IN USA			
Fenbendazole	50, daily for 3 days	PO	<i>Toxocara canis</i> , <i>Toxascaris leonina</i> , <i>Ancylostoma caninum</i> , <i>Uncinaria stenocephala</i> , <i>Trichuris vulpis</i> , <i>Trichuris pisiformis</i>
Epsiprantel	5.5	PO	<i>D caninum</i> , <i>T pisiformis</i>
Milbemycin oxime	0.5	PO	<i>T canis</i> , <i>T leonina</i> , <i>A caninum</i> , <i>T vulpis</i>
Milbemycin oxime + spinosad	0.5/30	PO	<i>T canis</i> , <i>T leonina</i> , <i>A caninum</i> , <i>T vulpis</i>
Moxidectin	0.17	SC	<i>A caninum</i> , <i>U stenocephala</i>
Piperazine (various salts)	48–66 ^{b,d}	PO	<i>T canis</i> , <i>T leonina</i>
Praziquantel	5–12.5	PO	<i>D caninum</i> , <i>T pisiformis</i> , <i>Echinococcus granulosus</i> ^c , <i>E multilocularis</i> ^c
	5–11.4	SC, IM	<i>D caninum</i> , <i>T pisiformis</i> , <i>E granulosus</i> , <i>E multilocularis</i>
Pyrantel pamoate	5 (10 for dogs ≤2.3 kg)	PO	<i>T canis</i> , <i>T leonina</i> , <i>A caninum</i> , <i>U stenocephala</i>
Ivermectin + pyrantel pamoate	0.006/5	PO	<i>T canis</i> , <i>T leonina</i> , <i>A caninum</i> , <i>A braziliense</i> , <i>U stenocephala</i>
Praziquantel + pyrantel pamoate	5/5	PO	<i>T canis</i> , <i>T leonina</i> , <i>A caninum</i> , <i>A braziliense</i> , <i>U stenocephala</i> , <i>D caninum</i> , <i>T pisiformis</i>
Praziquantel + pyrantel pamoate + febantel	5/5/25	PO	<i>T canis</i> , <i>T leonina</i> , <i>A caninum</i> , <i>U stenocephala</i> , <i>T vulpis</i> , <i>D caninum</i> , <i>T pisiformis</i> , <i>E granulosus</i> , <i>E multilocularis</i>
Praziquantel + pyrantel pamoate + ivermectin	5/5/0.006	PO	<i>T canis</i> , <i>T leonina</i> , <i>A caninum</i> , <i>A braziliense</i> , <i>U stenocephala</i> , <i>D caninum</i> , <i>T pisiformis</i>
APPROVED ONLY IN UK

^a Many of these drugs are also approved for use against other types of parasites (eg, fleas, heartworm) not listed here.

^b Repeat in 10–20 days

^c Only some products

^d Only in the USA

^e Only in the UK

kept out of contaminated areas during pregnancy. Sanitary quarters should be provided for whelping and nursing. Concrete runways that can be washed at least twice a week in warm weather are best. Sunlit clay or sandy runways can be decontaminated with sodium borate (1 kg/2 m²).

In dogs, fenbendazole, moxidectin, and pyrantel are approved for treatment of *A caninum* and *U stenocephala* infections. Milbemycin is also approved for treatment of *A caninum* infections (see TABLE 8). Nitroscanate is also approved for both hookworms at 50 mg/kg in some countries (eg, Canada). When anemia is severe, chemotherapy may have to be supported by blood transfusion or supplemental iron,

followed by a high-protein diet until the Hgb level is normal. Heartworm prevention with products containing milbemycin control *A caninum*, whereas ivermectin/pyrantel, ivermectin/pyrantel/praziquantel, moxidectin, and moxidectin/imidacloprid control *A caninum* and *U stenocephala*. Heartworm preventives containing pyrantel also have activity against *A braziliense* (see TABLE 8) and are approved for this purpose. Finally, the injectable formulation of moxidectin for heartworm prevention in dogs also has significant efficacy against infection with *A caninum* and *U stenocephala* for at least 3 mo. For *A ceylanicum*, the combination product containing pyrantel embonate/febantel/praziquantel is approved for treatment in Australia.

TABLE 9

DRUGS FOR INTESTINAL HELMINTHS OF CATS APPROVED IN THE USA AND UK

^a Many of these drugs are also approved for use against other types of parasites (eg, fleas, heartworms) not listed here.

^b Repeat in 10–14 days for most products

^c Only some products

^d Only in the USA

In cats, drugs approved for treatment of *A. tubaeforme* include emodepside, fenbendazole, ivermectin, milbemycin, moxidectin, pyrantel, and selamectin (see TABLE 9). Heartworm prevention with ivermectin, milbemycin, milbemycin/praziquantel, moxidectin/imidacloprid, or selamectin controls *A. tubaeforme*, whereas ivermectin also controls *A. braziliense* (see TABLE 9).

When neonatal pups die due to hookworm infection, subsequent litters from the bitch should be treated weekly for *A. caninum* for ~12 wk beginning at 2 wk of age. In addition, fenbendazole (25 mg/kg, PO) given daily to pregnant bitches from day 40 of pregnancy to day 2 after whelping greatly reduces transmammary transmission to the pups (approved in the UK). Likewise, treatment of the bitch with ivermectin (0.5 mg/kg) on two occasions (4–9 days before whelping and 10 days later), or with moxidectin/imidacloprid spot-on on day 56 of pregnancy, has the same effect (extra-label use).

Resistance of *A. caninum* to pyrantel has been reported in parts of Australia.

WHIPWORMS

Adult *Trichuris vulpis* are 45–75 mm long and consist of a long, slender anterior portion and a thick posterior third. They commonly inhabit the cecum and colon of dogs, where they are firmly attached to the wall with their anterior end embedded in the mucosa. Thick-shelled eggs with bipolar plugs are passed in the feces and become infective in 1–2 mo in a warm, moist environment. Although eggs may remain viable in a suitable environment for up to 5 yr, they are susceptible to desiccation. The life cycle is direct. After infective eggs are ingested, the larvae hatch and develop in the wall of the distal ileum, cecum, and colon, and the adults mature in ~11 wk. They may remain for up to 16 mo.

No signs are seen in light infections, but as the worm burden increases and the inflammatory (and occasionally hemorrhagic) reaction in the cecum and colon becomes more pronounced, weight loss and diarrhea become evident. Fresh blood may be seen in the feces of heavily infected dogs, and anemia occasionally follows.

Trichuris infections are rarely seen in cats in North and South America and the Caribbean but may occasionally be associated with clinical signs similar to those described for dogs.

Treatment and Control: The eggs are susceptible to desiccation; therefore, by

maintaining cleanliness and eliminating moist areas, the risk of infection in dogs can be reduced considerably, although *T. vulpis* infections can be difficult to control. For anthelmintic treatment of dogs, approved compounds include febantel, fenbendazole, milbemycin, moxidectin (topical), and oxantel (see TABLE 8). Treatment should be repeated three times at monthly intervals because of the long prepatent period. Finally, milbemycin, milbemycin/lufenuron, milbemycin/spinosad, milbemycin/praziquantel, and moxidectin/imidacloprid, when administered for heartworm prevention, are also approved for control of *T. vulpis* infections.

Effective therapy has yet to be described for *Trichuris* infections in cats. If required, treatment should be attempted on an experimental basis using a compound with approved activity against *T. vulpis*.

ACANTHOCEPHALANS

(Thorny-headed worms)

Oncicola spp

Oncicola canis and other species are rarely found in the small intestine of dogs and cats. They are white and ~8–15 mm long, and their thorny heads are embedded in the mucosa. The females lay brown, thick-shelled, embryonated, wide oval eggs (43–50 × 67–72 µm). The life cycle is not completely known, but it is thought to include an arthropod intermediate host and paratenic hosts such as lizards, birds, or armadillos. Most infections cause no clinical signs.

Macracanthorhynchus sp

Macracanthorhynchus ingens, naturally a parasite of raccoons, is occasionally found in dogs. The usual observation is of a large (8–12 cm), white, wrinkled worm passed in the feces. No clinical signs have been definitively associated with the infection. The life cycle requires a millipede as an intermediate host, but other animals may serve as paratenic hosts. The eggs look similar to those of *Oncicola canis* but are larger (~50 × 100 µm). Diagnosis of patent infections is unlikely, because experimentally induced infections did not persist after 1–12 days of patency. No treatment is necessary.

TAPEWORMS

(Cestodes)

Most urban dogs and cats eat prepared foods and have restricted access to natural

Dipylidium caninum segments. Courtesy of Dr. Andrew Peregrine and Ontario Veterinary College.

Taenia sp segments. Courtesy of Dr. Andrew Peregrine and Ontario Veterinary College.

prey. Such animals may acquire *Dipylidium caninum* (the double-pored dog tapeworm) by ingesting fleas. Cats with access to infected house (or outdoor) mice and rats also can acquire *Taenia taeniaeformis*. In certain parts of the world (eg, India, the Middle East, North Africa, southeast Asia, southern Europe), dogs and cats with access to reptiles may acquire *Joyeuxiella pasqualei*. Suburban, rural, and hunting dogs have more access to various small mammals, in addition to raw meat and offal from domestic and wild ungulates. A number of cestodes can be expected in such dogs (see TABLE 10). On sheep ranges and wherever wild ungulates and wild canids are common, dogs may acquire *Echinococcus granulosus* (the hydatid tapeworm). Sylvatic *Echinococcus multilocularis* (the alveolar hydatid tapeworm), previously known only from arctic North America, has been found in wildlife in midwestern and western USA and Canada. The parasite is also endemic in many parts of central and eastern Europe, particularly France, Germany, and Switzerland. Thus far, infections in cats or dogs are generally rare. However, in addition to multiple reports from dogs and cats in central Europe, the parasite has recently been identified in a few dogs

TABLE 10 CESTODES OF DOGS AND CATS IN NORTH AMERICA

Cestode	Definitive Host	Intermediate Host and Organs Invaded ^a
<i>Dipylidium caninum</i>	Dog, cat, coyote, wolf, fox, other wild canids and felids	Fleas and more rarely lice; free in body cavity
<i>Taenia taeniaeformis</i>	Cat, dog, lynx, fox, other animals	Various rats, mice, other rodents; in large cysts in liver
<i>Taenia pisiformis</i>	Dog, fox, wolf, coyote, other animals	Rabbits and hares, rarely squirrels and other rodents; in pelvic or peritoneal cavity attached to viscera
<i>Taenia hydatigena</i>	Dog, wolf, coyote, weasel, fox	Domestic and wild cloven-hoofed animals, rarely hares and rodents; in liver and abdominal cavity

across Canada. *Spirometra mansonoides* is an uncommon (but not rare) parasite of cats and occasionally of dogs along the eastern and Gulf Coast areas of North America.

Association with infected dogs may result in human infection with metacestodes of *E. granulosus*, *E. multilocularis*, *T. multiceps*, *T. serialis*, or *T. crassiceps* in various tissues (by ingestion of eggs passed in dog feces), or adult *D. caninum* in the intestine (by ingestion of infected fleas). The presence of metacestodes in livestock may limit commercial use of such carcasses or offal meats. Thus, cestodes of dogs and cats may be of both economic and public health importance (see TABLE 11).

Adult cestodes in the intestine of dogs and cats rarely cause serious disease, and clinical signs, if present, may depend on the degree of infection, age, condition, and breed of host. Clinical signs vary from unthriftiness, malaise, irritability, capricious appetite, and shaggy coat to colic and mild diarrhea; rarely, intussusception or blockage of the intestine, emaciation, and seizures are seen.

Diagnosis is based on finding proglottids or eggs in the feces. The eggs of *Taenia* spp and *Echinococcus* spp cannot be differentiated by microscopic examination; PCR

methods are required. Direct microscopic examination of fecal samples or fecal flotation may reveal the eggs of *Spirometra mansonoides*, which are sometimes mistaken for trematode eggs, although they are larger and possess an operculum that is often difficult to see.

Control of tapeworms of dogs and cats requires therapy and prevention. Animals that roam freely often become reinfected by ingestion of metacestodes in carrion or prey animals. *Dipylidium caninum* is different, because it can cycle through fleas that may be associated with confined infected animals. An accurate diagnosis is necessary for effective advice on preventing reinfection.

Effective treatment should remove the attached scolices from the small intestine of infected animals. (See TABLE 10 for specific approved treatments.) For dogs, fenbendazole and praziquantel are approved for treatment of *Taenia* spp (ie, more than just *T. pisiformis*, for which epsiprantel is approved); epsiprantel, nitroscanate, and praziquantel are approved for *D. caninum*; and praziquantel is approved for treatment of *Echinococcus* spp (see TABLE 8). For cats, fenbendazole and praziquantel are approved for treatment of *Taenia* spp (ie, more than just *T. taeniaeformis*, for which epsiprantel is approved); epsiprantel and

TABLE 10 CESTODES OF DOGS AND CATS IN NORTH AMERICA (continued)

Diagnostic Features of Adult Worm	Comments	Approved Treatment ^b
Strobila 15–70 cm long and up to 3 mm in maximum width, 30–150 rostellar hooks of rose-thorn shape in 3 or 4 circles; large hooks 12–15 μ m, smallest 5–6 μ m long. Segments shaped like cucumber seeds, with pore near middle of each lateral margin.	Probably most common tapeworm of dogs and cats; cosmopolitan. Occasionally infects people, particularly infants.	Dogs and cats: epsiprantel, praziquantel
Strobila 15–60 cm long, 5–6 mm in maximum width, 26–52 rostellar hooks in double row; large hooks 380–420 μ m, small hooks 250–270 μ m long. No neck. Sacculate lateral branches of uterus difficult to count.	Common cestode of cats, rare in dogs; cosmopolitan	Cats: epsiprantel, praziquantel, fenbendazole
Strobila 60 cm to 2 m long, 5 mm in maximum width, ~34–48 rostellar hooks in double row; large hooks 225–290 μ m, small hooks 132–177 μ m long. Each side of gravid uterus has 5–10 lateral branches.	Particularly common in suburban, farm, and hunting dogs that eat rabbits and rabbit viscera.	Dogs: epsiprantel, fenbendazole, praziquantel
Strobila to 5 m long and 7 mm in maximum width; ~26–44 rostellar hooks in double row; large hooks 170–220 μ m, small hooks 110–160 μ m long. Each side of gravid uterus 5–10 lateral branches.	In farm dogs, more rarely hunting dogs; cosmopolitan	Dogs: praziquantel, fenbendazole

TABLE 10 CESTODES OF DOGS AND CATS IN NORTH AMERICA (continued)

Cestode	Definitive Host	Intermediate Host and Organs Invaded ^a
<i>Spirometra mansonoides</i>	Cat, dog, raccoon, bobcat	Copepods, frogs, rodents, snakes; connective tissue
<i>Diphyllobothrium</i> spp	People, dog, cat, other fish-eating animals	Encysted in various organs, or free in body cavity of various fish
<i>Echinococcus granulosus</i>	Dog, wolf, coyote, fox, and several other wild carnivores	Sheep, goats, cattle, pigs, horses, deer, moose, some rodents, occasionally people and other animals; commonly in liver and lungs, occasionally in other organs and tissues
<i>Echinococcus multilocularis</i>	Arctic, red, and gray foxes; coyote, cat, dog	Microtine rodents, occasionally in people; in the liver and other organs
<i>Mesocestoides</i> spp	Many wild canids, felids, mustelids; other animals, including dog and cat	Complete life cycle unknown; arthropod intermediate hosts suspected; juvenile tetrathyridia in abdominal cavity and elsewhere of various mammals, birds, and reptiles; tetrathyridia in intestine of dogs may enter abdomen through intestinal wall.
<i>Taenia multiceps</i>	Dog, coyote, fox, wolf	Sheep, goats, and other domestic or wild ruminants, rarely people; usually in brain or spinal cord
<i>Taenia serialis</i>	Dog, coyote, fox, wolf	Rabbit, hare, squirrel, rarely people; in subcutaneous connective tissue or retroperitoneally
<i>Taenia crassiceps</i>	Dog, coyote, fox, wolf	Various rodents, a few records in people; subcutaneous and in body cavities

TABLE 10

CESTODES OF DOGS AND CATS IN NORTH AMERICA (continued)

Diagnostic Features of Adult Worm	Comments	Approved Treatment ^b
Strobila 0.5 m long, 8 mm in maximum width. Scolex with 2 grooves and no hooks. Genital pores ventral midline of segment.	Eastern and Gulf Coast, North America	See text for extra label treatment
Strobila to 10 m long, 20 mm in maximum width but usually smaller. Scolex with 2 grooves (bothria) and no hooks. Genital pores ventral midline of segment.	Canada, Alaska and various other states of the USA, Siberia, and other areas	See text for extra-label treatment
Strobila 2–6 mm long with 3–5 segments; 28–50 (usually 30–36) rostellar hooks in double row; large hooks 27–40 µm, small hooks 21–25 µm long.	Foci among North American range sheep and dogs associating with them; sylvatic moose-wolf cycle where these animals are found; probably cosmopolitan	Dogs: praziquantel
Strobila 1.2–2.7 mm long with 2–4 segments; 26–36 rostellar hooks in double row; large hooks 23–29 µm, small hooks 19–26 µm long.	Central and eastern Europe, former USSR, Alaska, and midwestern USA and Canada; thus far, significant cycle in cats and dogs in North America not recognized. However, multiple cases of alveolar echinococcosis have been diagnosed in dogs across Canada.	Dogs and cats: praziquantel
Strobila 10 cm long and 2–5 mm wide. Scolex with 4 suckers but no rostellum or hooks. Genital pore ventral in midline of worm. Gravid segments with parauterine organ.	Reported in dogs and cats in midwest and west; in wild animals elsewhere in USA and Canada	Dogs: praziquantel
Strobila 40–100 cm long and up to 5 mm wide. Scolex with 4 suckers and 22–32 hooks in double row; large hooks 150–170 µm, small hooks 90–130 µm long. Vagina with reflexed curve near lateral excretory canal; 9–26 lateral branches on gravid uterus.	Rare in domestic carnivores in western North America; more common in wild animals	Dogs: praziquantel, fenbendazole
Strobila 20–72 cm long and 3–5 mm wide; 26–32 hooks in double row; large hooks 110–175 µm, small hooks 68–120 µm long. Vagina with reflexed curve near lateral excretory canal; 20–25 lateral branches on gravid uterus.	Primarily in wild canids; considered by some authorities as not distinct from <i>T. multiceps</i>	Same as for <i>T. multiceps</i>
Strobila 70–170 mm long and 1–2 mm wide. Scolex with 30–36 hooks in double row; large hooks 158–187 µm, small hooks 119–141 µm long. Uterus has 16–21 lateral branches, sometimes becoming diffuse.	Reported from Canada and northern USA, including Alaska	Same as for <i>T. multiceps</i>

TABLE 10 CESTODES OF DOGS AND CATS IN NORTH AMERICA (continued)

Cestode	Definitive Host	Intermediate Host and Organs Invaded*
<i>Taenia krabbei</i>	Dog, coyote, wolf, bobcat	Moose, deer, reindeer; in striated muscle
<i>Taenia ovis</i>	Dog, wild canids	Sheep and goat; in skeletal and cardiac muscle, rarely elsewhere

praziquantel are approved for treatment of *D caninum*, and praziquantel is approved for treatment of *E multilocularis* (see TABLE 9). Outside the USA and UK, praziquantel is approved for use in multiple countries at 5 mg/kg for treatment of *J pasqualei* in dogs (as praziquantel/pyrantel/febantel) and cats (as praziquantel/pyrantel).

Praziquantel at 7.5 mg/kg, PO, for 2 consecutive days is effective against *Diphylllobothrium* sp in dogs. Furthermore, a single dose of 35 mg/kg, PO, eliminates *D latum* from infected cats. Both treatments are extra-label.

Infections with *Spirometra* sp in dogs and cats can be treated with praziquantel at 7.5 mg/kg, PO, for 2 consecutive days. *Spirometra* sp infections in cats can also be treated with a single dose of praziquantel at 30 mg/kg, SC, IM, or PO. Mebendazole at 11 mg/kg, PO, has also been successful. All these treatments are extra label.

FLUKES

Intestinal Flukes

Nanophyetus salmincola, the "salmon poisoning" fluke, is a small (~0.5 × 0.3 mm), oval fluke found in the small intestine of dogs, cats, and many wild fish-eating mammals in the northwestern USA, southwestern Canada, and Siberia. The eggs, which pass in the feces of infected hosts, are light brown, 72–97 × 35–55 μm, and indistinctly operculated with a small knob at one pole. The life cycle includes an extended period (3 mo)

of embryonation. The first intermediate hosts are snails found in endemic locations (eg, *Oxytrema silicula* in the USA). The cercariae from these snails penetrate the skin of young salmonid fishes and encyst as metacercariae in their muscles and organs. Dogs and other animals become infected by eating raw or improperly prepared infected fish.

Because these flukes embed deeply between the villi of the intestine, infection with a large number may cause enteritis. Most infections, however, are complicated through development of the salmon poisoning complex caused by rickettsial organisms, which the fluke transmits (see p 808). Praziquantel (20–30 mg/kg, PO or SC, once) and fenbendazole (50 mg/kg/day, PO, for 10–14 days) are both effective, but not approved, treatments for dogs.

Alaria alata, *A canis*, and other *Alaria* spp are small (2–6 mm) flukes usually found in the small intestine of dogs, cats, foxes, mink, and wild carnivores in the western hemisphere, as well as in Europe, Australia, and Japan. The anterior part of the body is flat, and the posterior part is conical. The eggs are oval, light brown, and fairly large (98–134 × 62–68 μm). The life cycle includes freshwater snails (eg, *Helisoma* spp) as first intermediate hosts. Cercariae emerge from the snails, penetrate tadpoles, and develop into mesocercariae. Frogs, snakes, and mice then acquire infection by eating tadpoles; the mesocercariae transfer to their tissues and remain as this life-cycle stage. Dogs and other definitive hosts become infected by feeding on these animals. The young flukes migrate through various organs of the definitive host, including the diaphragm and

TABLE 10 CESTODES OF DOGS AND CATS IN NORTH AMERICA (continued)

Diagnostic Features of Adult Worm	Comments	Approved Treatment ^b
Strobila ~20 cm long and up to 9 mm wide. Scolex small with 26–36 hooks in double row; large hooks 146–195 µm, small hooks 85–141 µm long. Gravid uterus has 18–24 straight and narrow lateral branches.	Reported from Canada and northern USA, including Alaska; considered by some a subspecies of <i>T. ovis</i>	Same as for <i>T. multiceps</i>
Strobila 45–110 cm long and up to 4–8.5 mm wide. Scolex with 32–38 hooks in double row; large hooks 170–191 µm, small hooks 111–127 µm long. Gravid uterus has 20–25 lateral branches. Vagina crosses ovary on portal side of segment.	Reported from western and central Canada and the southern USA	Same as for <i>T. multiceps</i>

^a In all cases in which the life cycle is known, cats and dogs become infected by eating animals (or parts) that contain the infective metacestode. These intermediate hosts become infected by ingesting tapeworm eggs (except in *Mesocestoides*, *Spirometra*, and *Diphylobothrium* spp, which have an extra stage in the life cycle), which are passed in the feces of the definitive host.

^b See TABLE 8 and TABLE 9 for drug dosages.

lungs, before reaching the small intestine. Although the flukes are generally considered to be nonpathogenic, large numbers may cause pulmonary hemorrhages during migration or enteritis when they mature in the small intestine. These flukes may infect people. Infections can be treated with praziquantel using the approved cestocidal dosage (see TABLE 8 and TABLE 9 for drug dosages.). However, such treatment is extra-label.

Other species of flukes, usually not pathogenic, have been found occasionally in the intestine of dogs, cats, and other carnivores; these include *Heterophyes heterophyes* in some north African and Asian countries; *Metagonimus yokogawai* in Asia; *Cryptocotyle lingua* in the USA, Canada, Japan, Siberia, and Europe; and *Apophallus donicum* in North America and eastern Europe. Their life cycles include snails as first intermediate hosts and fish as second intermediate hosts, in which metacercariae become encysted.

Heterobilharzia americana is found in the mesenteric veins of dogs and wild animals, especially raccoons, in the southeastern USA. The eggs pass through the tissues of the intestine to the lumen and then are voided in the feces. From the snail intermediate host, cercariae escape into water and penetrate the skin of dogs and other definitive hosts, migrate to the liver, mature, and move to the mesenteric vessels. Granulomas form around the eggs in the

wall of the intestine, the liver, and other parts of the body. Lethargy, weight loss, vomiting, and/or diarrhea may develop in heavy infections. "Water dermatitis" is sometimes seen when cercariae penetrate the skin. The eggs do not readily float and, if placed in water, hatch within minutes; therefore, a sedimentation method using 0.85% saline is useful in separating eggs from ingesta. In infected dogs, eggs are passed intermittently, so on a given day eggs may not be found in feces. Fenbendazole at 50 mg/kg/day, PO, for 10 days, is an effective treatment. Praziquantel at 25 mg/kg, tid, for 2 days is also effective. Both are extra-label uses.

Hepatic Flukes

Flukes in the bile ducts and gallbladder cause mild to severe fibrosis. Many species of distome trematodes have been reported from the liver of dogs and cats in most parts of the world. Mild infections may pass unnoticed; however, in severe infection, dogs may develop progressive weakness, ending in complete exhaustion, coma, and death. The following are some of the most commonly encountered trematodes.

Opisthorchis felinus is parasitic in the bile duct, pancreatic duct, and small intestine of dogs and cats in Italy, eastern Europe, and parts of Asia. *O. viverrini* is seen in dogs as well as in domestic and wild cats in southeast Asia. They are small

TABLE 11

CESTODES OF PUBLIC HEALTH IMPORTANCE

Cestode ^a	Host of Adult Worm	Name of Metacestode (Intermediate) Stage	Measurements of Metacestode	Principal Intermediate Hosts	Site of Metacestode
<i>Taenia saginata</i>	People only	Cysticercus "beef measles"	9 × 5 mm	Cattle	Skeletal and cardiac muscle
<i>Taenia solium</i>	People only	Cysticercus "pork measles"	6–10 × 5–10 mm	Pigs, rarely dogs (people may be both definitive and intermediate hosts)	Skeletal and cardiac muscle, occasionally nervous system
<i>Diphyllobothrium</i> spp	People, dogs, cats, and other fish-eating mammals	Proceroid in copepod, plerocercoid in fish	2–25 × 2.5 mm for plerocercoid	Copepod, then fish	Mesenteric tissues, testes, ovary, muscles of fish
<i>Echinococcus granulosus</i>	Dogs, wolves, foxes, and several other wild carnivores	Hydatid cyst	Diameter 50–100 mm, sometimes ≥150 mm	Sheep, cattle, pigs, horses, moose, deer; occasionally people	Commonly in liver and lungs, occasionally in other organs and tissues
<i>Echinococcus multilocularis</i>	Canids and domestic cats	Alveolar hydatid cyst	Variable, penetrates like neoplastic tissue	Field mice, voles, lemmings, sometimes domestic mammals and people	Usually liver, various other organs and tissues

^a Human infections with the metacestodes of *Taenia crassiceps*, *T. multiceps*, *Mesocostoides* spp, and other cestodes not listed here occur rarely. Children occasionally become infected with adult *Dipylidium caninum*, which appears to have no medical significance but important aesthetic aspects.

(9 × 2 mm) and elongate. Their life cycle includes certain snails (*Bithynia* sp) and cyprinid fishes as intermediate hosts. A related species, *Clonorchis sinensis*, the Oriental liver fluke of people, also has been found in the bile ducts and pancreatic ducts of dogs, cats, and other animals. It is larger than *Opisthorchis* spp. The operculated eggs of these parasites may be identified in the feces of infected animals.

Longterm presence of these flukes in the bile duct causes epithelial hyperplasia and fibrosis of the duct wall. Carcinomas in the liver or pancreas have been seen in chronic

and severe cases. Treatment of *Opisthorchis* spp infections in dogs may be attempted with fenbendazole (200 mg/kg/day, PO, for 3 days) or praziquantel (20 mg/kg, PO, once). Treatment of *C. sinensis* infections in dogs may be attempted with praziquantel (30 mg/kg/day, PO, for 3 days). All these treatments are extra-label.

Platynosomum concinnum is a small fluke (6 × 2 mm) found in the bile and pancreatic ducts of Felidae in southeastern USA, Puerto Rico and other Caribbean Islands, South America, some of the Pacific islands, and parts of Africa. Its life cycle
